Our value, obtained at 25°, we regard as undoubtedly accurate within a few tenths of a millivolt: Brislee's value was obtained in the neighborhood of 17° and the wide difference between the two values may be in part due to the difference in temperature, which would indicate, however, an exceptionally large temperature coefficient for the thallium electrode.

[CONTRIBUTIONS FROM THE RESEARCH LABORATORY OF PHYSICAL CHEMISTRY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, NO. 48.]

THE IONIZATION OF SALTS IN MIXTURES WITH NO COMMON ION.

BY MILES S. SHERRILL.

Received April 14, 1910.

Contents.

1. Purpose of the Investigation. 2. Principles Relating to the Ionization of Salts in Mixtures. 3. The Experimental Method. 4. The Conductance Data. 5. Method of Calculation and Results. 6. Discussion of the Results.

1. Purpose of the Investigation.—The general purpose of this investigation was to determine what modification must be made of the empirical principles which have been found to express the ionization of salts in mixtures with a common ion, in order that they may be applicable also to mixtures with no common ion; in other words, to determine the *general* law governing the ionization relations of salts.

Although many researches have been carried out on the conductance of mixtures with a common ion, few data exist upon mixtures with no common ion suitable for the purpose just mentioned.[1] At the suggestion of Professor A. A. Noyes, this investigation was therefore undertaken, the plan being to measure the conductance of mixtures of two salts with no common ion, and to compare the results with the conductance calculated by the principle discussed in the following section. The salts chosen were potassium chloride and sodium sulphate, and sodium chloride and potassium sulphate. Thus mixtures of salts of two ionic types could be prepared, whereby a more satisfactory test of the theory would be afforded.

2. Principles Relating to the Ionization of Salts in Mixtures.—The principles already established may be first briefly reviewed.

The mass-action law requires that the ionization γ of any salt vary with the concentration C, in accordance with the equation:

$$\frac{(\gamma C)^n}{(1-\gamma)C} = K. \qquad (1)$$

where K is the ionization constant for the salt, and n is the number of ions produced by the ionization of 1 molecule of the salt. The numerical value for n should therefore vary with the ionic type of salt, being 2 for uni-univalent salts, like potassium chloride, 3 for uni-bivalent salts like potassium sulphate, etc. As is well known, however, the mass-action law does not apply, even approximately, to the ionization of salts, strong acids, and bases when the conductance ratio Λ/Λ_0 is taken as a measure of the ionization.[1]

---

[1] The only measurements that exist seem to be those of Barmwater (*Z. physik. Chem.*, 28, 427 (1899)), on certain mixtures of uni-univalent salts.

Kohlrausch,[2] Rudolphi,[3] and van't Hoff[4] first proposed various empirical functions containing only a single constant for the purpose of expressing the change of ionization with the dilution. Storch[5] then suggested that, in order to secure closer agreement with the observed values, a general expression of the form of equation (1) be employed, the exponent n being regarded as a second empirical constant to be derived for each particular salt from the conductance measurements. van't Hoff[6] had already shown that an approximate agreement between the formula and the existing data could be secured in the case of a large number of di-ionic salts by taking $n = 1.5$. Storch showed that a nearly complete agreement in the case of the eight di-ionic and four tri-ionic substances studied was attained up to 0.1 normal by assuming values of n varying only within the limits 1.42 and 1.52. Bancroft[7] showed that Storch's formula with values of n varying within about the same limits was applicable to certain other di-ionic salts. By the extended investigations made in this laboratory it has been shown that the same is true also for tri-ionic and tetra ionic salts, and for the salts of all three types through a very wide range of temperature Thus the values of n obtained, though varying somewhat with the nature of the salt and the temperature, all fall within the narrow limits of 1.40 to 1.55.[8]

Equation (1) may also be written in the following form, which expresses the ionization as a function of the ion concentration ($C\gamma$):

$$\frac{\gamma}{1-\gamma} = K(C\gamma)^{1-n}. \qquad (2)$$

A study of the conductance of mixtures of two salts with a common ion has thrown further light on the ionization relations of salts. The results of such measurements can be satisfactorily expressed by the following principle derived from theory of isohydric solutions of Arrhenius,[9] and shown, most fully by the investigations of MacGregor, McIntosh, Archibald, and McKay,[1] to be valid not only for uni-univalent salts, but also for those of higher types, even in cases, as has been pointed out by Noyes,[2] where the mass-action law would require a very different effect. In a mixture of two salts with a common ion each salt has a degree of ionization equal to that which it has when alone present in a solution in which its ions have a concentration equivalent to that of the common ion in the mixture.

---

[9] *Z. physik. Chem.*, **2**, 285 (1888); **31**, 218 (1899).

This principle evidently shows that the ionization of any salt is the same function of the ion concentration, whether the salt is present alone or together with another salt with a common ion. Therefore, in correspondence with equation (2), it may be expressed as follows:

$$\frac{\gamma_1}{1-\gamma_1} = K_1(C_1\gamma_1+C_2\gamma_2)^{1-n_1}; \text{ and } \frac{\gamma_2}{1-\gamma_2} = K_2(C_1\gamma_1+C_2\gamma_2)^{1-n_2}; \qquad (3)$$

the subscripts referring to the two salts, respectively. These equations may readily be transformed into the following ones:

$$\frac{C_1\gamma_1(C_1\gamma_1+C_2\gamma_2)}{C_1(1-\gamma_1)} = K_1(C_1\gamma_1+C_2\gamma_2)^{2-n_1}; \text{ and}$$

$$\frac{C_2\gamma_2(C_1\gamma_1+C_2\gamma_2)}{C_2(1-\gamma_2)} = K_2(C_1\gamma_1+C_2\gamma_2)^{2-n_2}. \qquad (4)$$

That signifies that in a mixture of salts with a common ion the ratio of the product of the concentrations of the constituent ions of each salt to the concentration of its un-ionized part is proportional to the equivalent concentration of the common ion raised to the (2-n) power. In this case of a mixture of salts with a common ion, it is to be noted that the expression (γ_1C_1 + γ_2C_2) for the concentration of the common ion is also the expression for the sum of the equivalent concentrations (Σi) of all the positive or negative ions. If, as seems reasonable, it is this "total ion concentration" which in general determines the equilibrium, then for any salt of the general type A_xB_y present in any solution where the total equivalent ion concentration is (Σi), the following expression will hold true:

$$\frac{(A)(B)}{(A_xB_y)} = K(\Sigma\text{i})^{2-n}. \qquad (5)$$

It is evident from this equation that for a given total ion concentration in the solution the ratio (A)(B)/(A_xB_y) has a definite value which can be calculated from the values of K and n that may be derived by equation (1) from the ionization values of the salt when present in water alone. This makes it possible to calculate the concentrations of all the ions and the un-ionized substances present in a solution containing any definite mixture of salts, as will be shown later.

3. The Experimental Method.—Exactly 0.2 normal solutions of the four separate salts[1] were made by weighing out the ignited substances, transferring them to a two-liter graduated flask, and adding sufficient conductivity water to bring the solution at 18° to the graduation mark. The more dilute salt solutions and the solutions of the mixed salts were prepared by mixing with the aid of carefully calibrated pipettes definite volumes of the stock solutions with water or with each other. The specific conductance of the water used did not exceed 0.9×10^{-6} reciprocal ohms.

The conductance measurements were made at 18°, observing the usual precautions, in a U-tube of one of the forms described by Kohlrausch and Holborn,[2] with platinized electrodes. The conductance capacity of this cell was calculated from the conductance values given by Kohlrausch and Maltby[3] for various solutions of potassium chloride. The thermometer, slide-wire, and resistance coils used had all been calibrated.

4. The Conductance Data.—The results of the measurements with the separate salts are given in Table I.

TABLE I.

	Specific conductance × 1000 at 18°.			
Equiv. conc.	NaCl.	KCl.	Na_2SO_4.	K_2SO_4.
0.2	17.546	21.592	13.99	17.57
0.1	9.202	11.203	7.707	9.491
0.05	4.785	5.787	4.182	5.098

The specific conductance values for potassium chloride, sodium chloride, and potassium sulphate agree within 0.1 per cent. with the latest measurements of Kohlrausch and Maltby and Kohlrausch and Grüneisen.[1] Compared with the earlier conductance values of Kohlrausch, marked deviations, amounting in the stronger solutions to 2 per cent., exist in the case of sodium sulphate.

In Table II are given the results obtained with the mixtures. The first column gives the number of the mixture. The next four columns show the equivalent concentrations of the solutions from which each mixture was prepared. The next four columns show the relative volumes of these solutions which were mixed. The last column gives the specific conductance (×1000) in reciprocal ohms of the mixture at 18°.

It may be pointed out that a check upon the purity of the salts and the preparation of the solutions is afforded by the complete agreement of the conductances of mixtures Nos. 3 and 7, of which the former was prepared from sodium chloride and potassium sulphate and the latter from potassium chloride and sodium sulphate.

[1] These salts were kindly furnished to me by Mr. A. C. Melcher, who had prepared them in a pure state for other conductivity work.

5. *Method of Calculation and Results.*—When two salts with no common ion (for example NaCl and K_2SO_4) are mixed there are formed by metathesis two other salts (KCl and K_2SO_4). In any definite mixture of this kind the composition shows the value of the total sodium (ΣNa), total potassium (ΣK), total sulphate (ΣSO_4), and total chloride (ΣCl). The various forms in which these constituents exist are expressed by the following equation, in which the symbols within parentheses represent the *equivalent* concentrations:

$$(\Sigma \text{Na}) = (\text{Na}^+) + (\text{NaCl}) + (\text{Na}_2\text{SO}_4). \qquad (6)$$

$$(\Sigma \text{K}) = (\text{K}^+) + (\text{KCl}) + (\text{K}_2\text{SO}_4). \qquad (7)$$

$$(\Sigma \text{SO}_4) = (\text{SO}_4^{=}) + (\text{K}_2\text{SO}_4) + (\text{Na}_2\text{SO}_4). \qquad (8)$$

$$(\Sigma \text{Cl}) = (\text{Cl}^-) + (\text{NaCl}) + (\text{KCl}). \qquad (9)$$

According to the principle stated in the second section, the ratio of the product of the concentrations of the ions of any one salt to that of its un-ionized part is proportional to the total equivalent ion concentration raised to the (2-*n*)-power. (This ratio will, in the following discussion, be designated the ion-product-ratio of the salt.)

This principle applied to each salt in the mixture furnishes the four additional equations that are needed in order to make it possible to solve for the concentration of each of the eight substances present. The equations are:

$$\frac{(\text{Na}^+)(\text{Cl}^-)}{(\text{NaCl})} = K_1(\Sigma i)^{2-n_1}. \qquad (10)$$

$$\frac{(\text{K}^+)(\text{Cl}^-)}{(\text{KCl})} = K_2(\Sigma i)^{2-n_2}. \qquad (11)$$

$$\frac{(\text{Na}^+)(\text{SO}_4^{=})}{(\text{Na}_2\text{SO}_4)} = K_3(\Sigma i)^{2-n_3}. \qquad (12)$$

$$\frac{(K^+)(SO_4^=)}{(K_2SO_4)} = K_4(\Sigma i)^{2-n_4}. \qquad (13)$$

In these equations, $(\Sigma i) = (Na^+) + (K^+)$ or $(Cl^-) + (SO_4^=)$, and K_1, K_2, K_3, K_4, and n_1, n_2, n_3, n_4 are the coefficients and exponents for the respective salts which occur in the dilution formula, $(\gamma C)^n = KC(1-\gamma)$ expressing their ionization when present in water alone.

The above equations were easily solved by trial in the following way: The separate ion concentrations were estimated, and the numerical value of the ion-product-ratio for each salt corresponding to the sum of these ion concentrations was determined. This value for the salt in question was obtained from a curve plotted with its ion-product-ratios as abscissas and the corresponding ion concentrations as ordinates, the data given in Table I for the salts in water alone being employed. From these values of the ion-product-ratios and the values of the ion-concentrations estimated at the start, the concentrations of the un-ionized parts of the salts were calculated by equations (10) to (13). By substitution of the latter concentrations in equations (6) to (9) were obtained better values for the separate ion-concentrations. With these new values of the ion-concentrations the whole process was repeated until all eight equations were satisfied.

The specific conductance L of any given solution was then calculated from the equivalent concentrations, obtained as just described, and from the equivalent conductances (Λ_K, etc.), at zero concentrations of the separate ions by the equation

$$1000\,L = (Na^+)\Lambda_{Na} + (K^+)\Lambda_K + (SO_4^=)\Lambda_{SO_4} + (Cl^-)\Lambda_{Cl}. \qquad (14)$$

The values used for the equivalent conductances of the ions were those given by Kohlrausch,[1] namely, $\Lambda_{Na} = 43.6$, $\Lambda_K = 64.7$, $\Lambda_{SO_4} = 68.4$, and $\Lambda_{Cl} = 65.4$.

The results of the calculations are given in Table III. That the values given actually satisfy equations (6) to (9) can be readily proved by direct summation; and that they satisfy equations (10) to (13) can be shown by calculating the ion-product ratios and comparing these with those plotted for the salts in water alone, as above described.

6. *Discussion of the Results.*—A consideration of the last column of percentage differences shows that in the case of the first eight mixtures, in which the total salt concentration was 0.2 normal, the calculated conductance is greater by an average amount of 0.48 per cent., and that the variations from this average in the case of the mixtures with different proportions of sulphate and chloride are insignificant. In the case of the last seven mixtures, in which the total salt concentration was 0.1 normal, the same is true except that the average value of the percentage

---

[1] *Landolt-Börnstein-Meyerhoffer Tabellen*, p. 763.

difference is about one-half as large, namely 0.27 per cent., indicating that the deviation would probably be scarcely appreciable at 0.05 normal.

10	6 75	3 02	7.31	3 26	52 61	27 05	56.90	22 76	9 321	9 303	0 19
11	3.75	3 37	8.13	7 31	38 12	39.32	42 88	34 56	9.374	9 346	0 30
12	1 64	2 97	7 16	12 92	24.53	50 78	28 72	46 59	9 420	9.378	0 45
13	0.58	2.11	5 08	18 50	14 34	59 39	17 31	56 42	9 460	9 430	0.32
14	3 37	6 04	3 68	6 57	26 28	54.06	57 26	23.08	9 964	9 933	0 31
15	3 29	1 49	14 27	6 45	49 11	25 39	28 55	45.95	8 795	8 778	0 19

Since the conductance is substantially determined by the sum of the concentrations of the ions (irrespective of their separate concentrations), these results show that *when the concentrations of the separate ions of the salts in the mixtures are calculated by the principle expressed by the equation* $(A)(B)/(A_xB_y) = K(\Sigma i)^{2-n}$ *the sum of the ion concentrations is obtained with an accuracy of about* $^1/_2$ *per cent. at 0.2 normal and of about* $^1/_4$ *per cent. at 0.1 normal.*

The possibility must, of course, be recognized that a compensation takes place owing to the un-ionized tri-ionic salts being present in a larger or smaller proportion and the un-ionized di-ionic salts being present in a correspondingly smaller or larger proportion than that calculated. This might be the case, for example, if the ionization relations of the di-ionic and tri-ionic salts were determined by a different principle, instead of by the same principle, as has been assumed. All that can be said is that there are at present no facts known that make necessary this more complicated assumption.

One possibility deserves, however, brief consideration because of its possible theoretical significance. It might be assumed, namely, that the law of the equilibrium for a tri-ionic salt like K_2SO_4 should be written, in closer correspondence with the mass-action law, in the form

$$\frac{(K^+)^2(SO_4^=)}{(K_2SO_4)} = K(\Sigma i)^{3-n}, \text{ instead of } \frac{(K^+)(SO_4^=)}{(K_2SO_4)} = K(\Sigma i)^{2-n}.$$

When the salt is present in water alone or in a mixture with another potassium salt, these two expressions are identical, since then $(\Sigma i) =$

(K^+); but this is not true in any case where other positive ions are present, for example in mixtures with another sulphate, or in mixtures with no common ion like those above considered. Making the assumption that equations of the first form hold for potassium and sodium sulphates (in place of equations (12) and (13)) and that the other equations (6) to (11) hold true as before, the composition and conductance of Mixture No. 3 was calculated with the following result:

Concentrations in milli-equivalents per liter.								Spec cond. × 1000.		
NaCl.	KCl.	Na_2SO_4.	K_2SO_4.	Na^+.	K^+.	Cl^-.	$SO_4^{=}$.	Calc.	Obs.	% Diff.
9.70	8.40	12.40	10.91	77.9	80.7	81.9	76.7	19.22	17.52	9.6

It is seen that the conductance calculated under this assumption deviates very greatly (9.6 per cent. from the observed value).

BOSTON, April 10, 1910.

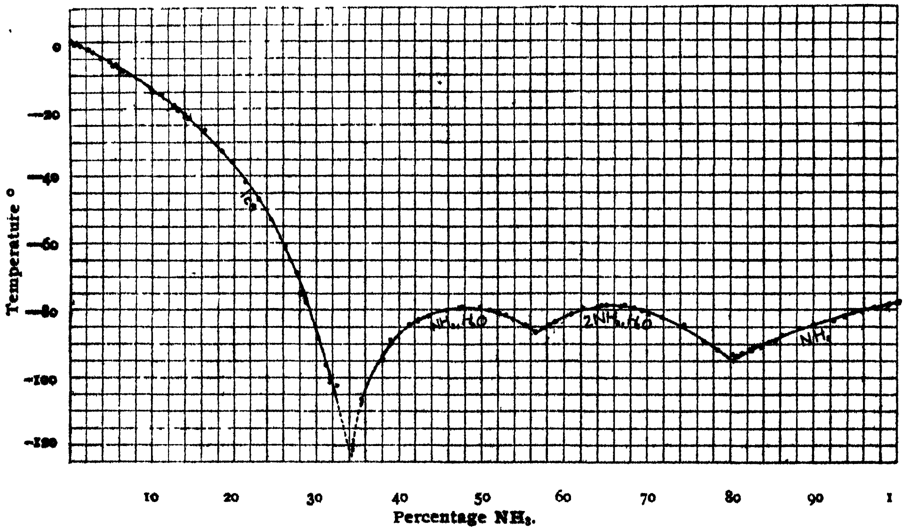
THE SOLID HYDRATES OF AMMONIA. II.

BY FRANK F. RUPERT.

Received April 11, 1910.

In a previous paper[1] the author gave the freezing-point curve for the system ammonia-water, showing the existence of two hydrates. Since then the work has been repeated, making a larger number of freezing-point determinations, and using better aids to accuracy.

The method used was substantially that described in the previous paper. Corrections were made for the weight of the ice inevitably collecting on the tube containing the solution, while being inserted in the vacuum tube. This amounted to 0.05 gram, with a possible error of 0.02 gram, in a total of 10 to 20 grams.



---

[1] THIS JOURNAL, 31, 866 (1909).

Temperatures above —100° were determined by using a standardized toluene thermometer, and are probably correct to within 0.5°; below that temperature by a thermo-couple standardized by comparison with the thermometer and with liquid air, but on account of the high viscosity of the solution, and consequent supercooling, the results for the latter determinations are unsatisfactory.

The table of freezing points follows:

Per cent NH_3.	Freezing point.	Per cent. NH_3.	Freezing point.	Per cent NH_3	Freezing point.
0.6	—0.6	30.2	—87.9	65.1	—79.0
0.7	—0.5	31.1	—96.0	66.9	—79.1
1.2	—1.0	31.7	Below —100.1	67.4	—78.6
2.1	—2.2	32.9	—102.5	68.4	—79.4
2.2	—2.2	34.5	Below —120.0	69.3	—80.2
2.9	—3.7	35.5	Below —101.5	70.1	—81.0
3.8	—5.0	38.0	—94.5	71.9	—82.0
4.0	—4.6	39.0	—88.8	74.3	—84.6
4.9	—5.9	41.4	—84.5	76.9	—88.8
5.1	—7.1	42.4	—84.2	78.6	—92.0
5.5	—7.0	42.4	—83.9	80.3	—92.9
5.7	—7.3	43.7	—82.0	80.8	—93.4
6.5	—8.5	45.9	—80.0	81.3	—92.8
6.7	—8.5	47.1	—79.6	82.3	—91.9
9.9	—13.4	47.7	—79.3	82.5	—92.4
11.1	—15.5	49.8	—79.3	82.8	—90.4
12.6	—19.0	51.1	—80.0	83.7	—90.6
13.2	—20.2	52.0	—80.6	84.9	—89.6
14.7	—22.9	52.2	—81.0	85.2	—88.8
16.4	—26.8	53.1	—81.8	86.1	—87.1
18.3	—32.6	53.9	—82.8	88.2	—85.3
19.6	—35.3	55.3	—84.2	90.0	—84.2
21.4	—41.9	56.7	—86.2	92.4	—82.9
23.0	—46.8	58.1	—84.9	93.6	—81.7
24.5	—52.6	58.9	—83.6	94.8	—81.0
26.1	—60.7	60.9	—81.2	95.7	—80.3
27.6	—68.5	62.2	—79.5	97.4	—79.4
28.5	—75.0	64.0	—79.4	98.9	—78.6
28.7	—77.8	64.6	—79.0	100.0	—78.0

The accompanying curve clearly shows two maxima, which do not differ from the theoretical compositions of NH_4OH and $(NH_4)_2O$, 48.6 and 65.4 per cent. ammonia respectively, by more than the experimental error. The eutectic points are: H_2O — NH_4OH, not determined; NH_4OH — $(NH_4)_2O$, —87°, 56.5 per cent. NH_3; $(NH_4)_2O$ — NH_3, —94°, 80.3 per cent. NH_3. Both ammonium hydroxide and ammonium oxide form fine white crystalline masses.

This work confirms the conclusion of the previous paper, namely, that ammonia forms two, and only two solid hydrates.

UNIVERSITY OF KANSAS.

THE INFLUENCE OF THE MAGNETIC FIELD ON THE PASSIVE STATE OF IRON.

By Horace G. Byers and Marc Darrin.

Received April 11, 1910.

In an article[1] by one of us it was shown that the passive state of iron may be produced in an anode in numerous electrolytes by a definite current density, and reference was made to the work of Fredenhagen[2] showing the same fact though incorrectly ascribed to the electromotive force employed. In an article by Nichols and Franklin[3] it was shown that the passive state of iron in nitric acid may be destroyed by placing the iron in a magnetic field of great intensity. It seemed of interest, therefore, to determine whether the passive state of iron as an anode might likewise be influenced by the magnetic field. To determine this question a number of experiments were carried out, but it was found impossible to destroy the passive state, when once established, by any magnetic field which we were able to produce with the apparatus available. Nevertheless, a distinct influence of the magnetic field upon the transition from the active

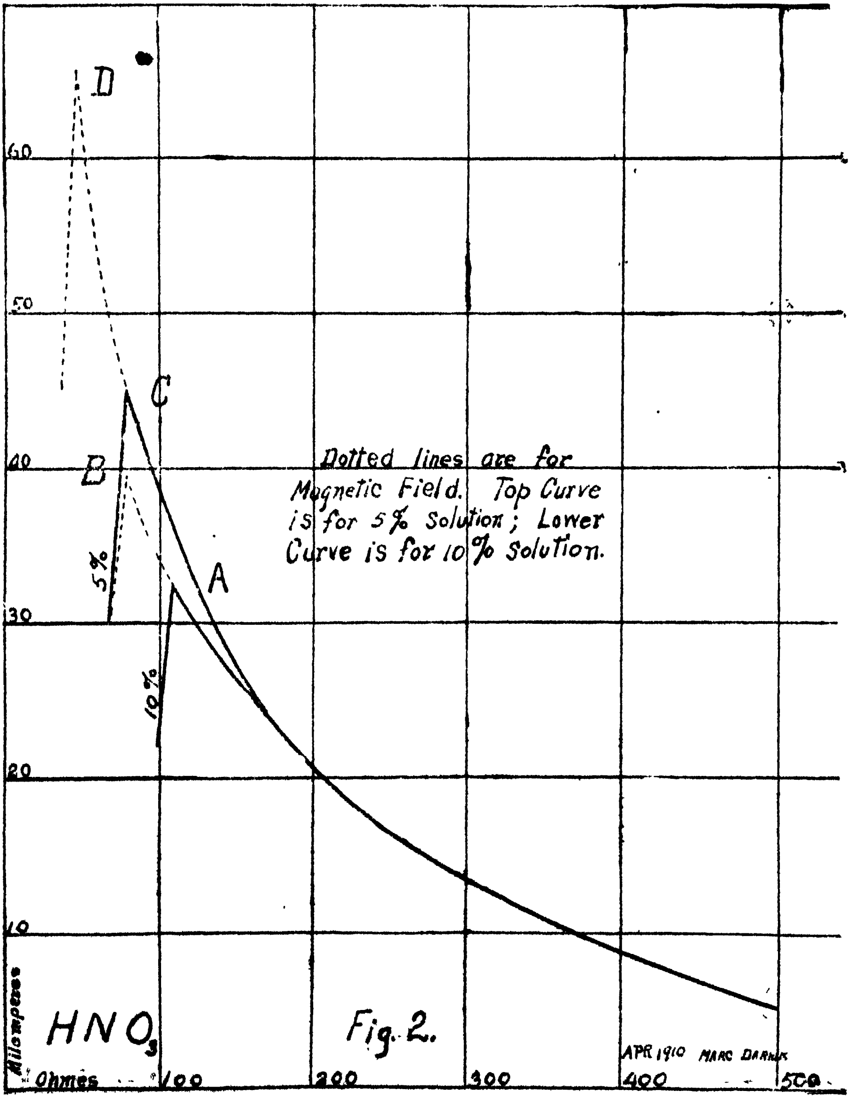
to the passive state was demonstrated in several solutions, the details of the work being given below. It should be noted that not only is the transition from the active to the passive state of iron when used as an anode produced by a given current density, but that this transition point is extremely sharp and well defined.

Experimental Method.—The apparatus was connected as shown in Fig. 1. A 20 cc. test tube, containing the electrolyte, was placed between the poles of a powerful electromagnet (5825 turns of No. 18 wire; run by 110 volts



Dotted lines are for Magnetic Field. Top Curve is for 5% Solution; Lower Curve is for 10% Solution.

Fig. 2.

d. c.; amperage, 3 amp.; distance between poles 2 cm.; area of poles 7 sq. cm.; diameter of coil 16 cm.; length of coil 17 cm.). The anode was made by sealing into a glass tube, with beeswax, a piece of soft piano wire (diameter 0.72 mm.) such that only 4 mm. was exposed at the immersed end; the cathode consisted of a small strip of platinum foil at the end of a similar glass rod. The electrodes were put in series with two U. S. storage cells *B* (giving a constant current of about 5 v.), a rheostat *R* and a delicate Weston milliammeter *M* reading directly to half milliamperes. A voltmeter *V*, with a telegraph key, was connected across the circuit between the two electrodes. When the iron anode was active, the voltmeter would indicate but slight differences in potential between the two electrodes, and the milliammeter would show between 10 and 70 milliamperes passing through the circuit; when the iron changed to the passive state, there was a sharp rise in the voltmeter (to about 4 v.) and a corresponding drop in the milliammeter of about 10 milliamperes.

Experimental Results: Nitric Acid Electrolyte without Magnetic Field.—The test tube was filled with a 10 per cent. solution of HNO_3. The rheostat was set at 500 ohms, and electrodes immersed in solution, as in Fig. 1. The result of this experiment is best understood by following the curve in Fig. 2; the resistance introduced at the rheostat is represented by abscissa, the amperage passing through the circuit by ordinates. As the resistance was lessened from 500 ohms to 400, 300, and 200, the

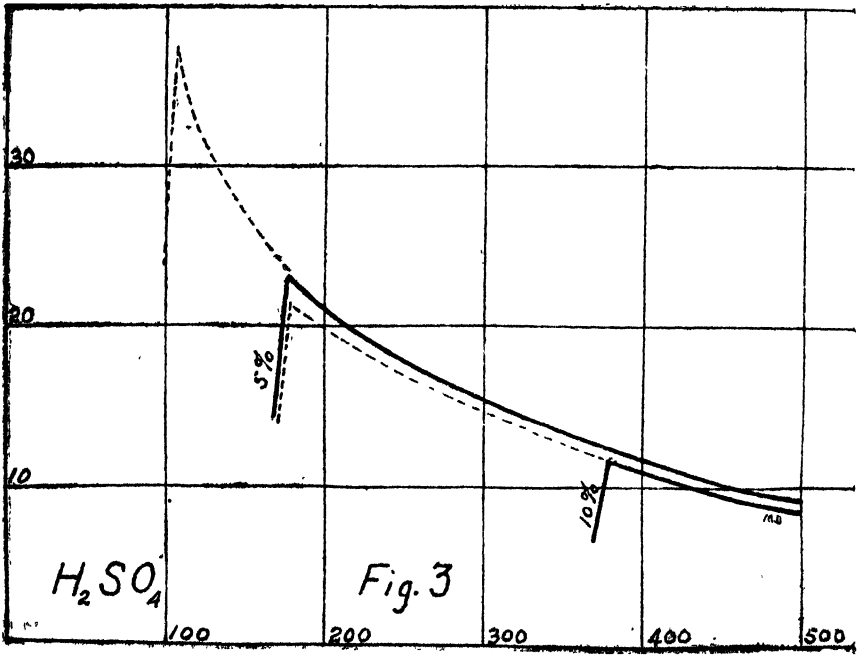


Fig. 3

amperage steadily increased till a point was reached at "A" when on removing 10 more ohms, the current dropped suddenly from 32.5 milliamperes to 20 milliamperes, marking the transition point from active to passive state, which is also shown by liberation of oxygen at the anode and a bright metallic surface of the iron.

In a Magnetic Field,—The above experiment was repeated in a magnetic field. Looking at the same curve (Fig. 2), the effect is readily seen; the transition point has been moved from *A* at 110 ohms resistance in rheostat, to *B* at 80 ohms. In other words, without the field, the sufficient and necessary strength of current to render the iron anode passive was 32.5 milliamperes; within a magnetic field, it would not become passive until the current had been raised to 40 milliamperes. This experiment with nitric acid was repeated many times, all results checking satisfactorily.

The above experiments were again repeated with a 5 per cent. solution of nitric acid. Here the effect of the magnet is even more marked (2), the transition point coming at *C* (45 milliamperes) without the field, and at *D* (65 milliamperes) within the field, a difference of 20 milliamperes. When the current through the electromagnet was stopped at any point between *D* and *C* (or in the former case between *B* and *A*) the iron *immediately* changed to the passive state, but once in this state the magnet was unable to restore it to the active condition. The only ways in which this could be done were by reducing the current

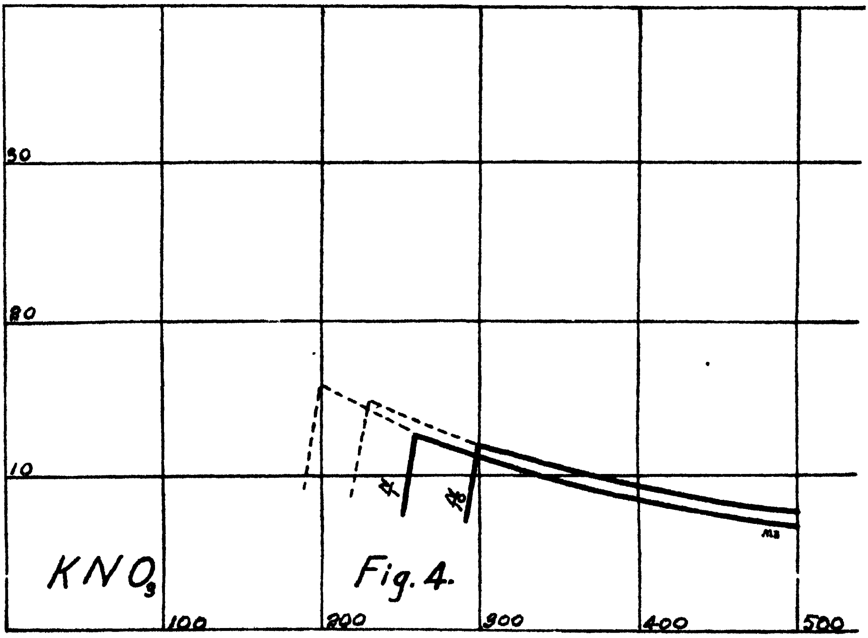

Fig. 4.

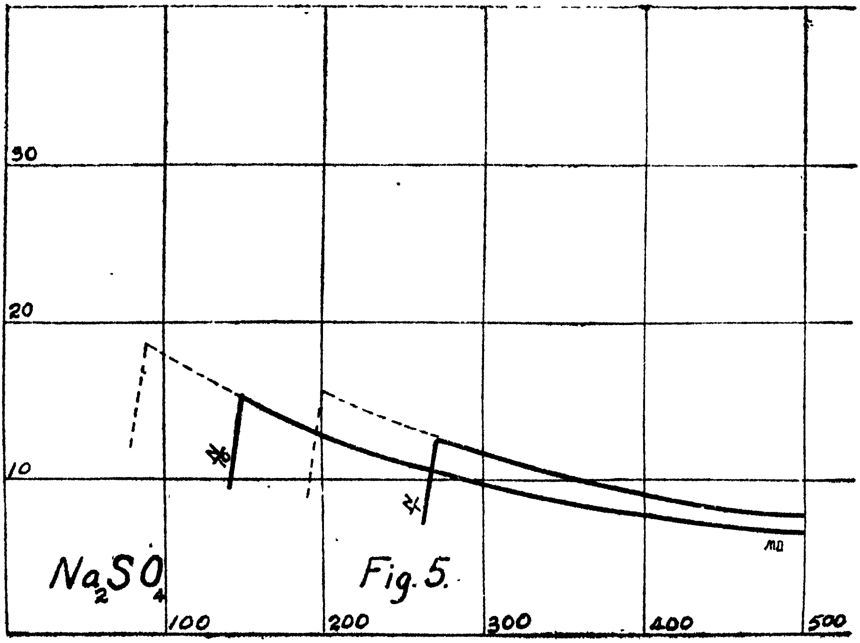
strength to a minimum with about 4000 ohms, by breaking the current, by bringing the electrodes into contact within the solution. This second transition point from *passive to active*, at about 4000 ohms was sharp, but difficult to measure accurately, and all efforts failed to show definitely whether it was affected by the magnetic field.

Results with Other Substances.—Using solutions of sulphuric acid instead of nitric acid, the four curves in Fig. 3 were plotted. They are of the same general nature as the nitric acid curves and illustrate well the effect of the magnet. Figs. 4 and 5 show the effect of the magnetic field on potassium nitrate and sodium sulphate solutions, respectively; in neither case is it nearly as great as for the active acids, but clearly of the same character. Fig. 6 is for phosphoric acid solutions. Here the effect of the magnet is greater than for the salts, but not as great as for the active acids. Similar experiments were made, using sodium hydroxide, potassium dichromate, dipotassium phosphate and monopotassium phosphate. Under all conditions solutions of the first three substances rendered the iron passive. In the case of a normal solution of monopotassium phosphate, however, by careful manipulation, the transition from active to passive iron could be found. However, this electrolyte did not behave as any one of the others, seeming to have properties akin to both the two opposite classes of electrolytes represented by sodium hydroxide and nitric acid, respectively. Although iron could be rendered active in this



solution, it would pass into the passive state within a considerable range of current density or by simply a short lapse of time. No effect of the magnetic field could be measured with this solution. With a 0.1 N solution, the passive properties were still more marked, so much so, that it could not be rendered active even temporarily. This is, of course, due to the hydrolysis of the salt. Two facts, which must be noted in connection with each of these passivity phenomena are: in no case, were any of the results affected in any way by the direction of the current through the electromagnet or by the relative positions of poles and electrodes; in no case, did the magnet cause a change in the amount of current passing through the electrolyte, or in the relative potentials of the two electrodes.

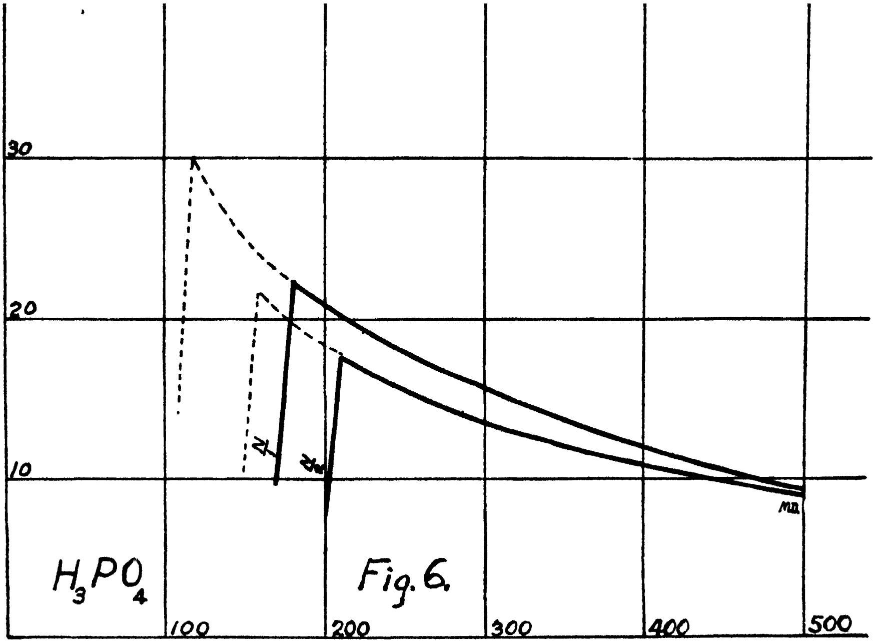


Fig. 6.

Conclusion.—In solutions of nitric, sulphuric and phosphoric acids, also of nitrates and sulphates, the transition point of passive iron to active iron is a function of current density but the transition is retarded by the magnetic field. It is of course recognized that passivity is also a function of temperature and concentration, but in these experiments they are constants and the only variables are current density and magnetic flux.

In the article previously referred to,[1] the writer gave a résumé of the various views in regard to passivity and stated that "none of them are satisfactory but that when experimental development warrants it he confidently expects the cause of passivity to be found to be an altered state of the metal itself, being produced by any one of several agents." The above experiments coupled with those of Nichols and Franklin seem to show that this altered state may be analogous to that of a number of magnets, the negative poles of which are all presented to the electrolyte, this orientation being produced by the various agents which cause the passive state. This view is not presented as proved but is tentative, and may lead to better work in this direction.

UNIVERSITY OF WASHINGTON

THE INFLUENCE OF CHLORINE UPON THE DETERMINATION OF NITRIC NITROGEN.

BY ROBERT STEWART AND J E GREAVES

Received April 9, 1910

It is known that chlorine has an appreciable effect upon the determination of nitric nitrogen by the phenyldisulphonic acid method. Very little information, however, is available as to the amount of chlorine which may be present and not affect the reliability of the results. In connection with the study of the influence of irrigating water upon the movement and production of nitric nitrogen in the soil, this question was investigated quite thoroughly in this laboratory.[1] The results are of interest to others working along similar lines and also to chemists who are working with problems in sanitary water supply.

The chlorine in the soil under consideration was determined as follows: An aliquot portion of the extract of the soil, prepared as for the nitric nitrogen determination, was titrated against a one-hundredth normal silver nitrate solution. The results obtained are given in Table I. The results are expressed as parts of chlorine per million parts of soil.

TABLE I.—AMOUNT OF CHLORINE PRESENT IN THE SOIL EXTRACT

	Depth of soil in feet									
No of plot	1	2	3.	4	5	6.	7	8	9	10.
41 G.	0.849	0.814	0.496	0.923	0.567	0.779	0.744	0.673	0.815	0.496
42 G.	0.886	0.779	0.697	0.838	0.795	0.602	0.567	0.602	0.673	0.496
43 G.	0.780	0.425	0.921	0.709	1.134	0.496	0.922	0.496	0.425	0.425

These results indicate quite clearly that the chlorine in the soil under consideration did not exceed 1.134 parts per million.

It was then necessary to determine whether this amount of chlorine would interfere with the determination of nitric nitrogen by the phenyldisulphonic acid method. With this object in view, varying amounts of sodium chloride were added to given quantities of the standard potassium nitrate solution. The nitric nitrogen was then determined in the usual way. The results are very interesting and will be found in Table II. The results are expressed as parts per million.

---

[1] Utah Experiment Station, *Bull.* 106, p. 80.

TABLE II.—THE EFFECT OF CHLORINE ON THE SENSITIVENESS OF THE METHOD.

Chlorine added.	Nitric nitrogen present	Nitric nitrogen found.	Chlorine added.	Nitric nitrogen present.	Nitric nitrogen found
0.5278	0.1	0.1	5.278	0.1	0.1
1.056	0.1	0.1	5.886	0.1	0.095
1.584	0.1	0.1	6.342	0.1	0.094
2.113	0.1	0.1	6.856	0.1	0.092
2.638	0.1	0.095	7.362	0.1	0.092
3.167	0.1	0.090	7.917	0.1	0.092
3.694	0.1	0.098	8.446	0.1	0.092
4.224	0.1	0.090	8.9776	0.1	0.090
4.749	0.1	0.090	9.496	0.1	0.086

Similar determinations were made until a concentration of thirty parts per million of chlorine was reached. No further decrease in the amount of nitric nitrogen found was obtained, *i. e.*, the amount of nitric nitrogen found tended to approach a constant value of nine-tenths of the amount actually present.

The results show that chlorine, when present in quantities as low as 2.638 parts per million, affects the results for nitric nitrogen obtained by this method, less nitric nitrogen being found than is really present.

CHEMICAL LABORATORY, UTAH EXPERIMENT STATION

ON A NEW VOLUMETRIC METHOD FOR COBALT AND NICKEL.

BY GEORGE S. JAMIESON

Received April 8, 1910

The well-known application of potassium ferrocyanide to the volumetric determination of lead and zinc has led the writer to investigate the application of this method to the determination of cobalt and nickel, and conditions have been found under which concordant and accurate results may be obtained. As far as can be found by consulting the literature, this method has not been previously suggested.

It is believed that the most important practical application of the method will be in the determination of nickel in steel, for it can be carried out in the presence of iron, it is rapid and requires no expensive reagents. As far as ease and rapidity are concerned, it appears that the cyanide method as applied in the presence of iron by C. M. Johnson[1] and also by Campbell and Arthur[2] is the only one which can compete with it. The writer has found that by combining the modifications of the authors just referred to, the cyanide method may be decidedly improved, as will be shown by the description and the results which are given beyond. The choice between the ferrocyanide and the cyanide methods for nickel in steel would depend upon the preference of the operator, but it is to be observed that the cyanide method is not applicable to large amounts of cobalt on account of a peculiar dark precipitate produced under these circumstances during the cyanide titration which interferes with the end reaction.

---

[1] THIS JOURNAL, 29, 1201 (1907).

[2] *Ibid.*, 30, 1116 (1908).

For the ferrocyanide titration a solution containing 20 grams per liter of potassium ferrocyanide is recommended as a suitable strength for most work. Then each cubic centimeter will be equivalent to about 3 milligrams of cobalt or nickel. To standardize this it is best to employ a cobalt or nickel solution of known strength prepared either from pure salts in known volume, or by gravimetric standardization. Three equal portions of this solution containing about 0.1 gram of the metal are taken in beakers. Ten cc. of a 10 per cent. solution of ferric chloride and 2 to 3 grams of citric acid are added to each and then ammonia is added with stirring until the solution has a faint odor of the reagent. It is important that the excess of ammonia should not be too great, as in this case the results will be irregular. The solutions are then diluted to about 100 cc. with hot water and are brought to a temperature of 65–75°. The ferrocyanide solution is now run in slowly with constant stirring. After a few drops of the ferrocyanide have been added, the nickel or cobalt ferrocyanide begins to precipitate. As the titration progresses, a drop or two of the solution is removed by means of the stirring rod to a paraffined white plate and acidified with a drop of dilute acetic acid. The solution is thoroughly stirred and a second test is made in the same way beside the other. This pair of tests is designated as No. 1 and a record is made of the volume of ferrocyanide used at this point. The titration is carried on in this way until a greenish color is developed in about five minutes at a definite point in the series. The most convenient practice is to titrate the first portion roughly, and then to get the exact point with the other two portions. The important precautions are to avoid more than a slight excess of ammonia and to titrate slowly with thorough stirring.

The actual determinations are made in exactly the same way as the standardization just described. The method cannot be applied in the presence of such metals as copper, zinc, and manganese which react with potassium ferrocyanide. In the case of substances containing a considerable amount of iron, which must be in the ferric condition, no addition of ferric chloride is required.

The following results were obtained with varying quantities of cobalt and nickel solutions:

The following directions may be followed for the determination of nickel in steel: Weigh out 1.0000 gram of borings into a 150 cc. flask, add 10–15 cc. of dilute nitric acid (equal volumes of 1.42 sp. gr. acid and water). Cover the flask with an inverted crucible cover, and when the violent action is over, remove cover and boil gently over a free flame, keeping the flask in constant motion and inclined at about 45°, until the

14	0.0377	19.8	0.0373	—0.0004

steel is decomposed. (If a steel is encountered which is not entirely dissolved by nitric acid, add a drop or two of strong hydrochloric acid or a crystal of potassium chlorate and continue the boiling.) Add 10 cc. of concentrated nitric acid as soon as the steel is in solution, heat to boiling again, and add half a gram of solid potassium chlorate. Boil until the chlorine is expelled. Add the same quantity of chlorate again and boil for about two minutes. Then allow the flask to cool a little and filter off the manganese dioxide on a Gooch crucible, washing with as small a quantity as possible of cold water. Proceed then according to the method already described. It is to be observed that the presence of a large amount of iron, as in the case of nickel steel, somewhat retards the appearance of the end reaction. It is advisable to standardize the ferrocyanide solution in the presence of about the same amount of iron as is present in 1 gram of steel. The following determinations were made in the three samples of steel by the method just described. The nickel in A was checked by the electrolytic, ether-cyanide, and dimethyl-glyoxime methods. The analyses of samples B and C were completed before the results by other methods were known.

No.	Ni steel. Grams	cc. $K_4Fe(CN)_6$.	Per cent nickel.	Ni by other methods

3C	1.0000	11.20	3.52	3.50

[1] Another ferrocyanide solution.

Duplicate analyses of nickel in a steel can be made in this way in about an hour, and the results show that the method is accurate.

The following application of the cyanide method to the determination of nickel in steel was worked out by the writer before the papers of Johnson and Campbell and Arthur, which have been previously referred to, had been seen. The former investigator used a large amount of citric acid, while the latter used a large amount of sodium pyrophosphate. The writer uses both of these reagents together, but in much smaller quantity. The directions, according to the writer's modification, are as follows:

Take 0.5 gram of borings in a 150 cc. flask, add 10 cc. of 1 : 1 nitric acid and dissolve according to the directions given for the ferrocyanide method. If the metal contains more than 0.5 per cent. of manganese, the writer prefers to remove it according to the directions just referred to. Add to the nitric acid solution 2 to 3 grams of citric acid and 2 grams of anhydrous sodium pyrophosphate, then add ammonia slowly with stirring until the precipitate formed at first just dissolves and the solution acquires a very faint odor of ammonia. If too much ammonia has been used, it must be nearly neutralized by the careful addition of nitric acid. Dilute to about 150 cc. and cool to a temperature below 20°, add a few drops of a 10 per cent. solution of potassium iodide, and enough tenth-normal silver nitrate solution, the volume of which must be noted, to produce a distinct turbidity. Then run in potassium cyanide solution very slowly with stirring until the turbidity just disappears and the solution lightens to a golden yellow color. The solution should remain bright for five minutes, otherwise the titration is incomplete. Sometimes it happens that the turbidity disappears when only one-third to one-half of the required amount of cyanide has been used, but in this case upon the addition of a drop or two of silver nitrate, or upon waiting a moment, the turbidity reappears. The end-point is best observed when the beaker is placed upon a white paper having an elliptical hole in it under which is placed a black glazed paper for contrast. In making the calculation the proper deduction for the silver nitrate used should be made.

The potassium cyanide solution should be standardized by means of the tenth-normal silver nitrate. To do this take 20 cc. in a beaker, dilute to about 150 cc. with cold water, add ammonia until the odor is distinct but slight, add a few drops of 10 per cent. potassium iodide solution, run in silver nitrate until a distinct turbidity is produced, and then finish by slowly adding the cyanide solution until the turbidity just disappears. The theoretical amount of nickel per 1 cc. of tenth-normal solution is 0.002935 gram, but instead of using this value it is perhaps preferable to standardize the solution with a steel of known content in nickel.

The theoretical value was used in the test analyses given below, which indicate very satisfactory results for the method.

SHEFFIELD LABORATORY, NEW HAVEN, CONN

[CONTRIBUTIONS FROM THE SHEFFIELD LABORATORY OF YALE UNIVERSITY.]

RESEARCHES ON AMINES: ALKYLATIONS WITH DIMETHYLSULPHATE. SYNTHESIS OF DIMETHYLPHENYLETHYLAMINE.

(THIRD PAPER.)

BY TREAT B JOHNSON AND HERBERT H. GUEST.

Received March 23, 1910

Contents.—1. Historical. 2. Purpose of Investigation and Discussion of Results. 3. Experimental Part.

1. Historical.

That dialkylsulphates (dimethyl- and diethylsulphates) can be used in place of the corresponding halides for the alkylation of amines has been known for a long time. Dumas and Peligot,[1] in 1835, examined the behavior of dimethylsulphate towards ammonia and observed the formation of methylalcohol and methylammonium sulphate (Sulfomethylan). Strecker[2] repeated this experiment and also investigated the action of diethylsulphate on ammonia. He found that the reactions were not as simple as assumed by Dumas and Peligot and obtained, with diethylsulphate, the ammonium salt of an acid, $C_{16}H_{23}NO_4.4SO_3 + NH_3$ (athylaminschwefelsäure Ammoniak), from which he prepared ethylamine by decomposition with alkali.

Babo[3] examined the action of dimethylsulphate (Schwefelsaures Methyloxyd) on aniline and showed that it alkylated smoothly giving monomethylaniline. He also observed that quinoline and nicotine reacted with this reagent and diethylsulphate giving crystalline addition products (quaternary compounds?).

The study of the action of these sulphates on amines received no further attention, apparently, until 1880 when a paper by Claesson and Lundvall[4] appeared, in which they describe their behavior towards ammonia and several aliphatic and aromatic bases. They repeated the work of Strecker and observed that diethylsulphate reacted with ammonia giving not only ethylamine, but also the quaternary salt $(C_2H_5)_4N.SO_4C_2H_5$. Quaternary salts were also obtained by alkylation of diethylamine, dimethylaniline and tribenzylamine with dimethylsulphate. They write: "Die Reaktion zwischen Ammoniak und Methylsulfat ist somit eine rein additionelle. Sie verläuft nach folgender Gleichung:

---

[4] *Ber.*, 13, 1700.

$$CH_3OSO_2OCH_3 + NH_3 = CH_3OSO_2ONH_3.CH_3."$$

The usefulness of dimethylsulphate as an alkylating agent for amines was later greatly enhanced by the work of Ullmann and his co-workers.[1] They showed that it not only reacted smoothly with organic bases (in ether, chloroform and benzene), but also that it can be employed successfully for the alkylation of cyclic amines, *viz.*: quinolines, aminonaphthacridines, phenylacridines, diaminoacridines and aminophenazines. They write:[2] "Die Resulte übersehen lassen, dass Dimethylsulfat in allen Fällen das Iodmethyl ersetzen kann, aber meistens noch bedeutend rascher und besser als dieses reagirt." Ullmann's[3] interpretation of the reactions between amines and dimethylsulphate is summarized in his own words—"Dieselbe verläuft nämlich nicht, wie Claessón und Lundvall augegeben,—Es entsteht also das methylschwefelsäure primäre Amin und die entsprechende secundäre Base."

$$(CH_3)_2SO_4 + 2RNH_2 = RNH_2.H.CH_3SO_4 + RN\overset{\cdot}{H}CH_3.$$

Decker and his students[4] have used the alkylsulphates for the preparation of quaternary derivatives of cyclic bases. For example, they were unable to obtain quaternary compounds of several quinolines by addition of methyliodide, while, on the other hand, dimethylsulphate reacted quantitatively giving the corresponding quaternary alkyl sulphates. Methyldiphenylamine reacted smoothly with dimethylsulphate at 140–150° giving the quaternary compound $(C_6H_5)_2(CH_3)_2NSO_4CH_3$[5] while no addition took place with methyliodide under the same conditions.

The action of dimethylsulphate on the glyoxaline ring was studied by Pinner.[6] He examined its behavior towards diphenylglyoxaline I, and triphenylglyoxaline (Lophine) II, but did not observe the formation of nitrogen methyl derivatives. Lophine reacted abnormally with the sulphate giving a characteristic double compound, $C_{21}H_{16}N_2.(CH_3)_2SO_4.2H_2O$, having the properties of a salt. Pinner remarks that the sulphate acts in this case as a weak acid and that the compound has not the possible structure of a quaternary compound III (Methylschwefelsaures Methyllophin). He writes: "Es ist nicht ohne Interesse, das Verhalten von Methylsulfat anderen Basen gegenüber zu untersuchen."

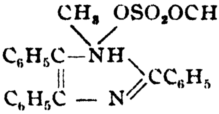
II.



III.

Bamberger[1] employed dimethylsulphate for the preparation of *o*-monomethyl- and *o*-dimethylaminobenzaldehydes from *o*-aminobenzaldehyde and also later for the alkylation of mesidine to monomethyl- and dimethylmesidines.[2] This reagent has also been used successfully for the alkylation of amino compounds by Johnston,[3] Baeyer,[4] Willstatter and Kahn,[5] Weil,[6] Smith,[7] Burmann,[8] Frohlich,[9] and Houben and Brassert.[10]

In no case, so far as the writer is aware, has it been observed that an amine can react with dimethylsulphate, in a similar manner as with an aliphatic ester, giving an amide of sulphuric acid. It is interesting to note in this connection that recent attempts by Ephraim and Gurewitch[11] to prepare sulfamide $SO_2(NH_2)_2$ from dimethylsulphate by action of ammonia, in alcohol solution and in liquid form, were unsuccessful. They reacted, under both conditions, with formation of methylamine according to the following equation:

$$SO_2(OCH_3)_2 + 2NH_3 = CH_3OSO_2ONH_4 + NHCH_3.$$

2. Purpose of Investigation and Discussion of Results.

The work described in this paper was undertaken with the object of determining the behavior of dimethylsulphate towards some aromatic β-amines.

Any methods, by which the nitrogen alkyl derivatives of phenylethylamine IV, or *p*-hydroxyphenylethylamine V, can be obtained easily are of value, on account of the interest, at the present time, of compounds of this character to pharmacologists. Of all the nitrogen alkyl derivatives of phenylethylamine, dimethylphenylethylamine, VII, is probably the the most interesting because of its close structural relationship to the naturally occurring alkaloid *hordenine*, VIII (dimethyl-*p*-hydroxyphenylethylamine). It seemed desirable therefore, to the writer, to determine whether this base, VII, can be synthesized by direct alkylation of phenylethylamine. Previous attempts to prepare it by alkylation of the latter with methyliodide have been unsuccessful.

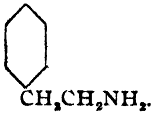
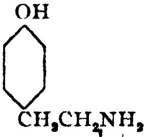
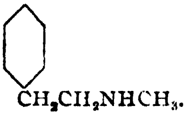
Johnson and Guest[1] showed in a paper from this laboratory that methyliodide reacts with phenylethylamine giving the hydriodide of the unaltered base and the quaternary derivative—*trimethyl-phenylethylammonium-iodide*. No matter what proportion of the methyliodide was used, they obtained no evidence of the formation of monomethyl- or dimethylphenylethylamines, VI and VII. This observation was later confirmed by Barger.[2]



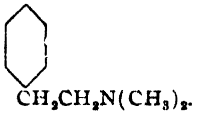
IV.



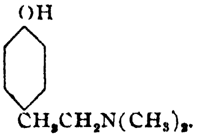
V.



VI.



VII.



VIII.

We now find that this base, VII, can be prepared from phenylethylamine by alkylation with dimethylsulphate. Several negative experiments, however, were performed before we finally succeeded in obtaining conditions favorable for its formation. All attempts to alkylate in aqueous solution, in the presence of alkali, were unsuccessful. The action of dimethylsulphate, in ether, was also investigated, but the results were similar to those obtained in our alkylation experiments with methyliodide. The products of the reaction were the phenylethylamine salt of methylsulphuric acid and a hydroscopic salt having the properties of a quaternary derivative. Conversion into the tertiary base was finally accomplished by alkylation, in methyl alcohol, in the presence of sodium methylate. In this manner a good yield of the base was obtained, which boiled at 200–204° at ordinary pressure.

This same amine (b. 198–202°) has also recently been prepared by Barger[3] by heating phenylethylchloride with dimethylamine, but so little

[1] *Am. Chem. J.*, 42, 340.

[2] *J. Chem. Soc.* (London), 95, 2194.

[3] *Loc. cit.*

material was obtained by him that it was not analyzed nor well characterized. Since he showed that the base gives, by nitration at —10°, a good yield of the paranitro derivative IX (60 per cent.), which can be converted into a base identical with *hordenine*, our synthesis of the amine VII therefore offers a method of preparing *hordenine* directly from phenylethylamine.

$$C_6H_5CH_2CH_2NH_2 \longrightarrow C_6H_5CH_2CH_2N(CH_3)_2 \longrightarrow$$
$$\underset{\text{IX.}}{NO_2C_6H_4CH_2CH_2N(CH_3)_2} \longrightarrow HOC_6H_5CH_2CH_2N(CH_3)_2$$

The interesting behavior of phenylethylamine towards dimethylsulphate led us to examine also the action of this reagent on *p*-nitrophenylethylamine.[1] To our surprise, this base underwent no alkylation, in methyl alcohol, in the presence of sodium methylate and practically 90 per cent. of the amine used was recovered unaltered. It was identified by its hydrochloride, and on reduction was converted smoothly into *p*-aminophenylethylamine.[2]

This difference between phenylethylamine and *p*-nitrophenylethylamine, in their behavior towards dimethylsulphate, is probably due to the fact that one is a much stronger base than the other. Phenylethylamine, being the most basic, adds dimethylsulphate at once, and undergoes alkylation before the sulphate is decomposed by the sodium methylate. On the other hand, *p*-nitrophenylethylamine, which is the weaker base on account of the negative influence of the *p*-nitro group, has a much less tendency to add the sulphate, under the conditions of the experiment; consequently the latter is completely decomposed by the sodium methylate and the amine is recovered unaltered. Dimethyl sulphate would be expected to react readily with sodium methylate, in a similar manner as with methyliodide, giving dimethyl ether and the sodium salt of methylsulphuric acid or sodium sulphate,

$$CH_3OSO_2OCH_3 + NaOCH_3 = CH_3OSO_2ONa + (CH_3)_2O,$$

or

$$CH_3OSO_2OCH_3 + 2NaOCH_3 = Na_2SO_4 + 2(CH_3)_2O.$$

That our assumption is correct is supported by the fact that the odor of dimethyl ether was apparent during the reaction, and also by a previous observation of Nef.[3] He showed, for example, that dimethylsulphate is decomposed practically quantitatively when dissolved in a cold methyl alcohol solution of potassium hydroxide, giving dimethyl ether and potassium sulphate.

Attempts to prepare secondary and tertiary amines from *p*-nitrophenylethylamine by alkylation with methyliodide were also unsuccessful.

They reacted at 100°, in methyl alcohol, giving the hydriodide of the unaltered base and *trimethyl-p-nitrophenylethylammonium iodide.*

The writers[1] have shown that acetyl-*p*-nitrophenylethylamine can be obtained in good yield by nitration of acetylphenylethylamine. We now find that the corresponding methyl derivative of this nitro amide, XI, can be prepared, in a similar manner, by nitration of acetylmethylphenylethylamine, X. It was converted quantitatively into the unknown *p*-nitrophenylethylmethylamine, XII, by hydrolysis with acids.

$$\underset{\text{XII.}}{NO_2C_6H_4CH_2CH_2NHCH_3}.$$

3. Experimental Part.

Action of Dimethylsulphate on Phenylethylamine in Ether.—Five grams of the amine were dissolved in ether and 20 grams of the sulphate (8 mols.) added slowly to the solution. There was an immediate reaction with evolution of heat and about 10 grams of a colorless crystalline salt separated. After allowing to stand for an hour, this was filtered off and the ether filtrate allowed to evaporate. We obtained an oil (mostly unaltered dimethylsulphate) to which was added an excess of alkali and then subjected to steam distillation. No bases were carried over by the steam. A portion of the material, insoluble in ether, was purified by dissolving in alcohol and then precipitating by dilution with ether. Glistening plates separated and melted at 75–77° to an oil. A nitrogen determination indicated that the substance was the *phenylethylammonium salt of methylsulphuric acid,* $C_6H_5CH_2CH_2NH_3.SO_4CH_3$.

Calculated for $C_9H_{15}O_4NS$: N, 6.0; found: N, 5.55.

The remainder of the salt was shaken with an excess of ether and in presence of a strong aqueous solution of sodium hydroxide. A crystalline product remained undissolved by this treatment. It was soluble in cold water and alcohol and could be warmed in sodium hydroxide solution without decomposition. The compound was very hydroscopic, contained sulphur and decomposed from 100–110° with effervescence. Its chemical behavior indicated that it was a quaternary salt.

Phenylisothiocyanate was added to the ether solution above and the ether allowed to evaporate in the air. Beautiful prisms of 1-phenyl-2-phenylethylthiourea finally separated and melted, after one crystallization from alcohol, at 106°. A mixture of this compound and some of the pure thiourea prepared from phenylethylamine melted at the same temperature.

Dimethylphenylethylamine, $C_6H_5CH_2CH_2N(CH_3)_2$.—Eight and four-tenths grams of metallic sodium (3 at.) were dissolved in 135 cc. of methyl alcohol and 14.5 grams of phenylethylamine added to the solution. Kahlbaum's dimethylsulphate (46 grams) was then added, in small portions, when there was a violent reaction with evolution of heat and separation of a gelatinous salt. After the final addition of dimethylsulphate, 50 cc. of methyl alcohol were added and the mixture heated on the steam bath for about 5 hours. It was then acidified with hydrochloric acid and evaporated to dryness to remove the excess of alcohol and acid. In order to separate the base, the hydrochloride was decomposed with an excess of sodium hydroxide and the bases distilled with steam and dissolved in hydrochloric acid. On evaporating to dryness a hydroscopic salt was obtained, which was dissolved in 75–100 cc. of cold water and treated with an excess of potassium nitrite, for about 10 minutes, to remove any primary and secondary amines. An excess of alkali was then added and the tertiary amine extracted with ether and dried over potassium hydroxide. It is a strong base which absorbs carbon dioxide from the air and boils at 200–205° at ordinary pressure. The yield was good.

---

[1] *Loc. cit.*

Calculated for $C_{10}H_{15}N$: N, 9.40; found: N, 9 38.

Platinum Salt.—Crystallizes from water in hexagonal tables which decompose at 221°. A mixture of this salt and the corresponding salt of methylphenylethylamine[1] (m. 212°) melted below 207°.

Hydrochloride, $C_6H_5CH_2CH_2N(CH_3)_2.HCl$.—This salt was prepared by dissolving the base in dilute hydrochloric acid and then allowing the solution to evaporate in a vacuum over potassium hydroxide. The salt separated under these conditions in colorless plates, which melted at 205° to an oil. It decomposed with effervescence when heated above 270°.

Acetylmethylphenylethylamine, $C_6H_5CH_2CH_2N(CH_3)COCH_3$.—This amide was prepared by carefully adding 15 grams of freshly distilled thioacetic acid to 19 grams of methylphenylethylamine[1] and then heating at 210° for 1–2 hours to complete the reaction. The amide was a dark-colored oil, which did not solidify after standing at ordinary temperature for several hours. It was used for the following preparation without further purification.

Acetylmethyl-p-nitrophenylethylamine, (*p*) $NO_2C_6H_4CH_2CH_2N(CH_3)COCH_3$.—This compound was prepared by dissolving 25 grams of acetylmethylphenylethylamine in 85 cc. of nitric acid (sp. gr. 1.51). The temperature was not allowed to rise above 5° during the nitration. After allowing to stand for a few minutes the solution was then diluted with ice water and the nitric acid neutralized with ammonia when the amide separated as an oil. This was extracted with ether and the ether solution allowed to evaporate spontaneously when the amide finally solidified. More separated from the aqueous filtrate on standing. The crude substance melted at 90–94°.

---

[1] Johnson and Guest, *Loc. cit.*

The amide is very soluble in ethyl acetate, ethyl alcohol, chloroform and benzene. It was purified for analysis by several recrystallizations from ethyl acetate and a mixture of petroleum ether and benzene. It melted at 100–101° to a clear oil without effervescence (Kjeldahl):

Calculated for $C_{11}H_{14}O_3N_2$: N, 12.6; found: N, 12.10.

Oxidation of Acetylmethyl-p-nitrophenylethylamine with Potassium Dichromate.—About 0.9 gram of this amide and 3.2 grams of potassium dichromate were dissolved in 6.5 cc. of concentrated sulphuric acid and the solution heated at 60° for about 10–12 hours. A crystalline acid was obtained, which crystallized from hot water in prismatic crystals, and melted, after purification, at 234°. It was identified as paranitrobenzoic acid. A mixture of our acid and paranitrobenzoic acid melted at the same temperature.

Methyl-p-nitrophenylethylamine, (*p*) $NO_2C_6H_4CH_2CH_2NH(CH_3)$.—This amine was obtained, in the form of its hydrobromide, when the above acetyl derivative was digested with hydrobromic acid. The base separated as a heavy, yellow oil when sodium hydroxide was added to an aqueous solution of the hydrobromide.

1-Phenyl - 2,2 - methyl - p - nitrophenylethylthiourea, (*p*) $NO_2C_6H_4CH_2CH_2N(CH_3)CSNHC_6H_5$.—This thiourea was prepared by the action of phenylisothiocyanate on the above methyl-*p*-nitrophenylethylamine. It crystallizes from 95 per cent. alcohol in plates, which melt at 137–138°. A mixture of this thiourea and 1-phenyl-2-paranitrophenylethylthiourea[1] melted at 109–115° (Kjeldahl):

Calculated for $C_{16}H_{17}O_2N_3S$: N, 13.3; found N, 12.8.

Action of Dimethylsulphate on Paranitrophenylethylamine, $NO_2C_6H_4CH_2CH_2NH_2$.—Nine and two-tenths grams of the hydrochloride of *p*-nitrophenylethylamine[1] were dissolved in 50 cc. of methyl alcohol containing 3.7 grams of sodium. Fourteen and three-tenths grams of dimethylsulphate, boiling at 104–110° at 28–30 mm., were then added slowly to the cooled solution by means of a dropping funnel. There was an immediate reaction with evolution of much heat. After the addition of dimethylsulphate the mixture was heated to boiling, allowed to stand for 2.5 hours, acidified with an excess of hydrochloric acid and finally concentrated on the steam bath. An excess of alkali was then added when unaltered *p*-nitrophenylethylamine separated. This was extracted with ether and dried over potassium carbonate. The yield was 6.0 grams. A theoretical yield of unaltered *p*-nitrophenylethylamine would be 7.0 grams. The hydrochloride melted at 213–214°.[1]

In Fig. 1 the curves for the five strong acids—hydrochloric, hydrobromic, nitric, sulphuric, and phosphoric—fall so closely together that one unbroken line is shown for them all. The enzyme begins to be destroyed by these mineral acids at a concentration of about 0.01 normal and the measurements of the activity were not made above this limit. The falling of the curve (Fig. 1) with increasing acidity shows a characteristic progression in the order, strong mineral acids, oxalic, tartaric, citric, acetic, and boric, which is also the order of the strengths of these

---

[1] Destruction of enzyme occurs.

acids. If the ionization of the acids is ta activity plotted against the actual hydrogen-i weaker acids all give curves agreeing closely mineral acids. The enzymotic activity is thus the hydrogen-ion concentration. The theoretical int characteristic relation between the activity and the true postponed until further investigations have been made.

The Destruction of Invertase by Acids and Alkalis at 30° C.—The tion of invertase by acids and alkalis at 30° was measured by mix portion of well dialyzed invertase solution with the appropriate acid alkaline solution, removing portions of this mixture after definite intervals of time and measuring their activities after bringing them to a uniform condition of slight acidity with acetic acid in order to find the maximum activity which is a measure of the quantity of invertase in the solution. If the activities of the successively removed samples showed a decrease it was concluded that the invertase was being destroyed by the acid or alkaline solution. The following typical experiment shows that the rate of this destruction follows the formula for unimolecular reactions, namely, $1/t \log A/A - x = k_2$, where A is the activity of the invertase at the beginning of the destruction, x is the activity after the destruction has proceeded for t minutes, and k_2 is a constant, the velocity coefficient. The concentration of acid in this experiment was 0.02 normal hydrochloric.

TABLE III.—THE UNIMOLECULAR ORDER OF THE DESTRUCTION OF INVERTASE.

Time Minutes	Activity (× 10000)	Rate of destruction (k_2).	Time Minutes	Activity (× 10000)	Rate of destruction (k_2).
0	50.5	.....	70	24.9	0.0044

th

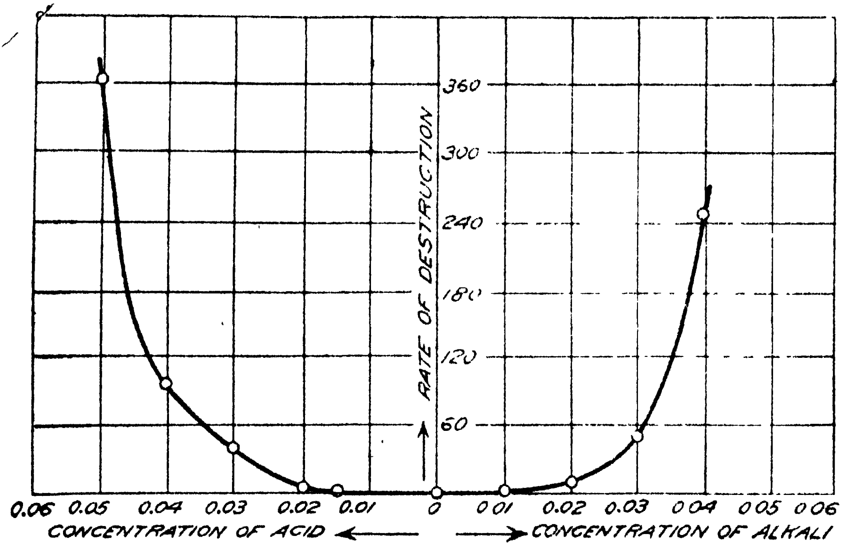

Fig. 2.—The rate of destruction of invertase at 30° C. by acid and alkali.

The activity of invertase in acid solutions which are not strong enough to destroy the enzyme was measured for hydrochloric, hydrobromic, nitric, phosphoric, sulphuric, boric, oxalic, tartaric, citric, and acetic acids; the activity depends almost entirely on the concentration of hydrogen ions in the acid solution and the various acids thus show typical differences which correspond with their recognized degrees of dissociation. The activity of invertase is zero in alkaline solutions, rises to a maximum in very weakly acid ones, and decreases with stronger acidity

FEHLING'S SOLUTION.

A CONTRIBUTION TO THE HISTORY OF CHEMICAL REAGENTS.

BY B HERSTEIN.

Received March 11, 1910.

A history of chemical reagents would form no small and not the least interesting part of the history of chemistry generally, and for obvious reasons. In studying the intramolecular ous filtrate on standing. The follows strictly inductive methods, taking t of direct observation, and while for the purpothyl alcohol, chloroform compelled to classify such results into some comral recrystallizations sistent system arrived at by logical induction, such hypnd benzene. It tions are not permitted to influence the direct results of th (Kjeldahl):

Intramolecular changes of matter however are not alw observable, and to bring them into a condition where our p would be able to grasp them, we must in the majority of cases reso Di- what may be described as secondary reactions induced by foreign su stances, the so-called chemical reagents. Our processes of differentiation, upon which chemistry in general and analytical chemistry especially ultimately rest, are based upon the behavior of the various forms of matter towards different chemical reagents, and it follows from this that the progress of chemistry to a very large degree depends upon the introduction of such chemical reagents and an intimate knowledge of their working.

Thus to quote but one modern instance it is only necessary to point to the fact that the wonderful insight which we have gained within the last generation into the nature of sugars and carbohydrates generally is due almost exclusively to the introduction of phenylhydrazine as a chemical reagent. Previous to this our knowledge of this group of substances was very limited indeed, and of the few reactions characteristic for this group of substances none was better known than their behavior towards a solution of copper salts. The reaction upon which the value of this reagent in all its various modifications depends is, as is well known, based upon the reducing effect which certain sugars exert upon such solution, and although analytical chemistry has only within comparatively recent years made use of this reaction, its history runs nevertheless far back into the primitive period of human knowledge.

It undoubtedly must first have been observed by the man who introduced the so-called *unguentum Ægyptiacum* —Egyptian ointment— into materia medica, and this probably was none other than an Egyptian priest, if we may draw such conclusions from the name. This *unguentum Ægyptiacum*, which has long since disappeared from all the modern pharmacopoeias, but which for long ages was considered a very valuable medicine, forming the basis of various ointments and cosmetical preparations, was prepared by boiling together a mixture of verdigris and honey to which a few drops of vinegar were added. During the boiling the color of the mass changes considerably owing to the interaction between the glucose and the copper acetate, a change of color so striking that it could not have escaped notice. Nevertheless it has never occurred to any of these pharmacists, who in those days were the principal guardians of whatever chemistry there was, to make these changes the independent object of their studies. Quantitative attempt an explanation of the phenomena observed during able to ction was Antoine Baumé, a celebrated pharmacist of the eighteenth century, who wrote his name indelibly into the history of chemical technology by the device of his spindle. In accordance with the theory then prevailing he said in his "Traité de Pharmacie Théorique et Pratique," that in boiling honey with verdigris and vinegar it is the phlogiston of the acetic acid which, uniting with the verdigris, forms metallic copper, which is deposited. For almost one-half a century this explanation was accepted as satisfactory. During this time, however, the phlogiston theory had been entirely overthrown by Lavoisier, and a period of reconstruction had set in, which may be best described by Hegel's phrase "the re-evaluation of all values." Speculative deductions gave place to experimental research, and the balance was made the chief arbiter of the laboratory. A thorough overhauling of all chemical knowledge was undertaken, and in course of time the phenomena observed during the reaction in question were also subjected to renewed scrutiny.

In January, 1815, Dr. Vogel, of Paris, read before the French Academy of Science a paper entitled "A Research Concerning the Decomposition of Salts and Metallic Oxides by Sugars."[1] As indicated by the title, the principal object sought in this investigation was an insight into the mechanism of the reaction, while the products formed during the reaction were studied as closely as the means then permitted, both qualitatively and quantitatively, but only with a view of obtaining light upon the reaction itself. Vogel was able to show that the reddish or brown precipitate which formed on boiling copper acetate with honey and several other sugars then known was not metallic copper, but cuprous oxide, or as it was then called, copper protoxide, that the color of the precipitate depended very much on the length of time the mixture was heated, and that the precipitation is obtained only from cane, starch and grape sugar, sugar of milk, also from molasses, manna, and honey, but not from the so-called sweet principle of Scheele.[2] Vogel also observed the evolution of carbonic acid gas and acetic acid, which, however, he attributed to the high temperature to which the mixture had been subjected. Using copper sulphate instead of the acetate he claims to have precipitated metallic copper while copper chloride and copper nitrate, which were likewise tried, seemed not to be influenced at all. Similar observations made almost simultaneously with the preceding were given by J. A. Buchner, Professor of Chemistry in Munich, and published in the succeeding number of the same periodical.[3] On the whole he merely confirmed the result obtained by Vogel with this exception, that ous filtrate on standing. The red precipitate to consist of cuprous oxide, Bu the reaction the sugar is split up and that one of thyl alcohol, chloroform combines with the copper to form the precipitate. ral recrystallizations

[1] *Abstracted in Schweigger's Journal*, 1815, Vol. XIII, page 162.

[2] By this name glycerol, discovered in 1779 by Scheele, was known until well up into the first part of the 19th century.

[3] *Schweigger's Journal*, 1815, Vol. XIV, p. 224.

From time to time other chemists were attracted by the nd benzene. It Their work, however, did not materially broaden the problem (Kjeldahl): mained one more of theoretical than practical value until the y when Trommer published his paper, "The Differentiation between Dex Di- Cane and Grape Sugar."[2] Here the subject was approached from an entirely different and more practical point of view. Trommer was able to show that in making the copper salt solution alkaline, it became a valuable reagent for the differentiation between the various sugars and sugar giving substances. He used an alkaline solution of copper sulphate, and showed that such a solution will yet give a distinctive precipitate of cuprous oxide when boiled with solutions of grape sugar containing only one part in one hundred thousand, and that when the solution of the grape sugar is ten times more dilute, *i. e.*, containing one part to one million, the reaction is yet noticeable in reflected light. The fact that the reaction takes place only in the presence of certain sugars such as glucose, for instance, while cane sugar or dextrin are not acted upon, was fully noticed and made the basis of the differentiation between the different sugars. To Trommer thus belongs the credit of having first introduced the alkaline copper sulphate solution into analytical chemistry, though it was at first used only for qualitative purposes. But the next step was not long in coming, and within a very short time the very same reagent was recommended for use in quantitative chemical analysis.

The estimation of sugars in those days was far from being satisfactory to the chemist engaged in this line of work, depending entirely on two methods. First, the fermentation process devised by Lavoisier and others, and second, the process introduced by Biot, which was based on the deflection of polarized light by sugar solutions. Both methods have their disadvantages, the first requiring considerable time for its completion, quite aside from the fact that the decomposition into alcohol and carbonic acid gas is by no means quantitative, by-products being formed which interfere with the accuracy of the results. The polariscope gives quick and fairly accurate results; requires however clear and colorless solutions containing no foreign substances which would deflect the polarized ray. The necessity for an improved method of estimating sugars became so imperious that in 1838 a prize of 3000 francs was offered by the "Société d'encouragement pour l'industrie nationale" to the chemist who would devise a successful

their studies. quantitative estimation of sugar. Of the answers received observed during able to the committee, and the offer was renewed from macist of the eigil in 1844 Ch. Barreswil submitted his solution.[1] The history of chemicommittee, the well-known Peligot, did not consider the with the theory satisfactory, but he nevertheless recommended that Théorique the prize, *viz.*, 1000 francs, be awarded to Barreswil for his it is the which, in his opinion,[1] though limited in its application, nevermes offered a valuable improvement on the existing methods. Barthwil's proposal consisted merely in the extension of the method suggested by Trommer for qualitative differentiation to the quantitative estimation of sugars. The main principle of Trommer's suggestion, *i. e.*, the use of the alkaline copper sulphate solution, was maintained, and the improvement introduced consisted in the addition of a solution of potassium tartrate to prevent the decomposition of the solution on heating. As proposed by Barreswil, the method was a volumetric one, the copper solution being standardized against a pure grape sugar solution of known strength, which latter was added drop by drop to the boiling copper solution, the end point of the reaction being reached when the blue color of the solution had disappeared. He also points to the necessity of inverting the cane sugar to glucose, and making two determinations, before and after inversion, where mixtures of the sugars are to be analyzed.

The principle of the method was thus established, and its practicability depended very largely upon the stability of the copper solution, which was not very satisfactory. The further efforts of the chemists who studied the subject were therefore directed mainly in this direction, although the use of the method was fully recognized and extended, as by H. Schwartz,[2] who in 1849 proposed it for the estimation of starch, which had previously to be hydrolyzed by dilute sulphuric acid to glucose. H. Fehling, by whose name the method is apparently destined to remain known in chemistry, published his first paper concerning the subject in 1848 in a medical publication, and only in 1849 he gave a more detailed account of his work to the chemical fraternity.[3] Fehling's merit consisted chiefly in having worked out with great care the details of the method, giving some account of the stoichiometrical equivalents, but neither did his solution keep for any length of time, nor did he, any more than his predecessors, recognize the fact that the reaction is quantitative only within very narrow restrictions as to the concentration of the solutions and the time of reaction. This point has been established only by the concerted efforts of the many chemists, who worked on the subject after Fehling, the necessity for keeping the copper solution divided into two parts being soon recognized. Soxhlet especially devoted much of his time to the study of the method and established[1] the exact conditions under which the determination must be carried out in order to get satisfactory results.

BUREAU OF CHEMISTRY, WASHINGTON, D. C.

A REVIEW OF SOME RECENT INVESTIGATIONS IN THE QUINAZOLINE GROUP.[2]

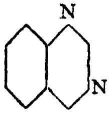
BY MARSTON TAYLOR BOGERT.

Received March 31, 1910

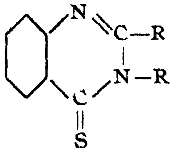
For several years past, the Organic Laboratory of Columbia University has been engaged in the synthesis and study of compounds belonging to that group of organic heterocycles known as quinazolines or phenmiazines.

To us, the work has been most interesting and enjoyable. The compounds obtained have been generally crystalline solids, quite readily purified, stable, and very satisfactory to work with.

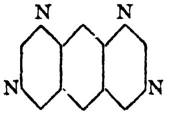
Our investigations have included—A. Quinazolines, B. Thioquinazolines, and C. Naphthotetrazines of quinazoline structure:



(Quinazoline)



(Thioquinazoline)



(1,3,7,9-Naphthotetrazine)

Incidentally, a great many new preparatory, intermediate and subsidiary products have been obtained. From the standpoint of new substances, the field has been an unusually fruitful one

It is, therefore, not only an honor but also a pleasure to present on this occasion a brief synopsis of the major lines of the work to date.

A. Quinazolines.

Colby and Dodge,[3] as the result of their investigations of the interaction of nitriles and organic acids, under conditions of heat and pressure, came to the following conclusions:

I. Fatty nitriles and aromatic acids give fatty acids and aromatic nitriles.

II. Aromatic nitriles and fatty acids give mixed secondary amides.

III. Aromatic nitriles and aromatic acids give secondary amides, unless the temperature is very high, when the nitrile of the higher radical may form.

Mathews,[4] in continuation of this work, heated acetonitrile and anthranilic acid together under pressure, hoping thereby to obtain the anthranilic nitrile. On examining the contents of the tube, he found not the nitrile desired but a colorless crystalline compound, melting at 232° (uncor.), which was not identified at the time.

[2] Address at the Twentieth Anniversary Celebration of Clark University, Worcester, Mass., Sept. 14, 1909.

[3] *Am. Chem. J.*, 13, 1 (1891).

[4] THIS JOURNAL, 20, 654 (1898).

Later, Bogert and Gotthelf[1] made a more careful study of this reaction and found that the crystalline substance melting at 232° was identical with the 2-methyl-4-ketodihydroquinazoline first described by Weddige,[2] and later obtained by Bischler and Burkart,[3] Bischler and Lang,[4] and Niementowskii.[5] By varying the nitrile, they obtained other quinazolines of analogous structure.

Continuing this work, Gotthelf[6] heated anthranilic acid under pressure with a:

IV. Fatty nitrile alone (using aceto-, propio-, *n*-butyro-, *i*-valero- and *i*-capronitriles).

V. Fatty nitrile and the corresponding fatty acid (acetonitrile and acetic acid, propionitrile and propionic acid, etc.).

VI Fatty nitrile and a higher fatty acid (acetonitrile and propionic acid, *n*-butyronitrile and capric acid, etc.).

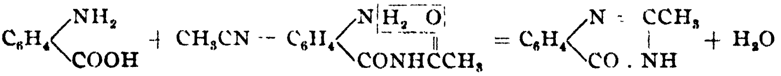
VII. Fatty nitrile and a lower fatty acid (isocapronitrile and propionic acid, etc.).

VIII. Fatty nitrile and the corresponding acid anhydride (propionitrile and propionic anhydride, valeronitrile and valeric anhydride, etc.).

IX. Fatty nitrile and higher acid anhydride (acetonitrile and propionic anhydride, etc.).

X. Fatty nitrile and lower acid anhydride (acetonitrile and formic acid, etc.).

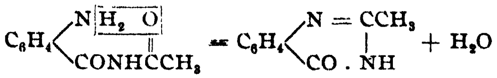
In considering case IV, Bogert and Gotthelf at the time thought it probable that the production of a quinazoline was due to the formation of an intermediate secondary amide,



$$C_6H_4\Big\langle\begin{matrix}NH_2\\COOH\end{matrix} + CH_3CN = C_6H_4\Big\langle\begin{matrix}N\boxed{H_2\ \ O}\\CONH\overset{\|}{C}CH_3\end{matrix} = C_6H_4\Big\langle\begin{matrix}N = CCH_3\\ \ \ \ \ \ \ \ |\\CO\ .\ NH\end{matrix} + H_2O$$

just as acetonitrile and acetic acid when heated under pressure give diacetoamide.[7]

One objection to this explanation of the course of the reaction lies in the fact that it involves a lactam condensation, whereas Weddige's investigations in this very field have made it quite clear that these condensations follow preferably the lactim course. If the intermediate secondary amide assumed by us passes directly into the quinazoline by loss of water, two different quinazolines should result according to whether the condensation is of lactam or lactim type:



$$C_6H_4\Big\langle\begin{matrix}N\boxed{H_2\ \ O}\\CONH\overset{\|}{C}CH_3\end{matrix} = C_6H_4\Big\langle\begin{matrix}N = CCH_3\\ \ \ \ \ \ \ \ |\\CO\ .\ NH\end{matrix} + H_2O$$

(*a*)

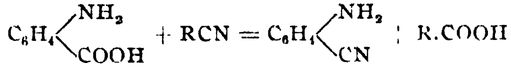
$$C_6H_4\left\langle\begin{array}{l}NH|H\ \ OH|\\ CON : CCH_3\end{array}\right. = C_6H_4\left\langle\begin{array}{l}NH.CCH_3\\ CO.N\end{array}\right. + H_2O$$

(b)

As a matter of fact, the product obtained by us is identical with (a).

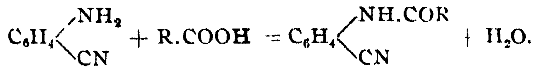
Another objection is that it is not in harmony with the conclusions of Colby and Dodge[1] cited above. According to their experiments, the first products of the action of a fatty nitrile upon an aromatic acid at high temperature and pressure are the aromatic nitrile and the fatty acid, which may and often do subsequently combine to a mixed secondary amide. That the secondary amide is not the first product seems established by their results, for in no case where a fatty nitrile acted upon an aromatic acid was the secondary amide found unaccompanied by aromatic nitrile, while in many cases aromatic nitrile and fatty acids were found unaccompanied by any secondary amide. Thus, acetonitrile and benzoic acid at 220° gave no acetobenzamide, but only benzonitrile and acetic acid, whereas when the latter two were heated together at 220°, only acetobenzamide was formed.

It therefore seems probable that the first phase of the reaction between anthranilic acid and a fatty nitrile is as follows



$$C_6H_4\left\langle\begin{array}{l}NH_2\\ COOH\end{array}\right. + RCN = C_6H_4\left\langle\begin{array}{l}NH_2\\ CN\end{array}\right. + R.COOH$$

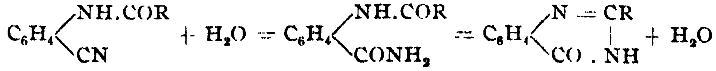
As aniline when heated to sufficiently high temperatures with fatty acids yields the corresponding anilides,[2] the second phase of the reaction is probably



$$C_6H_4\left\langle\begin{array}{l}NH_2\\ CN\end{array}\right. + R.COOH = C_6H_4\left\langle\begin{array}{l}NH.COR\\ CN\end{array}\right. + H_2O.$$

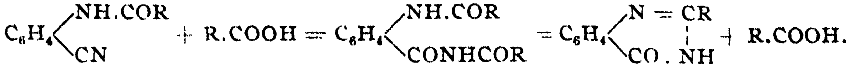
As the ease with which this acylation takes place decreases with increase in the molecular weight of the fatty acid, the higher nitriles should give smaller yields of the quinazoline, and this was found to be the case. The yield with propionitrile, for example, was 22 5 per cent., while with valeronitrile it was only 5 per cent. of the theoretical.

The acylanthranilic nitrile may then pass into the quinazoline by either of the following reactions:



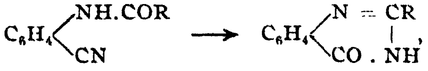
$$C_6H_4\left\langle\begin{array}{l}NH.COR\\ CN\end{array}\right. + H_2O = C_6H_4\left\langle\begin{array}{l}NH.COR\\ CONH_2\end{array}\right. = C_6H_4\left\langle\begin{array}{l}N = CR\\ |\\ CO.NH\end{array}\right. + H_2O$$

or



$$C_6H_4\left\langle\begin{array}{l}NH.COR\\ CN\end{array}\right. + R.COOH = C_6H_4\left\langle\begin{array}{l}NH.COR\\ CONHCOR\end{array}\right. = C_6H_4\left\langle\begin{array}{l}N = CR\\ |\\ CO.NH\end{array}\right. + R.COOH.$$

That a simple molecular rearrangement of the acylanthranilic nitrile occurs,



$$C_6H_4\left\langle\begin{array}{l}NH.COR\\ CN\end{array}\right. \longrightarrow C_6H_4\left\langle\begin{array}{l}N = CR\\ |\\ CO.NH\end{array}\right.,$$

seems unlikely, for the reason that when acetoanthranilic nitrile was heated for some time above its melting point, or when its solution in dry toluene was heated to high temperatures in sealed tubes, no change whatever occurred.[1] Moisture was, of course, rigidly excluded in these experiments, since a small amount of water, by successive addition and splitting off, would suffice to convert an indefinite amount of the nitrile to the quinazoline.

---

[1] *Loc. cit.*

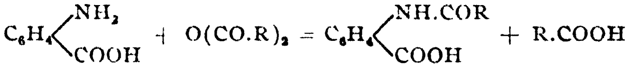
[2] Williams, *Ann.*, 131, 288; Pebal, *Ibid.*, 91, 152.

In further support of the assumption that the acylanthranilic nitrile is an intermediate product, are the following facts: (1) Acetanilide is found as a by-product in the tubes.[2] (2) The presence of a small amount of acetic anhydride greatly increases the yield of quinazoline. (3) The same quinazoline results when acetoanthranilic acid is heated in a sealed tube with acetonitrile as when anthranilic acid itself is used.[3] (4) Acetoanthranilic nitrile on partial hydrolysis changes immediately to the quinazoline.[4]

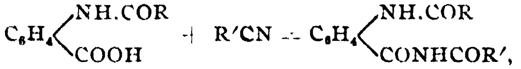
The by-products observed in the experiments were carbon dioxide, aniline, anilides, amides and ammonia. Of these, carbon dioxide and aniline are normal decomposition products of anthranilic acid at high temperatures. Partial hydrolysis of the nitrile accounts for the presence of amide. Aniline acting on the latter,[5] or upon the fatty acid present, yields the anilide, the by-product in the former case being ammonia.

In those cases (V, VI and VII) where the anthranilic acid was heated with both the fatty nitrile and the fatty acid, the results are confusing and the interpretation obscure. Quinazolines were formed, but the course of the reactions is not clear and additional work is needed before any satisfactory conclusions can be reached.

When an acid anhydride was added to the tubes containing the anthranilic acid and fatty nitrile (VIII, IX and X), the anhydride used determined the quinazoline formed in practically every case. In these experiments, the reaction is therefore probably as follows:

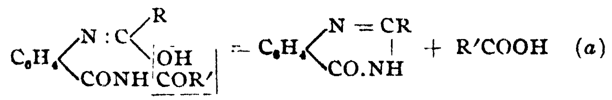


$$C_6H_4{<}\begin{array}{l}NH_2\\ COOH\end{array} + O(CO.R)_2 = C_6H_4{<}\begin{array}{l}NH.COR\\ COOH\end{array} + R.COOH$$

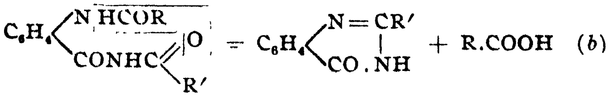


$$C_6H_4{<}\begin{array}{l}NH.COR\\ COOH\end{array} + R'CN = C_6H_4{<}\begin{array}{l}NH.COR\\ CONHCOR',\end{array}$$

the latter then condensing in either of the following ways:



$$C_6H_4{<}\begin{array}{l}N:C{<}\begin{array}{l}R\\ OH\end{array}\\ CONH\,COR'\end{array} = C_6H_4{<}\begin{array}{l}N = CR\\ \quad\;\;\vert\\ CO.NH\end{array} + R'COOH \quad (a)$$



$$C_6H_4{<}\begin{array}{l}N\,HCOR\\ CONHC{\ll}\begin{array}{l}O\\ R'\end{array}\end{array} = C_6H_4{<}\begin{array}{l}N = CR'\\ \quad\;\;\vert\\ CO.NH\end{array} + R.COOH \quad (b)$$

The nitrile was used with the corresponding acid anhydride (VIII), with a higher acid anhydride (IX), and with a lower anhydride (X). Of these, types VIII and IX invariably yielded pure quinazolines according to reaction (*a*) above. Only when a lower anhydride was used with the nitrile (X), were products encountered which were mixtures of quinazolines.

[3] Bogert and Gotthelf, *Loc. cit.*

[4] Bogert and Hand, *Loc. cit.*

[5] Kelbe, *Ber.*, 16, 1200 (1883).

Of these different sealed-tube reactions, much the best was that in which the anthranilic acid was heated with the fatty nitrile and the corresponding acid anhydride (VIII). The yield by this process was fair (30 to 50 per cent. of the theory) and, unless the heating was too high, the tube contents were invariably light-colored and crystalline.

In the foregoing, it is assumed that the secondary amide is an intermediate product in the formation of the quinazoline. Such an amide, R.CO.NH.CO.R′, being symmetrical, should be producible either from R.COOH and R′CN, or from R′COOH and RCN. In other words, since the formation of the —CO.NH.CO— group is due solely to the combination of the CN and COOH, it should make no difference which radical carries the CN and which the COOH. The same secondary amide and, therefore, the same quinazoline, should result whether the acylanthranilic acid is heated with the fatty nitrile, or the acylanthranilic nitrile with the fatty acid (or its anhydride). On testing this practically,[1] such was indeed found to be the case, and a number of quinazolines were thus obtained from the acylanthranilic nitriles by heating them in sealed tubes with the fatty acid or, better, its anhydride.

In experimenting with these acylanthranilic nitriles, a method of converting them into the quinazolines, far superior to any of the methods described above, was discovered. It consists in digesting the acylanthranilic nitrile for a few minutes with a warm alkaline dioxide solution, and is really a beautiful method, being very rapid, simplicity itself in execution, and giving large yields of practically pure quinazolines. It depends upon the hydrolysis of the nitrile to the amide, the acylanthranilamide then condensing to the quinazoline, as shown by Weddige.[2]

In those cases where the *o*-amino acid is best obtained from its nitrile by saponification, it is convenient to be able to pass direct from the nitrile to the quinazoline. Thus, homoanthranilic nitrile is readily prepared from *m*-nitro-*p*-toluidine, through *m*-nitro-*p*-toluonitrile, and from the acyl derivatives of this homoanthranilic nitrile and an alkaline dioxide solution (hydrogen dioxide solution made alkaline with sodium hydroxide), the 7-methyl-4-quinazolones were prepared.[3]

By a number of different processes, including those already mentioned, starting with brominated anthranilic acids, bromoquinazolines were prepared.[4]

Our attention was next turned to the nitroquinazolines, and many were made from nitroanthranilic acids by the methods already described, and also by heating the ammonium salt of the nitroanthranilic acid with formamide,[5] by the direct action of heat on the ammonium salts of nitroacylanthranilic acids,[6] and by the action of primary amines on nitroacetoanthranils.[7] The last is a very fine method indeed, and one we have developed quite extensively.

[2] *J. prakt. Chem.*, [2] 31, 124 (1885); 36, 141 (1887).

[3] Bogert and Hoffman, This Journal, 27, 1293 (1905).

[4] Bogert and Hand, *Ibid.*, 25, 943 (1903); 28, 94 (1906).

[5] Niementovskii, *J. prakt. Chem.*, [2] 51, 564 (1895).

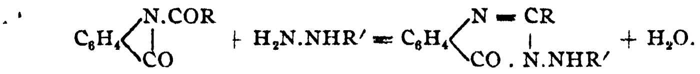
[6] Bischler and Burkart, *Ber.*, 26, 1349 (1893).

[7] Anschütz, Schmidt and Greiffenberg, *Ber.*, 35, 3480 (1902).

By these various methods, we prepared 5-nitro-,[1] 6-nitro-,[2] and 7-nitro-4-quinazolones.[3] Of the four possible types of benzoylnitroquinazolines, representatives of the 6-nitro,[4] and 8-nitro,[5] were already known. The preparation of the 5- and 7-nitro derivatives completed the series.

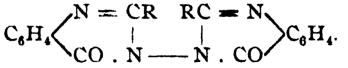
Reduction of the nitroquinazolines yielded the corresponding benzoylaminoquinazolines,[6] in which, as might have been expected, the amino group shows the usual aniline reactions.

Aminoquinazolines with the amino group on the miazine side of the nucleus were produced by condensing simple or substituted acylanthranils with primary hydrazines,[7]



$$C_6H_4\left\langle\begin{array}{l}N.COR\\ |\\ CO\end{array}\right. + H_2N.NHR' = C_6H_4\left\langle\begin{array}{l}N = CR\\ \qquad |\\ CO\,.\,N.NHR'\end{array}\right. + H_2O.$$

With hydrazine itself, it was also found possible to condense two molecules of the anthranil with one of the hydrazine, thereby giving 3,3′-diquinazolonyls,



$$C_6H_4\left\langle\begin{array}{l}N = CR \quad RC = N\\ \qquad | \qquad\quad |\\ CO\,.\,N \text{———} N\,.\,CO\end{array}\right\rangle C_6H_4.$$

The same result can be accomplished, though less satisfactorily, by condensing the 3-aminoquinazoline with a second molecule of the anthranil. The di-quinazolonyls so far isolated are all very difficultly soluble and inert.

The 3-aminoquinazolines proved interesting because of their unsymmetrical secondary hydrazine structure, $>N.NH_2$. In the main, their properties coincide with those of other N-amino heterocyclic compounds. Thus, nitrous acid does not diazotize the amino group, but replaces it by hydrogen; with diacetosuccinic esters, they often yield pyrrole derivatives;[8] with aromatic nitroso bodies, they do not give azo compounds; nor are they oxidized to tetrazones by mercuric oxide. On the other hand, they do not usually condense with ketones, while they do occasionally yield phenyluramino derivatives with phenyl isocyanate.[9] In the elimination of the N-amino group by the action of nitrous acid, there must be some unstable intermediate product formed, for if immediately after the addition of the nitrous acid the mixture be poured into an alkaline solution of alpha- or beta- naphthol, dyestuffs are formed of considerable tinctorial power, the structure of which has not been elucidated.

Further experimentation with the acylanthranils showed that they could also be condensed with amino nitriles or amino esters to the corresponding quinazolines.[1]

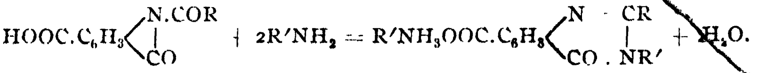
The ease with which acylanthranils condense with primary amines to crystalline quinazolines suggests the utilization of this reaction for the separation and identification of easily soluble or sirupy amines difficult to handle otherwise.

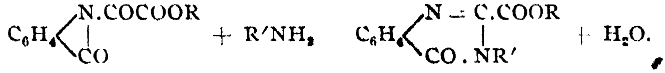
The same reaction was employed for the preparation of quinazoline carboxylic acids from acylanthranil carboxylic acids,[2]



$$HOOC.C_6H_3\left\langle\begin{matrix}N.COR\\|\\CO\end{matrix}\right. + 2R'NH_2 = R'NH_3OOC.C_6H_3\left\langle\begin{matrix}N - CR\\|\\CO.NR'\end{matrix}\right. + H_2O.$$

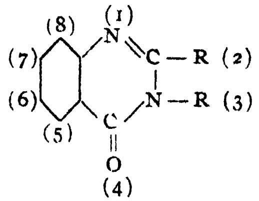
These quinazoline benzoylcarboxylic acids are colorless crystalline solids, melting with decomposition above 300°, more or less soluble in alcohol, but very difficultly soluble in other neutral organic solvents.

From the oxalyl anthranils, quinazolinecarboxylic acids were prepared carrying the carboxyl group on the miazine side of the nucleus,[3]

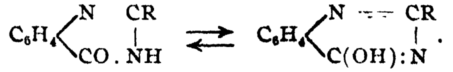


$$C_6H_4\left\langle\begin{matrix}N.COCOOR\\|\\CO\end{matrix}\right. + R'NH_2 \quad C_6H_4\left\langle\begin{matrix}N = C.COOR\\|\\CO.NR'\end{matrix}\right. + H_2O.$$

The particular quinazolines described in the foregoing are for the most part of the type designated as 4-ketodihydroquinazolines or, more simply, 4-quinazolones,



When there is an H at position 3 instead of a radical, there arises the possibility of keto-enolic tautomerism,



$$C_6H_4\left\langle\begin{matrix}N \quad CR\\|\\CO.NH\end{matrix}\right. \rightleftarrows C_6H_4\left\langle\begin{matrix}N == CR\\|\\C(OH):N\end{matrix}\right. .$$

(4-Quinazolone) (4-Hydroxyquinazoline)

All those 4-quinazolones (4-hydroxyquinazolines) which carry a hydrogen at position 3 are easily soluble in aqueous solutions of the caustic alkalies and re-precipitable from such solutions by carbon dioxide or acetic acid. When these alkali salts are treated with alkyl halides, the 3-(*N*)alkyl derivative is the chief product.[4] The nitro derivatives furnish an apparent exception to this, in that the product with the higher alkyl halides is reported as chiefly the oxygen ether (*i. e.*, the 4-(*O*)alkyl, or -OR compound).[5] We are somewhat skeptical, however, of the accuracy of these results and feel that they should not be fully accepted until the pure oxygen ethers have been prepared by other processes and the two products compared. One reason for this skepticism on our part is that certain of these supposititious oxygen ethers could not be hydrolyzed with concentrated mineral acids (hydrochloric), a result contrary to our experience and to that of others working with true oxygen ethers.

---

[3] Bogert and Gortner, *Ibid.*, 32, 119 (1910).

[4] Bogert and May, *Ibid.*, 31, 507 (1909).

[5] Bogert and Seil, *Ibid.*, 29, 517 (1907).

Pure 3-(*N*)alkyl derivatives are easily obtained by the acylanthranil reaction already described. For the isomeric 4-OR derivatives, the best method appears to be the treatment of the 4-chloroquinazolines with sodium alcoholates.[1] In the case of the simple alkyl derivatives of unsubstituted 4-quinazolones (4-hydroxyquinazolines), the (3)-NR compounds are colorless, odorless solids, quite soluble in water, generally very difficultly volatile with steam, of higher melting point than the 4-OR isomers, and are not hydrolyzed by strong hydrochloric acid. On the other hand, the 4-OR compounds are oily liquids or low-melting solids, usually of pleasant odor, readily volatile with steam, less soluble in water but more soluble in hydrochloric acid than the NR isomers, and are readily hydrolyzed by mineral acids to the hydroxyquinazoline (4-quinazolone) again. Some of the lower ones can even be distilled undecomposed at ordinary pressure.

In the preparation of the 4-chloroquinazolines from the 4-hydroxyquinazolines (4-quinazolones),[1] a methyl or ethyl group in position 2 exerts a peculiar influence upon the course of the reaction with phosphorus halides or similar halogenating reagents. In all such cases, it was found impossible to replace the OH at 4 by chlorine without simultaneously introducing three chlorine atoms in the benzene part of the nucleus. Even when 2,3-dimethyl-4-quinazolone was heated with phosphorus penta- and oxychlorides,[2] the 3-methyl group was split off, a Cl attached itself at 4, but again three Cl's entered the benzene nucleus.

Our investigations in this 4-quinazolone group have led to the synthesis and study of derivatives carrying the following substitutions:

1. At position, 2-,methyl, ethyl, normal and isopropyl, isobutyl, isoamyl, phenyl, *m*- and *p*-nitrophenyl, benzyl, *p*-tolyl, COOH, and various complex radicals and residues.
2. At position, 3-,methyl, ethyl, normal and isopropyl, iso- and secondary butyl, isoamyl, allyl, phenyl, *o*-tolyl, *p*-anisyl, benzyl, beta-naphthyl, CH_2COOR, CH_2CONH_2, CH_2CN, C_6H_4COOR, $C_6H_4CONH_2$, C_6H_4CN, the amino group and its derivatives, quinazolonyls, and dimethyl dicarbethoxypyrrole.
3. At position, 4-,OH, Cl, and OR.
4. On the benzene nucleus-,alkyls, halogens, nitro, amino (and derivatives), and COOH.

In the various series, where homologs of analogous structure are compared, it will be found that the melting point falls quite steadily with rise in molecular weight, the iso compounds melting higher than the isomers carrying normal alkyls. This is perhaps not so surprising since many series of anthranilic compounds (for example, the alkyl and acylamino anthranilic acids, the acylanthranilic nitriles, etc.) exhibit a similar behavior.

In addition to the 4-quinazolones, our studies have included also the 2-quinazolones (2-hydroxyquinazolines), 2,4-dihydroxyquinazolines (2,4-

---

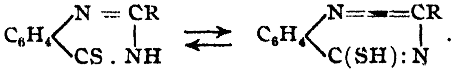
[2] Compare Fischer, *Ber.*, 32, 1297 (1899).

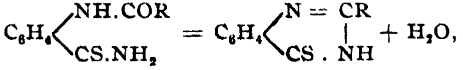
diketotetrahydroquinazolines, or benzoylene ureas), and a few other types.

B. Thioquinazolines.

The work in the domain of the oxygenated quinazolines led quite naturally to the production of bodies of analogous structure carrying sulphur instead of oxygen, and known as the 4-thioquinazolone or quinazolthion (4) type,[1]

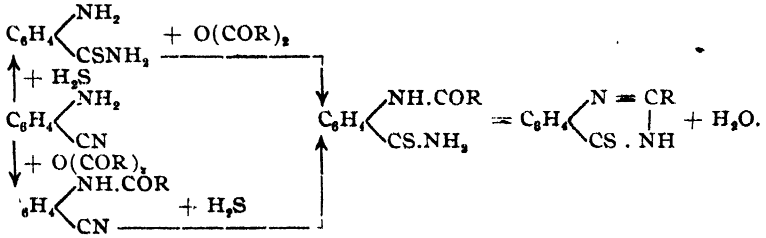


Since anthranilamides, as noted, easily condense to quinazolines by loss of water, it seemed probable that the corresponding thioamides would yield thioquinazolines,



and the results corroborated this fully.

The acylanthranilic thiamide was prepared either by first converting the anthranilic nitrile to the amide by the direct addition of hydrogen sulphide and then acylating, or by first acylating and then adding the H_2S:



By the use of thiol acids (for example, thioacetic acid) in sealed tubes, the thioquinazoline was obtained direct. The thiol acid first acylates the amino group. The by-product of this acylation, H_2S, cannot escape from the tube and is thus forced to attach itself to the CN, thereby changing it to the thioamide. The acylaminothioamide then passes to the thioquinazoline by loss of water.

As comparatively few thiol acids are readily available, we made our reaction more widely applicable by substituting the acid anhydride with sodium sulphide for the thiol acid. Thus, when anthranilic nitrile is heated with acetic anhydride and sodium sulphide in open flasks or, better, in sealed tubes, the anhydride first acetylates the amino group with formation of acetic acid as the by-product. The latter then attacks the sodium sulphide, setting free hydrogen sulphide and forming sodium acetate. The hydrogen sulphide converts the acetoanthranilic nitrile to the thioamide, which then splits out water and gives the quinazoline, the sodium acetate possibly assisting in the elimination of this molecule of water.

These thioquinazolines crystallize in beautiful yellow needles or prisms when alcohol is used as the solvent. By virtue of the $\text{—CS.NH—} \rightleftarrows \text{—C(SH) : N—}$ group, they dissolve freely in solutions of the caustic alkalies and are reprecipitated therefrom by carbon dioxide or by acetic acid.

---

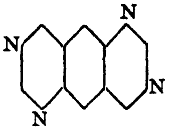
[1] Bogert, Breneman and Hand, This Journal, 25, 372 (1903); Bogert and Hand, *Ibid.*, 25, 935 (1903).

Like the corresponding oxygen compounds, the melting point of the 2-alkyl derivatives steadily falls with rise in molecular weight, the iso compounds melting higher than the isomers of normal structure.

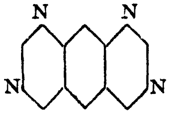
In the course of the investigation, we have used both simple and substituted anthranilic acids.

C. Naphthotetrazines.

Our syntheses of the simple quinazolines having resulted so satisfactorily, we decided to attempt the synthesis of compounds of the following types,



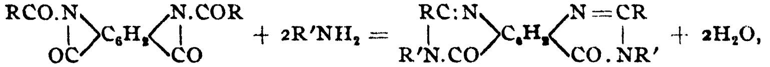
(1,3,6,8-Naphthotetrazine)



(1,3,7,9-Naphthotetrazine)

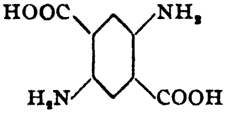
and in this were equally fortunate.

Naphthotetrazines of both types were prepared from the bis-acylanthranils of the appropriate diaminophthalic acid and various primary amines,[1]

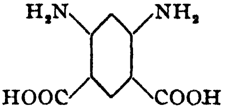


$$\begin{array}{c}RCO.N\\ |\\ OC\end{array}\!\!>C_6H_2<\!\!\begin{array}{c}N.COR\\ |\\ CO\end{array} + 2R'NH_2 = \begin{array}{c}RC:N\\ |\\ R'N.CO\end{array}\!\!>C_6H_2<\!\!\begin{array}{c}N=CR\\ |\\ CO.NR'\end{array} + 2H_2O,$$

as well as from the diaminophthalic acids themselves by reactions similar to those employed for the synthesis of the simple quinazolines. The diaminophthalic acids used, which must be, of course, of anthranilic structure, were



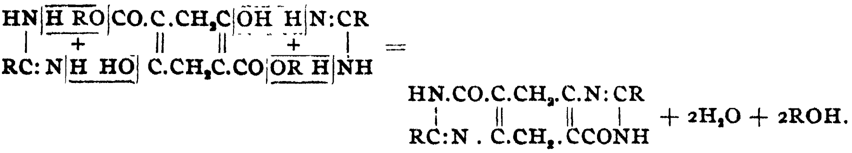
(3,6-Diamino-1,4-phthalic acid)



(4,6-Diamino-1,3-phthalic acid)

These acids, as can be seen by a glance at their graphic formulas, are only double anthranilic acids, and undergo similar reactions, the former yielding the 1,3,6,8-naphthotetrazines, and the latter the 1,3,7,9-isomers.

1,3,6,8-Naphthotetrazines were also obtained by condensing succinylosuccinic esters with amidines:[2]



$$\begin{array}{l} HN|H\ RO|CO.C.CH_2C|OH\ H|N:CR \\ |\quad + \qquad \| \qquad \| \qquad + \quad | \\ RC:N|H\ HO|\ C.CH_2C.CO|OR\ H|NH\end{array} = \begin{array}{l}HN.CO.C.CH_2.C.N:CR\\ |\qquad \| \qquad \| \qquad | \\ RC:N\ .\ C.CH_2.CCONH\end{array} + 2H_2O + 2ROH.$$

All of these naphthotetrazine derivatives so far obtained by the above processes are either infusible or melt very high. They are insoluble in the ordinary neutral organic solvents. When they carry the —NH.CO—

[2] Bogert and Dox, *Ibid.*, 27, 1127 and 1302 (1905).

$\rightleftarrows$ —N : C(OH)— group, they dissolve readily in solutions of the caustic alkalies, whence they are reprecipitated by carbon dioxide or by acetic acid.

The naphthotetrazine prepared from guanidine and succinylosuccinic ester gives a sodium salt crystallizing in beautiful yellow needles or prisms which have a magnificent greenish fluorescence.

This, in a very hasty and imperfect way, indicates the main lines along which this particular field of investigation has been developed. It would only weary you to refer even hurriedly to the many subordinate lines of investigation radiating from these main ones, necessitating or resulting in the synthesis of many hundreds of new organic substances. I can only say, as I did at the outset of this address, that it has all been most interesting to us, and that we are still carrying on the work.

The articles published in the progress of these researches are listed below. They have all appeared in *The Journal of the American Chemical Society*, to which the volume numbers refer:

THE CAUSE OF COLOR IN ORGANIC COMPOUNDS.[1]

BY RICHARD SYDNEY CURTISS

Received April 16, 1910.

During an investigation in the mesoxalic ester series, I have been led to a study of the causes which underlie the phenomenon of color in some of these very simple aliphatic compounds.[2] In doing so I have found the subject fascinating, and it has seemed to me that it might be of interest to a general audience, in which I assume the great majority are not organic chemists. I shall try to present some of the simpler facts and theories on which our ideas of color cause rest.

---

[1] Address of the Chairman of the Division of Organic Chemistry of the American Chemical Society delivered in general session of the Society at Harvard University, December 29, 1909.

[2] Curtiss and Spencer, THIS JOURNAL, **31**, 1033; Curtiss, *Am. Chem. J.*, **35**, 477.

To discuss a subject in an hour, upon which so many thousands of pages of interesting researches have appeared, would be difficult enough, but my task is the harder since our good secretary has limited us to thirty minutes.

In deference to my non-organic friends, I shall try to eliminate, as far as possible, those incomprehensibly long names and formulas, which, while so simple and luminous to us, are always thorns in the flesh to most young chemists.

By a colored substance we all understand one which has the power of retaining or holding back some of the ether vibrations of certain definite wave length of the white light falling on it, the color being the resultant effect of all waves which pass through the substance to the eye. In other words, the color seen is the complement of the color absorbed.

It might be asked, Why is one compound colored and another not? Why is benzene, , colorless while its isomer, fulvene,[1] , like its oxygen derivative quinone, , is yellow? Or again, why is malonic ester,  $H_2C(CO_2R)_2$, without color and oxomalonic ester,  $O = C(CO_2R)_2$, green, formaldehyde, $H_2C = O$, colorless, and diazo methane,  $H_2C\langle N{=}N\rangle$, yellow? These are simple cases of color. They all contain an *unsaturated* group of atoms—the ethylene, the carbonyl, the azo groups.

Graebe and Liebermann,[2] who made the first studies of the relation of color to structure, noticed in 1867 that reduction of these unsaturated groups destroyed the color instantly. In the sixties little was known about the constitution of any of the organic colored substances—though, alizarin, purpurin, fuchsin, indigo and others were being investigated. Quinone was the only one whose constitution was known. It was the study of compounds like quinone and azobenzene containing such groups, and their loss of color on reduction, that led Witt[3] to formulate in 1876 his celebrated "chromophore theory." This states that the color in an organic compound is caused by the presence of a certain group which he called a *chromophore*, or color-forming group.

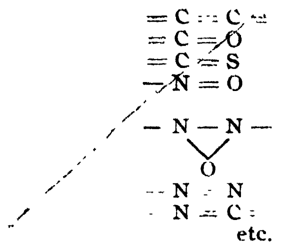
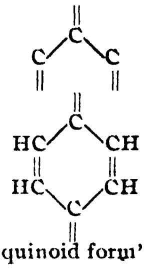
Chromophores.



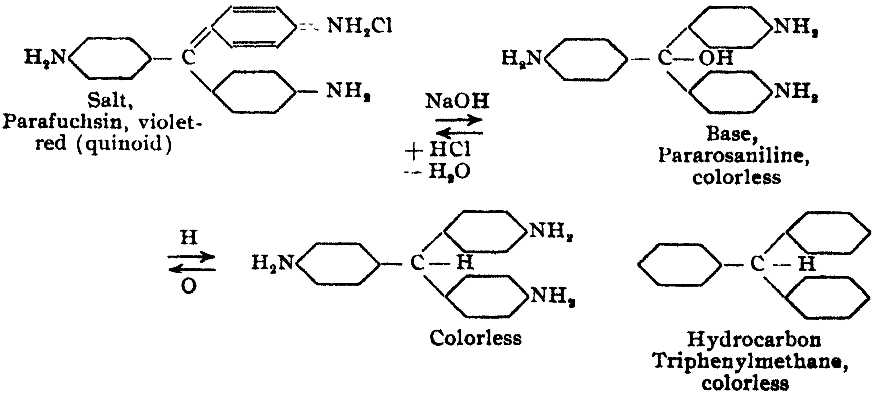


"quinoid form"
Color lost by reduction

Such a colored substance he called a *chromogen*. He also noticed that a colored substance might lack the power of imparting its color to a fabric, and that the presence of an hydroxyl or amine group, both salt-forming groups, usually tended to deepen the color and to cause it to fix to the fiber, that is, to produce a dye. Such groups he called *auxochromes*—and stated that both chromophore and auxochrome groups must be present to produce a *dye*. Witt's color theory has been of great value as a guide in the synthesis of a multitude of colored substances and dyes.

One feature that Graebe and Liebermann, in 1868, considered of fundamental importance for color production was the presence in aromatic chromogens of a quinone group or a quinone-like union of atoms, called also "quinoid form," and it is remarkable that this idea, based as it was at that time on wholly insufficient data, has been, and is even to-day in a modified form, one of the most valuable concepts in our theories of the cause of color.

In 1878–9 the cousins Emil and Otto Fischer,[1] in a series of masterly researches, established the relation of the important dyes, fuchsin and related compounds, to the parent hydrocarbon triphenylmethane and ascribed to parafuchsin a paraquinone structure, though they gave it the peroxide form. The chart shows the simple relation and color changes of this important class of dyes.



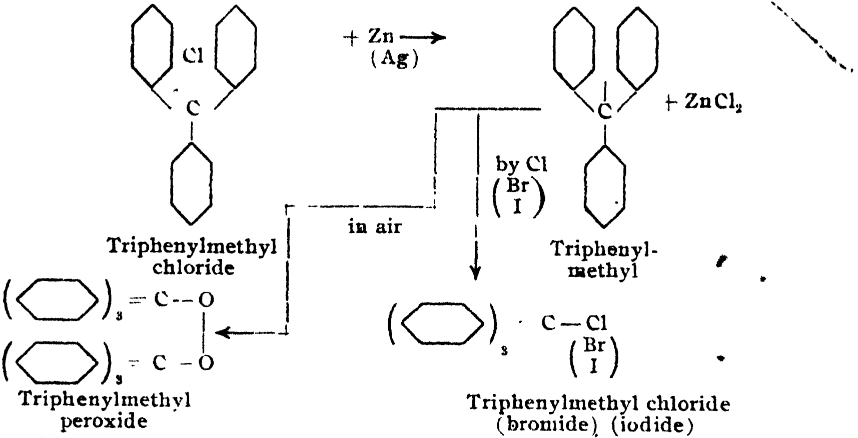
---

[1] *Ber.*, 12, 2344.

Such a molecular rearrangement as is shown in this salt formation, accompanied by an intensification of color, we shall note as a very important fact in the study of the causes of color.

The structure of these important dyes being thus settled as quinoid compounds, the color question of triphenylmethane derivatives remained quiescent for twenty years.

In 1900, Professor Gomberg[1] discovered triphenylmethyl, a colorless, crystalline product of the action of zinc on triphenylmethyl chloride in dry benzene, air being excluded during the reaction.



Its behavior is very remarkable. It unites with oxygen of the air to form a peroxide. Chlorine produces triphenylmethyl chloride. Its chloride forms with metallic chlorides colored addition products; with acids it gives colored salts. It even adds neutral substances like benzene and ether. Its great reactivity and apparently unsaturated character led Gomberg to believe that at last the object was attained for which Frankland had sought in vain in the early days of organic chemistry, the preparation of a free methyl radical. In the meantime the trivalency of carbon received an apparent set back when it was discovered that Gomberg's triphenylmethyl had a molecular weight corresponding to hexaphenylethane, $(C_6H_5)_3C{-}C(C_6H_5)_3$. The reactivity and unsaturated nature of this new substance cannot, however, be explained by this formula.

As a result of studies on this substance by Ullmann and Borsum,[2] Heintschel,[3] Chichibabin,[4] Schmidlin, Jacobson,[5] Gomberg,[6] Gomberg and Cone[7] and others, a formula was proposed by Jacobson, which well explains its properties, *when in solution.* This formula (below) shows it as a derivative of quinol. In quinol the CH_3 group easily dissociates, or wanders, to another part of the molecule.

When Gomberg's colorless crystalline substance dissolves in liquid sulphur dioxide a yellow color appears (as in all its solvents). This solution, as Walden[1] and also Gomberg and Cone[2] found, conducts electricity as that of an electrolyte. Gomberg[3] believes at the present time that this remarkable substance is, in the colorless crystalline form, triphenylmethyl, containing the methane carbon in the trivalent state, and the three benzene groups in the usual benzoid form.

When it dissolves, a tautomeric change occurs, one of the phenyl groups undergoes a molecular rearrangement to a yellow quinoloid form, while all three forms exist in equilibrium, in solution. Only the colorless crystalline form separates out when the yellow solutions are evaporated. These changes of triphenylmethyl are here shown.

Quinol

After Gomberg's brilliant discovery in 1900 there followed in rapid succession the announcements by Professor Norris and Mr. Sanders,[4] and later Kehrmann and Wenzel[5] that the colorless triphenylmethyl hydroxide and chloride dissolve in mineral acids giving colored solutions. Norris and Sanders also discovered the first colored double salt of triphenylmethyl, that of aluminium chloride. These were discoveries of fundamental interest for the development of the theories of color. Later Gomberg and Cone[6] discovered a neutral sulphate as a red crystalline compound and many other colored salts of this type. Other colored salts were made by Baeyer[7] and his co-workers. Salts of these types are shown below.

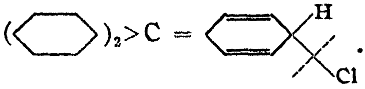
(I)$_3$C.HSO$_4$.H$_2$SO$_4$ brown

The old theories of color no longer sufficed. An intense interest was aroused in this whole class of colored derivatives. Baeyer started a very thorough investigation of the entire series of triphenylmethane derivatives, and his work appeared in eleven papers[1] in rapid succession in the *Berichte* and the *Annalen*, from 1902 on.

It is in this field that some of the most interesting color theories, and results, have been worked out.

Why should some of these simple salts of this triphenylmethyl radical be colored and others not? Kehrmann and Wenzel[2] assumed the existence of a colorless, and a colored isomer. The formula  represents the colorless crystalline chloride, while the structure of the isomeric colored salt (and double salts) containing a quinol chromophore are shown thus:



. This last form he considered to be derived from a hydrocarbon, , in which a para position carbon is divalent—very reactive—and has *basic properties.* This idea was contained in Professor Norris' work, which had just appeared. Gomberg holds strongly to this view of structure of all such colored salts and has brought out a large amount of experimental evidence to prove the quinol structure as the cause of color in the whole series of colored triphenylmethane derivatives. The idea of basic carbon has since been worked out by Baeyer, in his *carbonium valence theory*[3] and *halochromy.*[4]

Baeyer,[5] however, took exception to the above quinol formula of Kehrmann for these colored salts. He found chlorine not easily removable by silver salts, as is usually the case in a quinol. To explain the color Baeyer[6] assumed, like Kehrmann, Gomberg and others, a colorless non-

ionizable form, ( )$_3$CCl, and in addition an ionizable colored form, ()$_3$C∼∼∼Cl. To explain the cause of color in these compounds with identical structure and no chromophore group, Baeyer assumed, in the colored ionizable form, a peculiar difference in the properties of a methane carbon valence. This he indicated by a wavy, ionizing bond and called it the "carbonium valence." Like Kehrmann he considered the methane carbon basic, and to behave in such salt formations as the metal in potassium hydroxide. This property of a colorless carbon compound which contains no chromophore group, forming colored salts, he called *halochromy*. This explanation of color was novel, but not altogether satisfactory.

On the whole we find the chief ideas of the cause of color, as at present held by most chemists, to be, for triphenylmethyl and its two series of colorless and colored salts, first a colorless compound of benzoid structure, second—its molecular rearrangement to a colored form, having a quinone or a quinol structure, this unsaturated quinol ring being the chief cause of the color.

Let us turn to a new field.

The same general causes of color phenomena, namely, the change of a colorless compound into an isomeric colored form by a molecular rearrangement, Hantzsch found to exist in the nitrohydrocarbons, nitroketones,[1] and nitrophenols.

Colorless dinitroethane,[2]  $CH_3{-}CH\begin{matrix}NO_2\\NO_2\end{matrix}$, dissolves in sodium hydroxide with a yellow color. This color Hantzsch supposed to be due to a salt of a compound of a tautomeric form,  $H_3C{-}C\begin{matrix}NO_2\\N\,OH(M)\\\|\\O\end{matrix}$, which contains a chromophore, and in which there is a union of some sort between the nitro groups.

Such colorless substances which yield colored salts he classed among the *pseudo acids*.[3] This view of changing structure as the cause of color is confirmed by Hedley's[4] spectroscopic studies of nitroparaffins and their salts. After years of work on nitrohydrocarbons, Hantzsch was able to prove this theory. In 1906, Hantzsch and Gorke[5] obtained such isomers, not as metal salts, but as esters of nitrophenols. The formulas show this type, one colorless,  and the other intensely red,  Here at last was the confirmation of his theory of pseudo acids, for these crystalline esters of identical composition and like molecular weight, but differi in color, cannot have the same structure. This discovery was also important addition to our knowledge of the relation of color to chemic constitution. It also proved[1] the falsity of Oswald's theory[2] that the col of salts of such colorless compounds as phenolphthalein is *primarily* d to the formation of colored ions. Additional proof that such color chang are rather due to a molecular rearrangement has been well given t Hantzsch's[3] work on helianthin and methyl orange, and that of Vorlände Thiele,[5] and Hantzsch and Hilscher[6] on aminoazobenzenes and their tw series of colored salts.

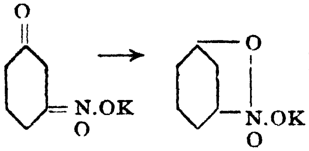
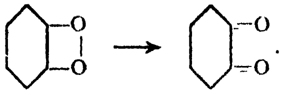
Hantzsch and Rosanoff[7] obtained isomeric colored salts of substitute metanitrophenols. One was lemon-yellow and unstable, easily changin into a stable red isomer. The structures have been suggested for these isomeric colored salts, though the question is a complicated one and remains unsettled.



Yellow salt Red salt

The existence of these two forms of metanitrophenol salts suggests the possibility of the existence of metaquinones—as well as two forms of *o*-benzoquinone. The latter were in reality found last year by Willstätter,[8] one labile and colorless, and readily changing to the other stable and colored form.



Colorless labile Yellow stable
orthoquinones.

Hantzsch and his co-workers extended these researches very widely over a period of several years and from a large amount of experimental data drew the following conclusion: All true nitro compounds of the hydrocarbons and derivatives are colorless.[9] The nitro group is *not* a chromophore. Its presence in a molecule only gives color when it interacts with a neighboring group containing a labile hydrogen atom, as the OH or CH group, whereby a tautomeric form is created which contains a chromophore group—yielding colored salts and esters. Kaufmann,[10] however, opposes this theory. Hantzsch makes this of general application in his statement as follows: "Every appearance of, or change of, color of a

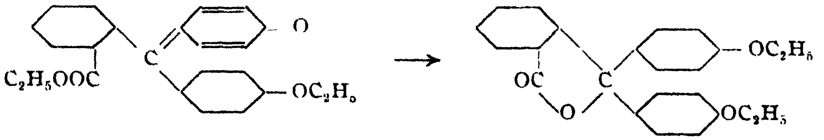
compound in salt formation with colorless metal atoms is to be ascribed to an intramolecular rearrangement." Such a phenomenon as indicated here he calls *chromotropy*, and the isomeric substances, *chromoisomers.*

An interesting application of this chromotropic theory is to those compounds, like phenolphthalein, methyl orange, aminoazobenzene, and others, which rapidly undergo color changes in salt formation in solutions.

The formula  shows Baeyer's lactone structure for phenolphthalein.

The well-known violet-red color of a phenolphthalein solution, when alkali is added, was supposed by many to be due to a monobasic salt, . In 1905 Meyer and Spengler[1] succeeded in separating and analyzing the red salt and found it dibasic, but considered its color due to halochromy. Baeyer[2] who also held this view of color rejected it in 1907, as did also Richard Meyer[3] last July in favor of the quinoid structure and tautomerism in the salts, as a cause of the color in phenolphthalein solutions. This idea had previously been suggested by Stieglitz and Acree.[4] Friedlander[5] had in 1893 assumed the presence of a red dibasic salt and had suggested the formula , which contains a quinoid ring, as the cause of color. Richard Meyer and Marx[6] showed, two years ago, that the production of color in colorless phenolphthalein solutions was due to a molecular rearrangement and the formation of a quinoid group. They were not able to show this in the salts, but with the corresponding esters. These they obtained in isomeric form and assigned the following structure to the yellow unstable one, which easily changes over to the colorless stable form, which contains no chromophore group:



Yellow crystals, labile Colorless crystals, stable

In this they indicated the tautomeric character of the change during color formation with phenolphthalein solutions. The color reactions and formation of colored esters in phenolphthalein cannot, however, be fully explained by the mere *presence* of the quinoid ring alone as chromophore. Arthur Green[1] in a recent paper (June last) has called attention to the fact that if, in this yellow quinoid ester, sodium be substituted for the ethyl radical in the phenol group  a very deep violet-red color is produced. This decided deepening of color cannot be due to the sodium atom as such, as it is not a chromophore, but in some way to its interrelation to the neighboring quinoid ring; in other words *the phenol and quinoid groups interact* as a strong chromophore. Such interaction of groups was proposed by Dr. Stieglitz[2] in his quinhydrone theory, to explain color formation, not only in phenolphthalein, but also in the rosanilines, rosolic acids, and eosins. He believed the presence of a quinone and a phenol group gave color by virtue of an intra- or intermolecular condensation, forming quinhydrones, compounds whose salts have intense colors, as we shall soon note below.

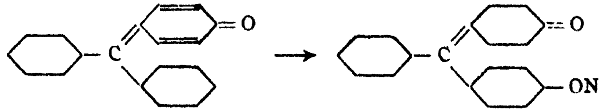
[4] *Am. Chem. J.*, 39, 543, 650 and 651.

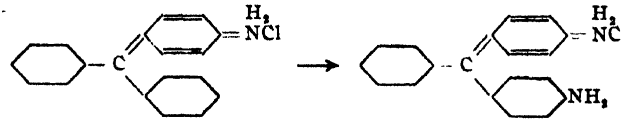
[5] *Ber.*, 26, 172.

[6] *Ibid.*, 40, 3603.

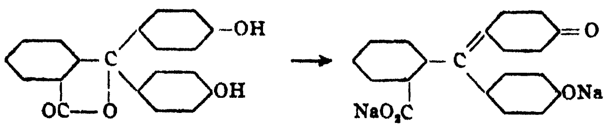
Baeyer[3] has recently discussed similar cases of color intensification. Oxo- and imino-triphenylmethane (the former called fuchsone) are only faintly colored orange, but an intense deepening of color is produced by simply introducing an hydroxyl, and an amine group respectively, in an adjacent phenyl group, and forming salts.



Fuchsone, orange **Benzaurin, violet-red**



Iminotriphenylmethane (salt), orange **Döbner's violet, violet-red**



Phenolphthalein, colorless **Salt, violet-red**

The mere presence of these added groups can neither explain this deep color change, nor the remarkable fact that the red salts have indentical absorption spectra—and therefore, identical color. They are also, in this respect, identical with the red salts of phenolphthalein. This is a very strong argument in favor of like structure in all three compounds. Such similarity of structure is not shown in the above formulas. Baeyer has, however, sought to indicate it[1] by assuming a rapid oscillatory change of the quinoid structure from one ring to the other, involving a corresponding movement of both the sodium or chlorine atom from oxygen to oxygen or nitrogen to nitrogen, respectively—and likewise an oscillation of a carbon to oxygen, or nitrogen, valence, as shown below:

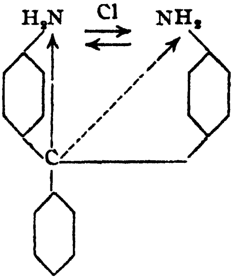
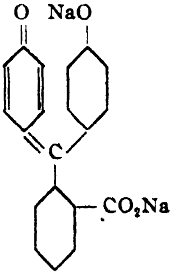
Benzaurin



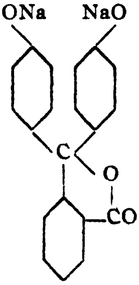
Döbner's violet

An auxochrome group is here shown to act not by its presence only, but by its interrelation or action with the rest of the molecule. This has also been clearly shown by Hantzsch[2] in the colored salts and esters of the colorless nitrophenols.

In interesting papers in the *American Chemical Journal* of April, 1908, and July of the present year on the subject of indicators, Acree and Slagle[3] assert that in addition to such quinoid and lactoid dibasic salts of phenolphthalein as shown here,



Quinoid



Lactoid

a third form exists,  , to which the color may be largely

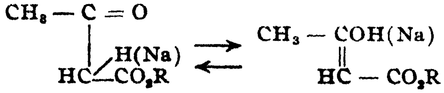
Green-yellow	Violet
Yellow	Indigo
Orange	Blue
Red	Green-blue
Purple	Green
Ultrared	———

The absorbed color is the complement of the color apparent to eye.

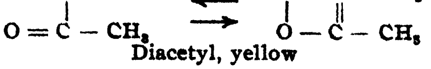
Baeyer's explanation of the intense color caused by salt formation in benzaurin and Döbner's violet as shown in the above formulas is an extension of Hartley's idea of intramolecular vibration and of the idea of isorropesis.

Equally interesting are the researches of Stewart, Baly and Desch.[1] They studied the absorption spectra of many unsaturated compounds, among them tautomeric substances which have a labile hydrogen atom capable of wandering to an adjacent carbon or oxygen atom. Such is acetoacetic ester, and its sodium salt, which have the tautomeric forms:



$$\begin{array}{l} CH_3 - C = O \\ \quad | \\ HC\begin{smallmatrix}H(Na)\\CO_2R\end{smallmatrix} \end{array} \rightleftarrows \begin{array}{l} CH_3 - COH(Na) \\ \quad \| \\ HC - CO_2R \end{array}$$

They found[2] in such compounds, and their tautomeric derivatives, that either form alone had little effect on the spectrum, but when light was passed through a solution in which both were present in tautomeric equilibrium, that characteristic absorption bands appeared. From this they concluded that it is not the fixed structure of a desmotropic molecule which causes absorption, but that it is due to the rapid oscillating change of atomic linking which occurs as a molecule changes from one form over to the other and reverses, which causes vibrations synchronous with certain light waves which thereby become absorbed, giving absorption spectra and consequently color. This rapid oscillating vibration of the valences, when unaccompanied by tautomeric atomic movement, they have called *isorropesis*[3] (equipoise). It can be most simply illustrated in the case of diacetyl or oxomalonic ester, in which the rapid oscillating change of double bonds between adjacent carbonyl groups is shown. It is not supposed that such isomeric forms really exist, but that the formulas represent the *limiting conditions* of such dynamic changes within a molecule of such a colored substance.



$$\begin{array}{l} O = C - CH_3 \\ \quad\ | \\ O = C - CH_3 \end{array} \leftrightarrows \begin{array}{l} O - C - CH_3 \\ |\quad\ \| \\ O - C - CH_3 \end{array}$$

Oxomalonic ester, green.

If we consider, then, these interesting optical results in the light of our present ideas of the constitution of the atoms, we should seek the *final* cause of color, in a disturbance of the equilibrium of electrons within the atoms, induced by the breaking of the Faraday tubes of force between the atoms. This is represented by our bonds or valence lines undergoing rapid oscillatory changes as suggested in the formulas above. We might well expect such a disturbed equilibrium to produce or annul ether vibrations of the order of those which produce color, and thus account for the absorption bands in the spectra of numberless organic compounds showing visible as well as invisible color.

NOTES.

The Instability of Alloxan.—On returning to the Chemical Laboratory after the summer vacation last year I found that an explosion had taken place in the case of specimens of organic chemicals in the lecture room. A pane of glass was pierced by a round hole as large as my fist and pieces of glass had been forcibly projected against the opposite wall of the room, ten feet from the case. Within the case quite a number of bottles were ruined. A careful examination of them showed very plainly that a bottle of alloxan containing 10 grams had been the cause of the wreck. This sample of alloxan had been in the case for several years and the past summer was an unusually cool one. I was not aware that alloxan had any such property and have been unable to find that it is subject to any such behavior. ALVIN S. WHEELER.

UNIVERSITY OF NORTH CAROLINA

The above note by Professor Wheeler on the instability of alloxan is of peculiar interest to the writer.

Several years ago, upon my return to the laboratory at the close of the summer vacation, I found that an explosion had occurred in one of our cupboards for fine organic chemicals. The force of the explosion shattered all the neighboring bottles on that end of the shelf, so that it was impossible to tell which particular bottle was responsible for the trouble. We checked up all the missing bottles by our shelf list, but among those destroyed there were none that we had ever heard mentioned as likely to decompose with explosive violence, and the matter remained very much of a mystery. Prof. Wheeler's article seems to solve this mystery, for among the wreck and ruin of broken glass in our cupboard were found portions of a bottle of alloxan which, according to our shelf list, hould have been standing about where the explosion occurred.

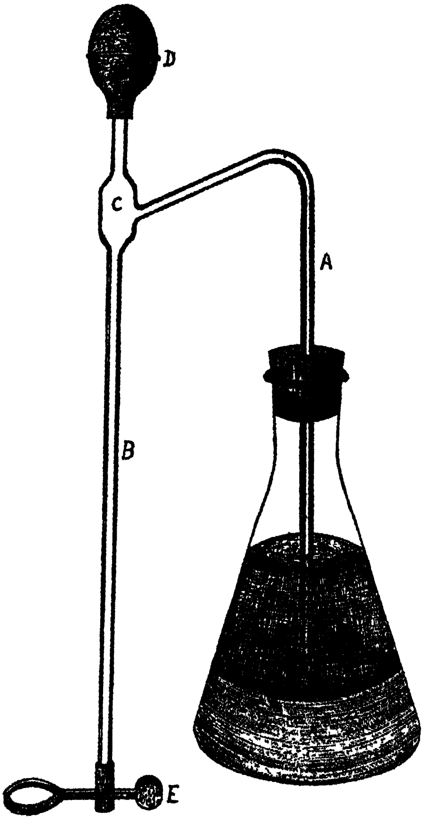
HAVEMEYER LABORATORIES, COLUMBIA UNIVERSITY

An Improved Siphon.—In our laboratory practice we have felt the need of a more efficient siphon than is now found on the market. In an effort to improve upon this form of apparatus, we have constructed a small glass siphon that combines simplicity of construction and ease of manipulation, and is especially adapted to extraction work with non-miscible solvents.

The siphon is really nothing more than a branched pipette, with the branch entering the bulb of the pipette as represented in the figure. The branch arm *A* consists of heavy capillary tubing with a 2 mm. bore, while the other glass parts are made of the ordinary thin glass. The bulb *C* has a capacity of 5 cc., which is ample for ordinary operations. Tube *B* is 22 mm. long, having an internal bore of 3 mm. The lower end of this tube is fitted with a short piece of rubber tubing, and is opened or closed by means of a small spring clamp. The upper end of the siphon is fitted with a small rubber bulb. Tube *A* is fitted with a cork having a vertical slit along the side, and fitting the separatory funnel or flask containing the liquid to be siphoned.



To operate the siphon, tube *A* is introduced into the liquid. The rubber bulb *D* is compressed, and the clamp at *E* closed. By gently releasing the pressure on the bulb, enough of the liquid will be drawn into *B* to start it to siphoning when clamp *E* is opened.

No other support, besides the cork, is necessary to hold the siphon in position. The hole through the cork should be large enough to permit the siphon to be raised or lowered during the operation. Tube *A* is made of heavy glass to give firmness to the siphon, and has a small bore to allow every drop of liquid in it to be transferred.

This form of siphon not only can be operated rapidly and conveniently, but it eliminates the danger of drawing the liquid into the mouth, or breathing offensive and poisonous vapors, which sometimes happens with the ordinary form of siphon.

Where it is absolutely necessary to avoid all contact with rubber, a piece of paraffin or wax may be pressed against the opening of the tube at *E*, until *B* is filled. A glass stopper might be inserted at *E*, but we consider that unnecessary.

The siphon is not only adapted for the removal of solution extracts but is applicable for the removal of supernatant liquids, where decantation would disturb the precipitate at the bottom; or for drawing off standard solutions, reagents, etc. It is especially convenient when colloidal solutions are to be filtered, or where one filtration requires several hours. In such cases the flow through the siphon is regulated by means of a chip of wood, holding the spring clamp open, so that the drip through the siphon equals that through the filter.

NEW BOOKS.

Neuvième Congrès International de Géographie. GENÈVE. 27 Juillet-6 Août, 1908. Compte Rendu des Travaux du Congrès. T. I. Organisation du Congrès. II. Travaux Scientifiques. A. Séances Générales. Genève, 1909. pp. xv + 475; pl. v; Figs. 15.

This report contains an account of the organization of the 9th International Geographic Congress held at Geneva in the summer of 1908. The character of the Congress is indicated by the fact that it was attended by 303 delegates, representing 24 governments, 32 universities, 81 geographical societies, and a number of other scientific organizations. In addition to the numerous social functions enjoyed by the membership in general, a large number of excursions and conferences were participated in by small groups of members. The number of papers read before the Congress was naturally great, but only a few possess any but a geographic interest. Only the non-technical ones appear in the volume under review. Of these the paper of most general interest is that by A. Penck, in which an account is given of the gratifying progress made toward securing a map of the entire world on the uniform scale of 1 : 1,000,000.

W. S. BAYLEY.

Wall Charts for Sugar Chemists: I. *Table for Finding the Sucrose Content of Juices,* clarified with 10 per cent. of subacetate of lead from the specific gravity of the original juice, and the readings in a Schmidt and Hänsch polariscope when observed in a 200 mm. tube. II. *Tables for the Correction of the Brix Hydrometer at Different Temperatures.* (*a*) When the hydrometer is tested at 84° F. (*b*) When the hydrometer is tested at 17.5° C. Published by NORMAN RODGER, Altrincham, England. Price 5/-net for the two, or 3/-net for either. Foreign postage 6d extra.

The subject matter of these two charts is familiar to every sugar chemist having been taken from Prinsen Geerligs' "Methods of Chemical Control in Cane Sugar Factories." The larger chart for finding the sucrose content of juices has a range of 0.5 to 24° Brix for polariscope readings extending from 1 to 90, the sucrose content for these limits ranging from 0.29 per cent. to 23.41 per cent. The smaller chart for correcting Brix hydrometers has a range of corrections for readings from 0° to 75° Brix for temperatures extending from 15° C. to 100° C. and 60° F. to 212° F. The two charts are mounted upon cloth and suitable for hanging upon the wall of laboratory or office. This new arrangement of Mr. Geerligs' excellent tables will be found a great convenience to the sugar chemist.

C. A. BROWNE.

Le Cinquantenaire de l'atomecanique ou de la Mécanique des atomes. I. *Quelques lettres de quelques Collèques Membres de l'Institut.* II. *Supplément.* III. *Fragments inédits.* By GUSTAVUS D. HINRICHS, St. Louis, Missouri. 64 pp. 4°; illustrated.

This brochure contains excellent pictures of a number of eminent chemists who have written to the author from time to time and facsimiles of some of their letters. The supplement gives extracts from a number of Professor Hinrichs's publications of the past half century. In the fragments several diagrams illustrating the author's method of calculating atomic weights are published for the first time.

W. A. N.

Manuel théorique et pratique d'analyse volumétrique. PAR LOUIS DUPARC, Professeur de minéralogie et de chimie analytique et Directeur des laboratoires d'analyse minérale de l'Université de Genève, et MARIA BASADONNA, Privat docent à l' Université. Avec 12 figures. 8vo, 170 pp. 1910. Paris: Felix Alcan.

This book is primarily designed for the instruction of pupils in the laboratory, a fact which probably accounts for the omission of nearly all matters of theory or of an explanatory character. A clear definition of normal solutions and brief descriptions of the most important volumetric apparatus are given and about two pages are devoted to the calibration of the latter. The analytical methods chosen for presentation are well selected and the descriptions are as lucid as is compatible with the highly condensed form of presentation adopted throughout. Many readers will regret that the author has restricted himself to one method for the standardizing of each solution, thus providing for no control over the accuracy of the work. Indeed, standardizing is sometimes omitted entirely, except by the second-hand way of comparison.

A surprisingly large number of individual determinations are described, considering the modest size of the volume, and are given in sufficient detail to serve as a needed reminder to one who has previously used the methods. The very short account of the theory of indicators entirely ignores the important work of the last five years, which has for the first time cleared up the main questions involved.

The work is very suitable for use in conjunction with thorough class instruction and may be welcomed as filling a field not yet satisfactorily occupied by other treatises comparable with it in size. There is no index, but only a tolerably full table of contents. L. W. Andrews.

QUANTITATIVE APPLICATION OF THE THEORY OF INDICATORS TO VOLUMETRIC ANALYSIS.

BY ARTHUR A. NOYES

Received May 4, 1910.

Contents.

I. GENERAL CONSIDERATIONS: 1. Purpose of the Article. 2. The Chemical Nature of Indicators. Equilibrium Relations of the Tautomeric Forms. 3. Equilibrium Relations of Indicators with Reference to the End-Point of Titrations. 4. Experiments Illustrating the Relation between the Color-Change of Indicators and the Hydrogen Ion Concentration. 5. Discussion of the Indicator-Function. 6. Concentration of the Indicator.

II. TITRATION OF MONOBASIC ACIDS AND MONACIDIC BASES: 7. General Formulation of the Theory. 8. The Error in the Titration. 9. Error in the Titration when a Neutral Salt is Originally Present. 10. The Best Value of the Indicator-Function. 11. Limiting Values of the Indicator-Function. 12. Limits beyond which the Titration is Impracticable.

III. TITRATION OF TWO MONOBASIC ACIDS OR OF TWO MONACIDIC BASES IN THE PRESENCE OF EACH OTHER: 13. Separate Titration of the More Ionized Acid. 14. Separate Titration of the More Ionized Base. 15. Titration of the Less Ionized Acid or Base.

IV. TITRATION OF DIBASIC ACIDS WITH MONACIDIC BASES: 16. General Formulation of the Theory. 17. Error in the Titration of the First Hydrogen. 18. Best Value and Limiting Values of the Indicator-Function for Titration of the First Hydrogen. 19. Error in the Titration of the Total Hydrogen. 20. Best Value and Limiting Values of the Indicator-Function for Titration of the Total Hydrogen.

V. TITRATION OF DIACIDIC BASES WITH MONOBASIC ACIDS: 21. Error in the Titration of the First Hydroxyl. 22. Best Value and Limiting Values of the Indicator-Function for Titration of the First Hydroxyl. 23. Titration of the Total Hydroxyl.

VI. SUMMARY: 24. Summary.

VII. APPENDIX: 25. Values of the Ionization-Constants of Indicators. 26. Values of the Ionization-Constants of Acids and Bases.

I. General Considerations.

1. *Purpose of the Article.*—Although the explanation of the behavior of neutralization indicators, originally given by Ostwald,[1] was one of the early triumphs of the Ionic Theory, and although many investigations upon indicators from a physico-chemical standpoint have since been made, yet the quantitative development of the theory of indicators in a systematic form immediately applicable to the problems of volumetric analysis seems not to have been undertaken.[2] It is the purpose of this article to present such a development.

The following discussion, owing to the large number of factors and special cases to be considered, unfortunately involves a somewhat lengthy, though comparatively simple, mathematical treatment. The reader who is interested in the results, rather than the method of derivation, is therefore recommended, after reading Sections 3 and 5 of this Part of the article, to pass directly to the Summary at the end, in which an attempt has been made to present the conclusions fairly completely and connectedly in a form in which they can be directly applied to the problems of volumetric analysis.

2. *The Chemical Nature of Indicators. Equilibrium Relations of the Tautomeric Forms.*—The original explanation of the behavior of indicators suggested by Ostwald was based on the simple hypothesis that the slightly ionized indicator acid or base has a different color from that of its ionized salt, into which it is converted by the addition of alkali or acid. More recent work has, however, shown that this explanation is inadequate in view of the well-known relations between the color and the structure of organic compounds, and in view of the results of the special investigations of Bernthsen, Nietzi and Burckhart, Hantzsch, and others on tautomeric colored substances.[3] It is in all probability true that a neutralization indicator always consists of tautomeric substances[4] of two different structural types possessing different colors, one of which types greatly predominates when the indicator exists as a slightly ionized acid or base, and the other when it exists as a largely ionized salt. Thus, the indicator may consist of a mixture of two tautomeric acids, HIn′ and HIn″, the equilibrium between these two acids being such that the acid HIn′ is present in greatly predominating quantity. Owing to the fact, how-

---

[1] *Lehrbuch der allgemeinen Chemie*, 1, 799 (1891). See also his *Wissensch. Grundlagen der anal. Chemie*, 3rd edit., pp. 117–23 (1901).

[2] It should be mentioned, however, that a brief treatment of a part of the problem has already been given by McCoy (*Am. Chem. J.*, 31, 512–6 (1904)), and by Salm (*Z. physik. Chem.*, 57, 497 (1907)).

[3] For a discussion of this matter, see Stieglitz, THIS JOURNAL, 25, 1112–20 (1903).

[4] From the modern standpoint tautomeric substances may be defined as isomeric substances which tend to go over into each other directly in one direction or the other until equilibrium is reached.

ever, that the acid HIn'' has a very much larger ionization-constant, its salt is formed in much larger proportion than that of the other acid when the mixture is neutralized with a base. Hence a change in color takes place in correspondence with the different structural type which predominates in the acid and alkaline solution. It has been shown by Stieglitz[1] that the conditions just stated do not make necessary any substantial modification of the equilibrium relations of indicators, so far as their behavior in titrations is concerned.

Since the limitations just mentioned with reference to the relative concentrations of the different forms are not in all cases necessary, it seems desirable to treat the matter from a somewhat more general standpoint, as follows.

Let us consider an acid indicator composed of two tautomeric substances, HIn' and HIn'', which when neutralized with a base BOH are converted into the corresponding salts BIn' and BIn'', these being largely dissociated into the ions B^+, In'^- and In''^-. In order that an indicator may be satisfactory in the respect that it show a sharp color-change on neutralization, it is evidently essential that the following conditions be fulfilled: (1) One of the structural forms must be colorless and the other colored; or else, the two structural forms must be of distinctly different colors. (2) Either form that may be colored must not exist in appreciable proportion in both acid and alkaline solutions.

In accordance with these general conditions, the three following cases may occur, the convention that the indicator shows in acid solution the color corresponding to the form HIn' being employed in their formulation:

(*a*) The indicator is colorless in acid and colored in alkaline solution. Hence HIn', BIn', and In'^- are colorless; HIn'', BIn'', and In''^- are colored; and $(HIn'')/(HIn')$[2] must be very small.

(*b*) The indicator is colored in acid and colorless in alkaline solution. Hence HIn', BIn', and In'^- are colored, HIn'', BIn'', and In''^- are colorless, and $(In'^-)/(In''^-)$ must be very small.

(*c*) The indicator has two sharply differentiated colors in acid and alkaline solution. Hence HIn', BIn', and In'^- have one color; HIn'', BIn'', and In''^- have a different color; and both $(HIn'')/(HIn')$ and $(In'^-)/(In''^-)$ must be very small.[3]

Corresponding criteria for a satisfactory color-change can also be readily formulated for the case of a basic indicator existing in alkaline solution in the two structural forms $In'OH$ and $In''OH$, which when neutralized with an acid HA are converted into the corresponding salts In′A and In″A, these being largely dissociated into the ions In'^+, In''^+, and A^-. It is not, however, necessary to formulate these conditions here.

---

[1] *Loc. cit.*, p. 1122.

[2] Throughout this article symbols enclosed within parentheses denote the molar concentrations of the substances represented by the symbols.

[3] For evidently, if there were present a considerable proportion of HIn'' in the acid solution, or of In'^- in the alkaline solution, a mixed color corresponding to the superposed colors of the two structural forms would result.

We may next derive a general expression (as has previously been done by Acree[1]) for the equilibrium-relations of any pair of tautomeric acids and their ions. The three fundamental equilibrium equations are as follows:

$$\frac{(H^+)(In'^-)}{(HIn')} = K_I'; \quad (1) \qquad \frac{(H^+)(In''^-)}{(HIn'')} = K_I''; \qquad (2)$$

and

$$\frac{(HIn'')}{(HIn')} = K_T. \qquad (3)$$

Multiplying (2) by (3), adding (1) to the product, and substituting in the denominator for (HIn′) its value $\frac{(HIn') + (HIn'')}{1 + K_T}$ given by

get:

$$\frac{(H^+)[(In'^-) + (In''^-)]}{(HIn') + (HIn'')} = \frac{K_I' + K_I''K_T}{1 + K_T} = K_{IA} \qquad (4)$$

If the indicator is a base existing as the two tautomeric substances In′OH and In″OH, having ionization constants K_I' and K_I'' and a tautomer constant K_T defined by equations analogous to (1), (2), and (3), the general expression for the equilibrium between the ionized bases and their ions is:

$$\frac{(OH^-)[(In'^+) + (In''^+)]}{(In'OH) + (In''OH)} = \frac{K_I' + K_I''K_T}{1 + K_T} = K_{IB} \qquad (5)$$

In these expressions a single constant K_{IA} or K_{IB} has been introduced in place of the function of the three constants K_I', K_I'', and K_T. This constant K_{IA} or K_{IB} will throughout this article be called simply the ionization-constant of the indicator acid or base.

The constant so calculated for a pair of tautomeric acids or bases can evidently be substituted for the ionization-constant of an ordinary (non-tautomeric) acid in any derived expression, provided the *sum of the* two ion-concentrations and the *sum* of two acid or base concentrations are the quantities that are known or are to be calculated. Thus the ionization-constant for a pair of tautomeric acids or bases as determined by conductance measurements would be that expressed by equation (4) or (5), since it is the sum of the ion-concentrations that are determined by such measurements. So also the degree of hydrolysis *h* of the sodium salts of a pair of tautomeric acids would be expressed, like that of the salt of an ordinary acid, by the familiar equation,[1] $\frac{\gamma_B h^2 C}{\gamma(1-h)} = \frac{K_W}{K_A}$, provided K_A, the ionization-constant of the tautomeric acids, be calculated by an expression of the form of equation (4); for it is the sum of the two forms of the acid that corresponds to the hydrolyzed portion, and it is the sum of the two forms of the salt that corresponds to the unhydrolyzed portion.[2]

---

[1] *Am. Chem. J.*, 38, 19 (1907).

Equations (4) and (5) can evidently be used to express the color changes exhibited by indicators or other tautomeric substances when, and only when, the intensity of the color is substantially proportional to the sum of the concentrations of the two tautomeric acids or bases, or to the sum of the concentrations of the two tautomeric ions. It has already been seen, however, that for a satisfactory two-color acid indicator (case *c*) the sum $(\text{HIn}') + (\text{HIn}'')$ must be substantially identical with (HIn') and the sum $(\text{In}') + (\text{In}''^-)$ substantially identical with (In''^-). It has also been seen that for a satisfactory one-color acid indicator (case *a* or *b*) either the former or the latter of these two identities must hold true; and it may now be pointed out that the intensity of the color is proportional to the other sum involved, namely to $(\text{In}'^-) + (\text{In}''^-)$ in case *a*, and to $(\text{HIn}') + (\text{HIn}'')$ in case *b*. This follows from the fact that these sums are proportional, in virtue of equations (1), (2), and (3), to (In''^-) and to (HIn') respectively, which are the substances on which the color alone depends in the two cases. From this it follows, in case *a* for example, that the ratio, of the color intensity of the indicator when partially transformed into its salt, to its color intensity when completely transformed, is equal to the ratio of the sums of the concentrations of the colored and colorless salts in the two cases. Similar conditions prevail in the case of two-color and one-color basic indicators.

Equations (4) and (5) may therefore be employed to express the equilibrium relations and color relations of such indicators as are included under cases *a*, *b*, and *c* described above and under the corresponding cases applicable to basic indicators—that is to say, of such indicators as can show a sharp color-change on neutralization. These equations will therefore be made the basis of the considerations presented in the next section; but for greater simplicity, (In^-) will hereafter be written for $(\text{In}'^-) + (\text{In}''^-)$, (HIn) for $(\text{HIn}') + (\text{HIn}'')$, (In^+) for $(\text{In}'^+) + (\text{In}''^+)$, and (InOH) for $(\text{In}'\text{OH}) + (\text{In}''\text{OH})$, thereby showing also that the indicator behaves as if it were a single acid or base.

---

[1] In this equation K_W is the ionization-constant of water, γ_B the ionization of the free NaOH, and C the concentration and γ the ionization of the salt in the solution.

[2] The contrary opinion expressed by Acree (*Am. Chem. J.*, 38, 35 (1907)) and his conclusion that the mass-action law would permit salts of tautomeric acids to exhibit "abnormal hydrolysis," even though equilibrium has been attained, seems to the writer clearly erroneous.

A satisfactory indicator must also fulfil the following conditions:

(*d*) The conversion of one tautomeric form into the other must take place almost instantaneously, for otherwise equilibrium will not be attained under the conditions of the titration.

(*e*) The color-change must be wholly due to the conversion of one tautomeric form into another; and it must moreover be determined only by the hydrogen-ion concentration, and not to an important extent by any other factor that may be involved, such as the presence of neutral salts in the solution.[1]

It is only to indicators which substantially fulfil these conditions that the principles presented in the following pages apply; and it is an important experimental problem to determine to what extent each special indicator conforms to these requirements.

3. *Equilibrium Relations of Indicators with Reference to the End-Point of Titrations.*—The end-point of a titration may be described as the condition attained when such quantities of base BOH and acid HA have been mixed that, as shown by the color-change, a definite fraction α of the indicator acid HIn is transformed into its salt BIn, or a definite fraction α of the salt InA of the indicator base is transformed into the free base InOH, the indicator transformation being for the sake of definiteness considered always to have taken place in the direction from acid to alkaline, in whichever direction the titration may actually have been made. For the ratio of the untransformed to the transformed fraction we then have, when the indicator is an acid,

$$\frac{1-\alpha}{\alpha} = \frac{(\mathrm{HIn})}{(\mathrm{In}^-) + (\mathrm{BIn})} = \frac{(\mathrm{HIn})}{(\mathrm{In}^-)/\gamma}, \qquad (6)$$

where γ represents the ionization of the indicator salt, which can be regarded as equal to the average value for other salts of the same (uni-univalent) type.

The ratio of the untransformed to the transformed fraction, when the indicator is a base, is:

---

[1] Thus Michaelis and Rona (*Z. Elektrochem.*, 14, 251 (1908)) have shown that the color of Congo red is greatly influenced by neutral salts, especially by those with bivalent and trivalent metallic elements, owing to coagulation of the particles of the indicator. They also state that the colors of methyl violet and (to a less extent) of methyl orange and phenolphthalein are similarly affected by neutral salts, though it is not shown that the effect is here due to the same cause. Several investigators have shown also that a small proportion of alcohol has a relatively large effect in discharging the color of phenolphthalein (cf. Hillebrand, THIS JOURNAL, 30, 1914 (1908)). The researches of Acree (*Am. Chem. J.*, 39, 528 (1908)) and Wegscheider (*Z. Elektrochem.*, 18, 510 (1908)) upon phenolphthalein have shown, moreover, that the behavior of an indicator may be complicated by its acting as a dibasic acid (thus making possible its existence in any of the six forms $\mathrm{H_2In}$, $\mathrm{H_2In'}$, $\mathrm{HIn^-}$, $\mathrm{HIn'^-}$, $\mathrm{In^=}$, and $\mathrm{In'^=}$).

$$\frac{1-\alpha}{\alpha} = \frac{(\mathrm{In}^+) + (\mathrm{InA})}{(\mathrm{InOH})} = \frac{(\mathrm{In}^+)/\gamma}{(\mathrm{InOH})}. \tag{7}$$

We may eliminate from each of these equations the concentration-ratio in the last member by combining with it the first or second of the following ionization equations, which correspond to equations (4) and (5) considered in the last section:

$$\frac{(\mathrm{H}^+)(\mathrm{In}^-)}{(\mathrm{HIn})} = K_{\mathrm{IA}}. \tag{8}$$

$$\frac{(\mathrm{OH}^-)(\mathrm{In}^+)}{(\mathrm{InOH})} = K_{\mathrm{IB}}. \tag{9}$$

The combination of these equations with (6) and (7) evidently leads to the following results:

$$(\mathrm{H}^+) = \frac{(1-\alpha)K_{\mathrm{IA}}}{\alpha\gamma}; \text{ and} \tag{10}$$

$$(\mathrm{OH}^-) = \frac{\alpha K_{\mathrm{IB}}}{(1-\alpha)\gamma}. \tag{11}$$

If in the last equation we substitute for (OH^-) the value of it given by the mass-action equation expressing the ionization of water,

$$(\mathrm{H}^+)(\mathrm{OH}^-) = K_{\mathrm{W}}, \tag{12}$$

we get the following expression:

$$(\mathrm{H}^+) = \frac{(1-\alpha)\gamma K_{\mathrm{W}}}{\alpha K_{\mathrm{IB}}} \tag{13}$$

Equations (10) and (13) are the fundamental equations upon which the theory of indicators is based. They express the principle that in any titration with a given indicator *the end-point* (determined so as to correspond to a definite color-change) *is reached when the hydrogen-ion concentration in the titrated solution attains a definite value,* and that the end-point is determined solely by that concentration. This definite value varies, however, with the ionization-constant of the indicator, and with the proportion of the indicator transformed.[1]

---

[1] It follows from this principle that the ionization-constant of an indicator can be determined, as has been done by Friedenthal, Salessky, Fels, and Salm, by adding it to a series of solutions of decreasing hydrogen-ion concentration until the color-change shows that a definite fraction of it has been transformed. Conversely, the unknown hydrogen-ion concentration in any solution (for example, in that of a very weak acid or hydrolyzed salt) can be determined by adding to it a series of indicators of decreasing ionization-constants—a principle previously applied by Salm and others. This principle may be expected, on account of the ease with which the experiments can be made, to have many important technical applications, especially in cases where a small degree of acidity or alkalinity is to be approximately determined. In place of a series of indicators, the use of a single indicator (2,5-dinitrohydroquinone) which shows a series of markedly different colors in solutions varying in hydrogen-ion concentration by powers of 100 from 10^{-2} to 10^{-12} has recently been proposed by Hender-

It is evident from a comparison of equations (10) and (13), since the value of (H^+) determines the end-point, that a basic indicator of ionization-constant K_{IB} behaves exactly as if it were an acid indicator having an ionization-constant K_{IA} equal to $\gamma^2 K_W/K_{IB}$. Although it is for this reason impossible to determine from its behavior upon titration whether a given indicator is an acid or base, yet for practical purposes all that is essential to know about a basic indicator is the value of the constant, which an acid indicator would have that showed a behavior identical with that of the basic indicator in question.

Mention may finally be made of the fact that the ratios K_{IA}/γ and K_{IB}/γ that occur in equations (10) and (13) are equal to the ionization-constants that would be calculated if, disregarding the degree of ionization of the indicator salt, the color due to the latter were taken as a measure of the concentration of the indicator ion. That this is so becomes obvious upon dividing both members of equations (8) and (9) by γ. For the ratio K_{IA}/γ and for the ratio $\gamma K_W/K_{IB}$ will hereafter be written simply K_I, and this will be called the *apparent ionization-constant* of the indicator.

4. *Experiments Illustrating the Relation between the Color-Change of Indicators and the Hydrogen-Ion Concentration.*—The fundamental principle of the theory of indicators and the fact that the various indicators change color at different hydrogen-ion concentrations may be illustrated by the following experiments, which are described in a form adapted to lecture demonstration.[1]

Prepare one liter of each of nine solutions, whose hydrogen ion concentration differs progressively by each power of 10 from 10^{-3} normal to 10^{-11} normal by proceeding as follows:

(H^+) = 10^{-3} to 10^{-5}: Make up for use in preparing these solutions 3 liters of 0.1 normal acetic acid (concentration to be accurate within 5 per cent.) by dissolving 18.0 g. glacial acetic acid in 3000 cc. distilled water.

(H^+) = 10^{-3}: Mix 570 cc. 0.1 normal acetic acid solution with 430 cc. water, yielding a 0.057 normal solution of the acid. For this case:

$(H^+)(Ac^-) = (H^+)^2 = K_A(HAc) = (1.8 \times 10^{-5}) \times (5.6 \times 10^{-2})$; therefore $(H^+) = 10^{-3}$.

(H^+) = 10^{-4}: Dissolve 0.020 formula wt. sodium acetate, equal to 2.7 g. $NaC_2H_3O_2.3H_2O$, in one liter of 0.1 normal acetic acid. In this case:

$$(H^+) = K_A \frac{(HAc)}{(Ac)} = (1.8 \times 10^{-5}) \frac{10^{-1}}{0.9 \times 2.0 \times 10^{-2}} = 10^{-4}.$$

(The 0.9 in the denominator represents the ionization of the sodium acetate.)

---

son and Forbes (THIS JOURNAL, 32, 687 (1910)). Attention may in passing also be called to the fact that for the case that $\alpha = 1/2$, that is, that the indicator is half transformed, equations (10) and (13) assume the simple forms:

$$(H^+) = K_{IA}/\gamma \text{ and } (H^+) = \gamma K_W/K_{IB}.$$

[1] To Mr. B. H. St. John, who ably assisted me in working out these experiments, I desire to express my indebtedness.

$(H^+) = 10^{-5}$: Dissolve 0.11 formula wt. sodium acetate, equal to 15.0 g. $NaC_2H_3O_2.3H_2O$, in 500 cc. water, and add 500 cc. 0.1 normal acetic acid. In this case:

$$(\mathrm{H}^+) = K_\mathrm{A}\frac{(\mathrm{HAc})}{(\mathrm{Ac})} = (1.8 \times 10^{-5})\frac{5 \times 10^{-2}}{0.8 \times 0.11} = 10^{-5}.$$

$(H^+) = 10^{-6}$ to 10^{-11}. Make up 10 liters of a 0.1 formal[1] solution of $Na_2HPO_4.12H_2O$ by dissolving 358 grams of the crystallized salt in this quantity of water. (As the concentration of this solution should be known within about $^1/_2$ per cent., it is well as a control to evaporate a 100 cc. portion of it in a platinum dish and to ignite and weigh the residue of sodium pyrophosphate.) Prepare also a 0.1 normal solution of hydrochloric acid and one of sodium hydroxide (or some other strong base), and determine their concentrations within 0.3–0.5 per cent. By mixing the phosphate solution in appropriate proportion with the acid or base, we may prepare solutions of the desired hydrogen-ion concentration; for the added acid or base converts the hydrophosphate-ion $(HPO_4^=)$ almost quantitatively into dihydrophosphate-ion $(H_2PO_4^-)$ or into phosphate-ion $(PO_4\ )$; and the ratio which the concentration of these must bear to that of the hydrophosphate-ion in order to give the desired hydrogen-ion concentration can be readily calculated from the ionization-constants (K_2 and K_3) of the second and third hydrogens of phosphoric acid as determined by Abbott and Bray.[2] We have namely the relations:

$$\frac{(\mathrm{H_2PO_4^-})}{(\mathrm{HPO_4^=})} = \frac{(\mathrm{H}^+)}{K_2} = \frac{(\mathrm{H}^+)}{2.0 \times 10^{-7}}, \text{ and } \frac{(\mathrm{PO_4}\ )}{(\mathrm{HPO_4^=})} = \frac{K_3}{(\mathrm{H}^+)} = \frac{3.6 \times 10^{-13}}{(\mathrm{H}^+)}.$$

Substituting the various values of (H^+) we may get the values of the first members of these equations, and from them by a simple transformation the values of the ratios given in the following table:

(H^+)	$\frac{(H_2PO_4^-)}{(H_2PO_4^-) + (HPO_4^=)}$	$\frac{(PO_4\ )}{(PO_4^\equiv) + (HPO_4^=)}$
10^{-6}	0.833 (0.850)	....
10^{-7}	0.333 (0.450)	....
10^{-8}	0.047 (0.050)	....
10^{-9}	0.005 (0.0)	....
10^{-10}	...	0.0036 (0.030)
10^{-11}	...	0.036 (0.140)

(The values within parentheses are those derived by Salm (*Z. physik. Chem.*, **57**, 480 (1907)) by an entirely different method, namely, by determining (H^+) by measuring the electromotive force of hydrogen gas cells containing the phosphate solutions as electrolytes.)

These ratios evidently represent the fraction of the hydrophosphate in the original solution which is to be transformed by the addition of the acid or base. Assuming the latter to have the same formal concentration as the phosphate solution, then the various standards may be made up by mixing the quantities of the solutions shown in the following table:

(H^+).	Na_2HPO_4 solution. cc.	HCl solution. cc.	NaOH solution. cc.
10^{-6}	600	500	..
10^{-7}	700	350	..
10^{-8}	1000	47	..
10^{-9}	1000	5	..
10^{-10}	1000	..	3.6
10^{-11}	1000	..	36

[1] In accordance with the practice of this laboratory, a solution containing x formula weights of solute per liter is designated an x-formal solution.

[2] THIS JOURNAL, 31, 760 (1909).

(The accuracy of the first of these standards is evidently especially sensitive to errors in the relative concentrations of the hydrophosphate and acid solutions, since so large a proportion of the former is converted into dihydrophosphate.)

Arrange 27 lecture jars or large lecture test tubes in three rows of nine, preferably upon a wooden stand covered with white cloth or paper and made in the form of three long narrow steps, so that each row will be visible above or below the other rows. Place 200 cc. of the $(H^+) = 10^{-3}$ solution in each of the jars at the left end of the three rows, 200 cc. of the $(H^+) = 10^{-4}$ solution in the three jars next to these, and so on till all the jars are charged with the nine standard solutions. Place cards with large figures —3, —4, —5, etc., pasted or marked upon them above each set of three jars.

Prepare in small 100 cc. bottles about 100 cc. of the following indicator solutions:

(*a*) 0.5 per cent. solution of thymolphthalein (TP) in alcohol.
(*b*) 0.5 per cent. solution of phenolphthalein (PP) in alcohol.
(*c*) 0.5 per cent. solution of rosolic acid (RA) in 50 per cent. alcohol.
(*d*) 0.1 per cent. solution of methyl red[1] (MR) in water.
(*e*) extract of cochineal (Coc) commonly employed in volumetric analysis.
(*f*) 0.1 per cent. solution of methyl orange (MO) in water.

Place in each of these indicator solutions a straight tube about 15 cm. long and 8 mm. in bore slightly constricted at its lower end.

When the demonstration is to be made, add by means of the straight tubes, capped temporarily with the finger, about 2 cc. of the appropriate indicator solutions to the various jars in the manner shown in the following table, where the letters represent the indicators to be added:

10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}	10^{-9}	10^{-10}	10^{-11}
...	MR	MR	MR*	MR	TP	TP	TP	TP*
Coc	Coc	Coc*	Coc	...	PP	PP*	PP	PP
MO	MO*	MO	RA	RA*	RA	RA	...	...

The stars in the above table show the point at which the transition-color of the indicator is most marked.

5. *Discussion of the Indicator-Function.*—In the following discussion we will for the sake of brevity substitute for the cumbrous expressions for (H^+) given in equations (10) and (13) a single letter k. That is, we will put:

$$k = \frac{(1-\alpha)K_{IA}}{\alpha\gamma} = \frac{(1-\alpha)\gamma K_w}{\alpha K_{IB}} = \frac{1-\alpha}{\alpha}K_I. \qquad (14)$$

It is evident that k is a quantity that depends on the apparent ionization-constant of the indicator and on the proportion of it transformed in the titration. For brevity it will throughout this article be designated the *indicator-function.*[2]

---

[1] A new, apparently very satisfactory indicator recently described by Rupp and Loose (*Ber.*, 41, 3905 (1908)) and readily prepared according to their directions. See also *C. A.*, 3, 523 (1909).

[2] In consequence of some complication, such, for example, as would arise if the indicator were a dibasic acid or if neutral salts influenced its ionization relations or its tautomeric equilibrium, the hydrogen-ion concentration may be some other function of the fraction transformed than that expressed by equations (10) and (13). In that case the true functional relation $(H^+) = f(\alpha)$ might be determined by experiment; and

The function k plays a most important part throughout the following considerations; and it will be seen later that when the titration is sensitive to errors, its accuracy is determined by the closeness with which a definite value of k can be realized. It is therefore well to consider in advance the practical conditions regulating the values of the two factors α and K_I which determine k and their bearing on the quantity of indicator that should be employed. It is evident that theoretically any desired value of k could be secured with any indicator of any ionization-constant K_I by giving α, the fraction of it transformed at the end-point, an appropriate value. To secure accuracy, however, α must be given (1) such a value that the eye can best recognize a small percentage change in its value, and (2) such a value that k will not be unnecessarily sensitive to the unavoidable error in so determining the end-point as to give the desired value of α.

The second of these conditions, which can be treated very simply in a mathematical way, may be first considered. By differentiating equation (14), and dividing the result by the original equation, we get:

$$\frac{dk}{k} = \frac{dK_I}{K_I} - \frac{d\alpha}{\alpha(1-\alpha)}$$

This equation shows that any small fractional error in α (represented by $d\alpha/\alpha$) causes a fractional error in k (represented by dk/k) which is $1/(1-\alpha)$ times as large as that in α. The quantity $1/(1-\alpha)$, however, evidently approaches a minimum value of unity as α approaches zero. Yet, it is to be noted that $1/(1-\alpha)$ does not change very greatly until α assumes a fairly large value; thus for $\alpha = 25\%$, $1/(1-\alpha)$ becomes only 1.33; so that any value of α up to say 25 per cent. is nearly as good as a much smaller value, so far as this effect is concerned. The conclusion to be drawn is, therefore, that α should always be given a fairly small value, which may, however, if other conditions require it, be made as large as 25 per cent.

If the indicator is being transformed in the other direction, by the addition of an acid rather than a base, and the color-change being observed is that corresponding to the form of the indicator whose proportion is represented by $(1-\alpha)$, it also is true that the fraction of it *so* transformed must be relatively small. For the last term of the preceding equation can be written $+\frac{1}{\alpha}\frac{d(1-\alpha)}{1-\alpha}$, from which it is evident that the multiplying factor $1/\alpha$ approaches a minimum value of unity as α approaches unity.

if k were then understood to signify the value of that function in any given case, all the formulas derived in the following sections of this article would still be valid; for in the derivation of them k merely represents the value which (H^+) has at the end-point of the titration.

The other condition—that relating to the sensitiveness of the eye to the color-change—may be first considered for the case of one-color indicators, such as phenolphthalein, paranitrophenol, or cyanine, which are colorless in acid and colored in alkaline solution. Evidently in this case the definite depth of color, to a change in which the eye is most sensitive, may be attained by varying either the total concentration of the indicator (ΣIn) or the fraction (α) of it transformed, for the depth of color is proportional to the product $\alpha(\Sigma\text{In})$. Therefore by adding different quantities of indicator we can often vary α within fairly wide limits without sacrificing sensitiveness, and thereby attain even with a single indicator of constant K_I a fairly large variation in the value of k. Thus when the indicator is sufficiently soluble, it might well be practicable to vary α from 0.1 per cent. to 25 per cent.[1] which would correspond to a variation of k from 1000 K_I to $3K_I$. A minimum value for α is, however, often determined by the fact that the solubility of the indicator in water is not sufficient to allow the necessary depth of color to be secured without increasing α beyond that minimum value.[2] Thus, if I represents the value of the concentration α (ΣIn) of the transformed part of the indicator which gives the proper intensity of color, and if S is the solubility of the indicator (that is, the value of the concentration (ΣIn) in the saturated solution), the relation $\alpha > I/S$, and therefore also the relation $k < \frac{S - I}{I} K_I$, must evidently hold true.

In the case of a one-color indicator, the relation between depth of color, concentration of indicator, and fraction transformed can be experimentally determined by placing a measured quantity (1 to 5 cc.) of its solution in a graduate, adding 5 to 10 cc. of 0.1 normal alkali solution (whereby the indicator will be completely transformed) and enough water to make the volume 100 cc., and then diluting measured fractional portions (say 10 cc. and 1 cc.) of this solution to 100 cc. The resulting color corresponds to that which the quantity of indicator taken at the start gives to 100 cc. liquid when the fraction of it transformed equals the fraction ($^1/_{10}$ and $^1/_{100}$) of the solution that was diluted. In this way the quantity of indicator that must be added to secure any desired fractional transformation and at the same time the desired depth of color can readily be determined.

---

[1] The upper value of α here mentioned is so chosen as to accord with the considerations of the preceding paragraphs. The lower value, though not necessarily the limit in all cases, could hardly ever be much further reduced without adding an extraordinary amount of the indicator.

For example, experiments that have been made with p-nitrophenol in the way described in the next paragraph show that, if 10 cc. of its saturated solution in water were added to 100 cc. of water, a depth of color sufficient to constitute a satisfactory end-point would be obtained by transforming 0.1 per cent of the indicator into its salt.

[2] For example, experiments made with phenolphthalein have shown that when the solution to be titrated is saturated with it, about 4 per cent. of it must be transformed into its salt to give such a depth of color as would serve as a satisfactory end-point. This minimum value of α corresponds to a maximum value of k equal to 24 K_I. In the case of thymolphthalein, on the other hand, it was found that in an aqueous solution saturated with it a suitable color is obtained only when about $^1/_2$ of the indicator is transformed into its salt.

In the case of two-color indicators, such as methyl orange, dimethylaminoazobenzene, methyl red, cochineal, and rosolic acid, the fraction transformed can not be similarly varied without a great sacrifice of sensitiveness; for, owing to the fact that the indicator has a color in the untransformed state, the fraction transformed must have a considerable value in order that its own color may be visible. What the best fraction to have transformed is, depends on the character and intensity of the two colors which the indicator exhibits; but ordinarily it is probably between 5 and 20 per cent.[1] The value of k practically attainable with a two-color indicator which is being transformed by passing from the acid to alkaline condition and which has an ionization-constant K_I is therefore ordinarily in the neighborhood of 10 K_I. On the other hand, if the color-change be determined in passing from the alkaline to the acid condition, and if say 9 per cent. of the indicator be transformed in this direction at the end-point (in which case $1 - \alpha = 0.09$ and $\alpha = 0.91$), the value of k becomes $^1/_{10}K_I$.

While a two-color indicator does not possess the same graded adaptability that a one-color indicator possesses, yet it will be seen from the illustration just given that the color-changes at both limits of its transformation may be utilized, provided the eye is sufficiently sensitive to both these changes.

In the case of a two-color indicator, the relation between color-change and fraction transformed can be experimentally studied by preparing a solution of the indicator of any appropriate concentration, dividing this into two parts, adding a small quantity of hydrochloric acid to one part and of sodium hydroxide to the other so as to transform it completely in one direction or the other, then superposing in suitable tubes or beakers a layer of one of these solutions above a layer of the other, and looking through the two layers. The relative thickness of the two layers, or the concentration of the one or the other solution, may then be varied, and the colors compared.

Summing up these considerations we may therefore say that we can in general secure, in the case of one-color indicators (by using a suitably adjusted quantity of the indicator), and in the case of two-color indicators (by titrating in the one direction or the other), values of the indicator-function k which are given by the following expressions, in which K_I is the apparent ionization-constant of the indicator:

---

[1] Experiments made by me with methyl orange have shown that a satisfactory change of color in the direction from yellow to orange is secured when from 5–20 per cent. (depending on the concentration) is transformed, but that in the direction from pink to orange from 20–30 per cent. must be transformed.

$k > 3K_\mathrm{I}$ and $< \frac{S - I}{I} K_\mathrm{I}$ for one-color indicators of limited solubility S. (15*a*)

$k > 3K_\mathrm{I}$ and $< 1000\, K_\mathrm{I}$, for one-color indicators of sufficient solubility. (15*b*)

$k =$ approx. $10\, K_\mathrm{I}$ or $=$ approx. $^1/_{10}\, K_\mathrm{I}$, for two-color indicators. (16)

It is to be understood, however, that these are only rough general estimates. It is therefore desirable to emphasize the importance of supplementing in any investigation of specific indicators the determination of their ionization-constants by an experimental study of the absolute concentration (I) which the colored form of the indicator must have in order to give a satisfactory color-intensity, of its solubility in water, and of the limits between which it is practicable to vary the fraction of it transformed. Only in this way will an exact application of the theory of indicators to volumetric analysis be made possible.

6. *Concentration of the Indicator.*—Besides these limitations in regard to the fraction of the indicator transformed, there is for an entirely different reason a maximum limit placed on the total normal concentration (ΣIn) of the indicator. Namely, it is evident that the concentration of the indicator salt in the solution titrated to the end-point must in general be negligibly small in comparison with the molal concentration (C) of the salt produced by the neutralization of the base BOH and the acid HA; since otherwise an appreciable excess of the base BOH, if the indicator is an acid, or of the acid HA if the indicator is a base, will be used up in combining with the indicator. Since the fraction of the indicator existing as its salt is α if the indicator is an acid, and is $1 - \alpha$ if the indicator is a base, this condition in regard to the concentration of the indicator may be expressed as follows, if we represent by ρ the maximum fractional error that is considered permissible in the titration:

$$(\Sigma\mathrm{In}) < \frac{\rho C}{\alpha} \text{ for an acid indicator.} \qquad (17)$$

$$(\Sigma\mathrm{In}) < \frac{\rho C}{1 - \alpha} \text{ for a basic indicator.} \qquad (18)$$

By these expressions the maximum quantity of indicator that may be added to a given volume of solution in any titration without introducing a fractional error greater than ρ may readily be calculated.[1]

---

[1] Thus if an accuracy of 0.1 per cent. ($\rho = 10^{-3}$) is desired, if the indicator is an acid and the fraction of it transformed at the end-point is 10 per cent. ($\alpha = 10^{-1}$), and if the concentration of the salt in the titrated solution is 0.05 normal ($C = 5 \times 10^{-2}$),

II. Titration of Monobasic Acids and Monacidic Bases.

7. *General Formulation of the Theory.*—We may now proceed to the solution of our main problem, which consists primarily in deriving expressions for the difference between the quantity of the acid HA and that of the base BOH which have to be brought together in order that the end-point may be reached, confining ourselves in the first instance to the case where the acid is monobasic and the base monacidic. A general solution of this problem involves the treatment of combinations involving any acid of ionization-constant K_A, any base of ionization constant K_B, and any value of the indicator-function k.

The ionization-constants of the acid and base are expressed by the equations:

$$(B^+)(OH^-) = K_B(BOH). \qquad (19)$$

$$(H^+)(A^-) = K_A(HA). \qquad (20)$$

The ionization-constant of water (K_w) is also involved in the subsequent considerations, since it furnishes a relation between the concentrations (H^+) and (OH^-). It is expressed by equation (12) given above. Replacing (H^+) in this equation by k we get:

$$(OH^-) = K_w/k. \qquad (21)$$

It is to be noted that K_w has an extremely small value; namely, about 10^{-15} at 0°, 10^{-14} at 25°, 10^{-13} at 65°, and 5×10^{-18} at 100°.[1]

Let now the total concentration of the acid-constituent A in the solution titrated to the end-point be (ΣA) and that of the base-constituent B in that solution be (ΣB).[2]

---

the concentration of the indicator must be less than 5×10^{-4} normal or 1/2000 normal; and if the volume of the titrated solution is 100 cc., less than 1/20,000 of a formula weight of indicator must be added to it.

That the concentration of the indicator is in practice ordinarily less than 1/2000 normal will be seen from the following facts: Solutions of indicators are usually prepared so as to contain 1 to 5 grams of the indicator per liter. This latter value corresponds to 0.016 of a formula weight per liter (assuming the average formula weight to be 300). Of such solutions less than 1.0 cc. is commonly added to say 80 cc. of the titrated solution. This makes the concentration of the indicator in the latter less than 0.0002 formal.

[1] The values of this constant at 0 and 25° given by Kanolt (THIS JOURNAL, **29**, 1414 (1907)) are somewhat lower, namely, 0.88×10^{-15} at 0° and 0.81×10^{-14} at 25°. Other investigators have, however, found higher values; thus Heydweiller (*Ann. Phys.*, [4] **28**, 512 (1909)) through a recalculation of the experiments made by him and Kohlrausch obtained 1.16×10^{-15} at 0° and 1.04×10^{-14} at 25° and Lundén (*Meddel. fr. k. sv. vet. Nobelinstitut*, Vol. 1, No. 8, p. 16 (1907)) found 1.05×10^{-14} at the latter temperature. Whatever may be the correct result, the round values are sufficiently accurate for the purposes of this investigation.

[2] The products obtained by multiplying these concentrations by the volume of the titrated solution represent evidently the quantities of the acid HA and base BOH which have been mixed in order to reach the end-point; and the ratio of these concentrations to each other represents the ratio of the said quantities to each other (provided no salt of the acid or base was originally present in either solution).

The different forms in which these two constituents exist in the solution are shown by the following equations which sum up the concentrations of those various forms:

$$(\Sigma B) = (B^+) + (BOH) + (BA). \qquad (22)$$

$$(\Sigma A) = (A^-) + (HA) + (BA). \qquad (23)$$

We have also a further relation expressing the equality of the sums of the concentrations of all the positive and of all the negative ions in the solution, as follows:

$$(B^+) + (H^+) = (A^-) + (OH^-). \qquad (24)$$

It is to be noted that the quantities (H^+) and (OH^-) in a titrated solution are always small in comparison with the quantities (B^+) and (A^-). It is not, however, permissible to cancel them from this equation, since the difference $(B^+) - (A^-)$ is involved in the following derivation. In cases, however, where the value of (B^+) or (A^-) itself, and not their difference, is involved, no serious error will be made by assuming that (B^+) and (A^-) are equal.

8. *The Error in the Titration.*—In order to obtain an expression for the fractional error in the titration we may proceed as follows. We first subtract equation (23) from (22), whereby we obtain:

$$(\Sigma B) - (\Sigma A) = (B^+) - (A^-) + (BOH) - (HA). \qquad (25)$$

We then substitute in this equation the value of $(B^+) - (A^-)$ given by equation (24), whereby we get:

$$(\Sigma B) - (\Sigma A) = (BOH) - (HA) + (OH^-) - (H^+). \qquad (26)$$

Substituting the values of (BOH) and (HA) given by equations (19) and (20), we get:

$$(\Sigma B) - (\Sigma A) = \frac{(B^+)(OH^-)}{K_B} - \frac{(H^+)(A^-)}{K_A} + (OH^-) - (H^+).$$

Replacing in this equation (H^+) by k and (OH^-) by K_w/k, and putting $(B^+) = (A^-)$, which as stated above is justifiable so long as the difference between them is not involved, we get:

$$\frac{\Sigma B - \Sigma A}{(B^+) \text{ or } (A^-)} = \frac{K_w}{kK_B} - \frac{k}{K_A} + \frac{K_w}{k(B^+)} - \frac{k}{(A^-)}. \qquad (27)$$

For the quantity (B^+) or (A^-) in equation (27) expressions in terms of (ΣB) or (ΣA) may be obtained from equations (22) and (23) by substituting for (BOH) and (HA) the same values that were introduced into equation (26) and by substituting for $(BA)/(B^+)$ the quantity $(1 - \gamma)/\gamma$, where γ evidently represents the ionization of the salt BA in the titrated solution. The so-obtained expressions for (B^+) and for (A^-) are:

$$(B^+) = \frac{(\Sigma B)}{\frac{1}{\gamma} + \frac{K_W}{kK_B}} \quad (28); \qquad \text{and } (A^-) = \frac{(\Sigma A)}{\frac{1}{\gamma} + \frac{k}{K_A}}. \quad (29)$$

By introducing these values into equation (27), an exact expression applicable to any combination of base and acid can be obtained.

The practically important cases are, however, those in which either the base or the acid is largely ionized, since such a base or acid is almost invariably employed as a standard solution in the titration. It is therefore worthy of note that in the expression for (B^+) the last term in the denominator, which is equal to the concentration ratio $(BOH)/(B^+)$, is negligible in comparison with the first term when K_B is even moderately large; and that in the expression for (A^-) the last term in the denominator, which is equal to the concentration-ratio $(HA)/(A^-)$, is negligible when K_A is even moderately large.[1] Taking into account these facts, we may write equation (27) in the following substantially exact form, applicable according as (ΣB) or (ΣA) is written in the denominator to the case where the base or the acid is largely ionized:

$$\frac{(\Sigma B) - (\Sigma A)}{(\Sigma B) \text{ or } (\Sigma A)} = \gamma\left(\frac{K_W}{kK_B} - \frac{k}{K_A} + \frac{K_W}{k\gamma(\Sigma B)} - \frac{k}{\gamma(\Sigma A)}\right). \quad (30)$$

This equation also gives approximate results, which are, however, sufficiently accurate for almost all purposes, when applied to the case in which the base and acid are both slightly ionized; for the error in this case is only that arising from neglecting the last term in the denominator of (28) or (29), and this will not give rise to an error in the first member of (30) of more than 1 or 2 per cent. for any combination for which even a very rough titration is possible. Equation (30) will therefore serve as a general basis for the following discussion of the accuracy of the titration and of the conditions determining it.

It will be noted that the first member, which expresses the difference between the concentrations of the basic and acid radicals divided by the concentration of the one or other of these, really represents the fractional error (FE) in the titration in the common case in which the acid and base titrated against each other are the only source of those radicals. That error can therefore be calculated for any combination of indicator, acid, and base by equation (30) or still better by the following, more perspicuous equation,[2] which is obtained from it by a simple transformation and by the substitution of C, representing the normal concentration of the salt in the titrated solution, for (ΣB) and for (ΣA), which are obviously approximately equal to it and to each other so long as FE is even moderately small.

---

[1] Thus, if K_W/k in (28) or k in (29) has a value even as large as 10^{-4}, the last term will be entirely negligible when K_B or $K_A > 10^{-2}$. For the strongest bases like potassium hydroxide or the strongest acids like hydrochloric or nitric acid, the value of K_B or K_A at 0.1 normal is about 1, while for barium hydroxide it is about 0.3 and for the second hydrogen of sulphuric acid about 0.03.

[2] Consider, for example, the case where 0.1 normal ammonium hydroxide is titrated at 25° with 0.1 normal hydrochloric acid, using phenolphthalein as an indica-

$$\overline{\text{FE}} = \frac{\gamma K_w}{k K_B}(1 + K_B/\gamma C) - \frac{\gamma k}{K_A}(1 + K_A/\gamma C). \qquad (31)$$

Of the quantities occurring in this equation it is to be noted that the ionization γ has nearly the same value at the same concentration for all salts of monobasic acids and monacidic bases, the average value for uniunivalent salts at various concentrations at 20° being approximately as follows:

Normal concentration.	0.50	0.20	0.10	0.05	0.02	0.01
Ionization (γ).	0.70	0.78	0.83	0.86	0.91	0.93

If the intermediate value 0.80 be employed, the result will be sufficiently accurate in almost all cases.

It may also be mentioned that all of the most completely ionized monacidic bases and monobasic acids (such as sodium and potassium hydroxides and hydrochloric and nitric acids) have an ionization at room temperature in 0.1 normal solution which corresponds to a ionization-constant of about unity.[1] The corresponding values of the parentheses $(1 + K_B/\gamma C)$ or $(1 + K_A/\gamma C)$ when K_B or $K_A = 1$ are 24 for $C = 0.05$, and 4.0 for $C = 0.5$. These are evidently the maximum values for these parentheses, since their values approach unity as K_B or K_A decreases.

9. *Error in the Titration when a Neutral Salt is Originally Present.*—Equation (30) is also applicable to the not uncommon case in which there

---

tor (for which $K_I = 2 \times 10^{-10}$), the indicator being at the end-point 10 per cent. transformed. In this case:

$$k = \frac{K_I(1 - \alpha)}{\alpha} = \frac{2 \times 10^{-10} \times 0.90}{0.10} = 2 \times 10^{-9};\ \gamma = 0.86;\ C = 0.05;\ K_A = 1;$$

and $K_B = 1.8 \times 10^{-5}$.

Substituting the appropriate numerical values in equation (31) we get:

$$\overline{\text{FE}} = \frac{0.86 \times 10^{-14} \times 1}{(2 \times 10^{-9})(1.8 \times 10^{-5})} - \frac{0.86(2 \times 10^{-9})(1 + 1/0.043)}{1.0} = 0.24 = 24\%.$$

That is to say, an error of 24 per cent. will be made in the titration.

Suppose now that the same titration be made, using p-nitrophenol as indicator (for which $K_I = 9 \times 10^{-8}$), and causing it to be one per cent. transformed. Equation (31) then becomes:

$$\overline{\text{FE}} = \frac{0.86 \times 10^{-14} \times 1}{(9 \times 10^{-6})(1.8 \times 10^{-5})} - \frac{0.86(9 \times 10^{-6})(1 + 1/0.043)}{1.0} = 0.0005 = 0.05\%.$$

[1] The constant unity corresponds to an ionization-value 0.916 at 0.1 normal, while the ionization values at 18° derived from the conductivity measurements made in this laboratory are 0.926 for HCl, 0.918 for HNO_3, 0.902 for NaOH. Even if, as suggested by Noyes and Kato (THIS JOURNAL, 30, 334 (1908)), the ionization of these acids is as small as that of potassium chloride (86.0 per cent. at 0.1 normal), the ionization-constant would be of the same general magnitude; namely, 0.53 instead of 1.0.

is present in the original solution, together with the acid HA or base BOH which is to be titrated, some of the neutral salt BA. This is true since this equation expresses the equilibrium conditions prevailing in the solution in which the end-point has been reached, and since it evidently makes no difference whether all of the salt was produced by the titration or whether some of it was originally present. It is evident, however, that in the latter case equation (30) does not express the fractional error in the titration of the free acid or base, since the difference between the concentrations of the basic and acid constituents must then be referred, not to the total concentration (ΣB) or (ΣA) of either of them, which is substantially equal to the concentration C of the salt in the titrated solution, but to the concentration $C - C_0$ which has been produced in that solution through the addition of the standard base or acid (C_0 therefore corresponding to the quantity of salt originally present). We have therefore for the fractional error FE′ in the titration in this case:

$$\mathrm{FE}' = \frac{(\Sigma \mathrm{B}) - (\Sigma \mathrm{A})}{C - C_0} = \left(\frac{(\Sigma \mathrm{B}) \text{ or } (\Sigma \mathrm{A})}{C - C_0}\right)\left(\frac{(\Sigma \mathrm{B}) - (\Sigma \mathrm{A})}{(\Sigma \mathrm{B}) \text{ or } (\Sigma \mathrm{A})}\right),$$

$$\text{or } \mathrm{FE}' = \frac{C}{C - C_0}\,\mathrm{FE}, \qquad (32)$$

the value of the last parenthesis or of FE being that expressed by equation (30) or (31).

The fractional error in the case where a neutral salt of the acid and base involved in the titration is originally present is therefore greater in the proportion which the sum of the quantity of that salt and of the quantity of acid or base used in the titration bears to the latter quantity.

It can furthermore be shown, by formulating the condition equations as in section 7, that the fractional error in the titration can be correctly calculated by equation (32) also in the following cases:

(*a*) When a not largely ionized acid HA is titrated with a largely ionized base BOH, and a neutral salt B′A of another largely ionized base B′OH is originally present.

(*b*) When a not largely ionized base BOH is titrated with a largely ionized acid HA, and a neutral salt BA′ of another largely ionized acid HA′ is originally present.

10. *The Best Value of the Indicator-Function.*—Equation (31) may be employed to determine what the value of the indicator-function is which will give the best result in titrating an acid of known ionization-constant K_A with a base of known ionization-constant K_B, when the titrated solution has a given concentration C. To determine this, we need only place FE equal to zero and solve for k. We thus obtain the following expression, in which this "best value" of k is represented by k_0:

$$k_0 = \left(\frac{K_W(1 + K_B/\gamma C)}{K_B}\right)^{\frac{1}{2}} \left(\frac{K_A}{1 + K_A/\gamma C}\right)^{\frac{1}{2}} = \sqrt{\left(\frac{K_WK_A}{K_B}\right)\left(\frac{1 + K_B/\gamma C}{1 + K_A/\gamma C}\right)}. \qquad (33)$$

It is evident from equation (33) that the best value of the indicator-function is equal to the square-root of the ionization-constant of water when the ionization-constants of the base and acid are equal, and that it is smaller than this when the acid is slightly ionized and larger when the base is slightly ionized. The best value can, of course, be exactly calculated for any given case.[1]

11. *Limiting Values of the Indicator-Function.*—It is evident from equation (33) that for any combination of acid or base whatever there is a value of the indicator-function which would theoretically make possible an exact titration. Yet it is a well-known fact that, if either the acid or base has too small an ionization-constant, accurate results can not in practice be obtained. This arises from the impossibility of realizing in the titration a value of the indicator-function identical with the best value, and from the sensitiveness of the titration in certain cases to the deviation of the actual value k from the best value k_0. What the realization of the desired value of the indicator-function involves will be seen by considering the following expression for the ratio k_0/k, which may be obtained by combining equations (33) and (14):

$$\frac{k_0}{k} = \frac{(K_WK_A/K_B)^{\frac{1}{2}}}{K_I(1 - \alpha)/\alpha}\left(\frac{1 + K_B/\gamma C}{1 + K_A/\gamma C}\right)^{\frac{1}{2}}. \qquad (34)$$

In order to make this expression as nearly as possible equal to zero, one would in practice first select an indicator with such an ionization-constant K_I that k_0/k can become zero when a practicable fraction of the indicator is transformed, then would calculate by (34) just what the fraction transformed α should be to make k_0/k equal to unity, and finally would attempt to realize in the titration this fraction transformed by comparison with a standard color so prepared as to correspond to it (see Section 5). It will be seen that there are two errors involved in this process; first, the error in the calculation of α arising from the errors in the assumed values of the various ionization-constants, of which errors that in K_I is likely with our present knowledge to be the largest; and second, the error in the experimental determination of α arising from the failure to titrate to the depth or shade of color which corresponds to the proper fraction transformed. For these reasons the ratio k_0/k will inevitably vary from

---

[1] For example, suppose NH_4OH ($K_B = 1.8 \times 10^{-5}$) is to be titrated at 25° ($K_W = 10^{-14}$) with HCl ($K_A = 1$), the titrated solution of the salt being 0.05 normal ($C = 0.05$) and its ionization γ being 0.86. We then have:

$$k_0^2 = \frac{10^{-14} \times 1}{1.8 \times 10^{-5}} \times \frac{1}{24}; \text{ whence } k_0 = 4.8 \times 10^{-6}.$$

unity by a considerable amount; and it is therefore important to consider the conditions which determine the sensitiveness of the titration to this variation.

The practical problem may be concretely stated as follows: to determine how much the actual value of the indicator-function k may vary from the best value k_0 without causing a fractional error $\overline{FE}$ in the titration greater than the accuracy which is aimed at. To solve this problem we may multiply each of the terms of the second member of equation (31) by k_0/k_0, substitute in the denominator of the first and in the numerator of the second term the value of k_0 given by equation (33), and transform, whereby we get:

$$\overline{FE} = \gamma\left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{K_W}{K_A K_B}\right)^{\frac{1}{2}}\left(1 + \frac{K_B}{\gamma C}\right)^{\frac{1}{2}}\left(1 + \frac{K_A}{\gamma C}\right)^{\frac{1}{2}}. \quad (35)$$

It is obvious that in equation (35) the value of the first parenthesis, which is nearly identical with k_0/k or k/k_0 when this is greater than (say) 3, must evidently for a given value of $\overline{FE}$ be smaller, the larger the values of the other three parentheses. The last two of these do not, however, vary very greatly from unity; thus in the rather extreme case in which K_B or $K_A = 1$ and $C = 0.05$, one or other of these factors has the value 4.9. It is therefore the very variable second factor $(K_w/K_A K_B)^{1/2}$ that mainly determines how large the arithmetical value of k_0/k or k/k_0 may be without causing the fractional error in the titration to exceed any given value. It is evident now that this factor increases as the product $(K_A K_B)$ of the ionization-constants of the acid and base decreases, and assumes a considerable magnitude only when the value of this product approaches that of the ionization-constant of the water. The percentage error in the titration therefore increases under the same conditions.[1]

The maximum value, which k_0/k or k/k_0 may be allowed to assume when a definite fractional accuracy ρ is desired in the titration, may be calculated for various values of $K_w/K_A K_B$, by substituting, in equation (35) for $\overline{FE}$ the given value of ρ and for $K_B/\gamma C$ and $K_A/\gamma C$ in the last two factors, the values which they have in the titration under consideration.

---

[1] Compare, for example, the values of the percentage error ($100\ \overline{FE}$) given in the last column of the following table for various combinations of acids and bases. In the calculations of these quantities by (35) it is assumed that $K_W = 10^{-14}$ as it is at 25°, that $C = 0.05$, that $\gamma = 0.86$, and that k_0/k or $k/k_0 = 5$, which is about as small a value as can be realized in practice without taking unusual precautions.

Acid.	Base.	K_A.	K_B.	$(K_W/K_A K_B)^{\frac{1}{2}}$.	$100\ \overline{FE}$.
HCl	KOH	1	1	10^{-7}	0.001
$HC_2H_3O_2$	KOH	2×10^{-5}	1	2×10^{-5}	0.05
HCl	NH_4OH	1	2×10^{-5}	2×10^{-5}	0.05
HBO_2	KOH	7×10^{-10}	1	4×10^{-3}	9.0
$HC_2H_3O_2$	NH_4OH	2×10^{-5}	2×10^{-5}	5×10^{-3}	2.3

Such a calculation has been made under the assumption that $\rho = 0.1\ \%$ $= 0.001$, for the three following, practically limiting cases:

(1) K_B or $K_A = 1$ and $\gamma C = 0.86 \times 0.05 = 0.043$.

(2) K_B or $K_A = 1$ and $\gamma C = 0.70 \times 0.5 = 0.35$.

(3) $K_B/\gamma C$ and $K_A/\gamma C$ are negligible (less than 0.2).

The results of these calculations are given in the following table, the columns marked (1), (2), and (3) corresponding to the three cases just considered.[1]

TABLE I.—MAXIMUM VALUES OF THE RATIO BETWEEN THE ACTUAL AND BEST VALUES OF THE INDICATOR-FUNCTION FOR AN ACCURACY IN THE TITRATION OF 0.1 PER CENT.

$\frac{K_W}{K_AK_B}$	K_AK_B at 25°.	Maximum value of k_0/k or k/k_0. (1)	(2)	(3)	$\frac{K_W}{K_AK_B}$	K_AK_B at 25°.	Maximum value of k_0/k or k/k_0. (1)	(2)	(3)
10^{-12}	10^{-2}	214	720	..	10^{-7}	10^{-7}	1.44	2.7	4.2
10^{-11}	10^{-3}	74	230	..	10^{-6}	10^{-8}	1.13	1.43	1.8
10^{-10}	10^{-4}	24	73	..	10^{-5}	10^{-9}	1.04	1.12	1.22
10^{-9}	10^{-5}	7.6	23	40	10^{-4}	10^{-10}	1.011	1.04	1.06
10^{-8}	10^{-6}	2.7	7.4	13	10^{-3}	10^{-11}	1.004	1.01	1.02

These maximum values are valid for the case that the accuracy desired is 0.1 per cent. The table will hold true for an accuracy of about 1/3 per cent. if each value of K_w/K_AK_B be multiplied by 10, and it will hold true for an accuracy of 1 per cent. if each value of K_w/K_AK_B be multiplied by 100; and if correspondingly each value of K_AK_B at 25° be divided by 10 or 100.[2]

Attention may also be called to the fact that, since K_w increases rapidly with rising temperature, the maximum value of k_0/k or k/k_0 admissible when a given percentage accuracy is desired is for a given value of K_AK_B larger at lower than at higher temperatures. Thus the values of k_0/k or k/k_0 given in Table I correspond to values of K_AK_B one-tenth as large at 0° and ten times as large at 65° as the values of K_AK_B given in the same row in the table for 25° (since $K_w = 10^{-15}$ at 0° and $= 10^{-13}$ at 65°). Since K_A and K_B for weak acids and bases commonly change with the temperature in a direction opposite to that in which K_w changes (or, since when K_A and K_B change in the same direction they change in a smaller proportion than K_w), it is almost always true that greater accuracy will be secured with any combination of acid, base, and indicator that is sensitive to error by titrating at as low a temperature as possible.[3]

---

[1] In these three cases γ was taken as 0.86, 0.70, and 0.80, respectively.

[2] It will be shown later that this table is also applicable to titrations in which a diacidic base or dibasic acid is involved, provided K_W/K_AK_B be replaced by an appropriate function of the ionization-constants.

[3] Exceptions to this statement may occasionally arise from an entirely different cause—namely, from the fact that the equilibrium of the indicator acid or base with its salt is too slowly established at the lower temperature, owing to a very slow rate of transformation of the two isomeric forms of the indicator into each other.

Certain other practical conclusions that may be drawn from Table 1 and equation (35) may be pointed out. A comparison of columns (1) and (2) shows that the titration is more sensitive to variations in the value of k, the more dilute the solution. It is therefore desirable to titrate in as strong a solution as possible, whenever the conditions are such that an error is likely to arise.

It will also be seen from the table that, as the product K_AK_B decreases in value, greater care must be taken to approximate to the best value of the indicator-function by selecting a suitable indicator of known ionization-constant, using a measured quantity of it, and titrating to a standard color corresponding to the appropriate fraction transformed.

Another, more direct, method of treating the problem of determining the limits between which the indicator-function k may vary when a certain accuracy in the titration is desired is as follows. Representing the limits between which the fractional error permissible in the titration lies by ρ and $-\rho$, substituting $\pm\rho$ for FE in equation (31), and transforming, we get:

$$\frac{K_wK_A}{K_B}\left(\frac{1 + K_B/\gamma C}{1 + K_A/\gamma C}\right) = k^2 \pm \frac{\rho K_A}{\gamma(1 + K_A/\gamma C)}\,k.$$

Adding $\frac{\rho^2 K_A{}^2}{4\gamma^2(1 + K_A/\gamma C)^2}$ to both members to complete the square in the second member, taking the square-root of both members, and transforming, we get the following exact expression:

$$k\,{}^{(\mathrm{Max.})}_{(\mathrm{Min.})} = \frac{\rho K_A}{2\gamma(1 + K_A/\gamma C)} \times \left(\pm 1 + \sqrt{1 + \frac{4\gamma^2}{\rho^2}\,\frac{K_w}{K_AK_B}(1 + K_A/\gamma C)(1 + K_B/\gamma C)}\right). \quad (36)$$

The second term under the square-root sign is considerably smaller than unity in any case in which the titration is practicable. Thus it may be seen from column (1) of Table 1, when $\rho = 0.001$, $C = 0.05$, and K_A or $K_B = 1$, and k_0/k or $k/k_0 > 2.7$, that K_w/K_AK_B must be less than 10^{-8}; under these circumstances, however, the value of the second term in question is less than 0.72. In this case (where $K_w/K_AK_B < 10^{-8}$) it can readily be shown that expression (36) reduces to the following approximate, but sufficiently accurate forms:[1]

---

[1] This follows from the fact that $(1 + x)^{\frac{1}{2}}$ = approx. $(1 + {}^1/_2x)$, when x is small. The whole parenthesis in (36) then has a maximum value of $1 + 1 + \frac{1}{2}x$ = approx. 2, and a minimum value of approx. $-1 + 1 + \frac{1}{2}x$ = approx. $\frac{1}{2}x$, where x represents the second term under the square-root sign. Even in the limiting case where $x = 0.72$ the error in the maximum and minimum values of k when calculated by the approximate expressions (37) and (38) would be only 13 and 16 per cent. respectively.

$$k < \frac{\rho K_A}{\gamma(1 + K_A/\gamma C)}. \tag{37}$$

$$k > \frac{\gamma K_W(1 + K_B/\gamma C)}{\rho K_B}. \tag{38}$$

By means of these expressions the limits between which k must lie in order to give any desired accuracy ρ can evidently be calculated for any given values of K_W, K_A, K_B, and C.[1]

Expressions (37) and (38) show that the lower limit for k is determined by the ionization constant (K_B) of the base, and the upper limit by the ionization-constant (K_A) for the acid.

It is also worthy of note that, since the maximum value of K_B or K_A possessed by any base or acid is unity, since the concentration of the titrated solution can hardly in practice be made greater than 0.5 normal, and since an accuracy at least as great as 1/3 per cent. is almost always essential, the indicator-function k must at 25° under all circumstances have a value lying between the limits of 10^{-3} and 10^{-11}, and the ionization-constant of the indicator must have such a value as will make this possible.

In the important case in which K_A or K_B is even moderately small, say less than 0.1 C, the corresponding expression (37) or (38) remains sufficiently accurate for practical purposes, when written in the still simpler, easily remembered form:

$$k < \rho K_A; \text{ or } k > \frac{K_W}{\rho K_B}. \tag{39}$$

That is, in titrating any not largely ionized acid, the value of the indicator-function must be less than the product of the ionization-constant of the acid by the fractional error permissible in the titration; and in titrating any not largely ionized base, the value of the indicator-function must be greater than the ratio of the ionization-constant of water to the product of the ionization-constant of the base by the fractional error permissible in the titration.

12. *Limits beyond which the Titration is Impracticable.*—Considered from the converse point of view, equation (35) may be utilized to furnish an estimate of the minimum values below which the ionization-constants of the acid and base may not fall if the error in the titration is to be less than any assigned value ρ. For if we represent by β the smallest value

---

[1] As an example, consider first that acetic acid ($K_A = 1.8 \times 10^{-5}$) is to be titrated with potassium hydroxide ($K_B = 1$) at 25° ($K_W = 10^{-14}$) with an accuracy of 0.1 per cent. ($\rho = 0.001$), the resulting salt solution being 0.05 normal ($C = 0.05$ and $\gamma = 0.86$). By substituting these values in (37) and (38) we get:

$$k < 2.1 \times 10^{-8}, \text{ and } k > 2.1 \times 10^{-10}.$$

Consider secondly that ammonium hydroxide ($K_B = 1.8 \times 10^{-5}$) is to be titrated with hydrochloric acid ($K_A = 1$) under the same conditions. We then find:

$$k < 4.8 \times 10^{-5}, \text{ and } k > 4.8 \times 10^{-7}.$$

of $(k_0/k - k/k_0)$ that one can hope to realize in practice, even when reasonable care is taken in choosing a suitable indicator and in securing the proper fraction transformed, equation (35) may be replaced by the following expression:

$$\frac{K_w}{K_A K_B}\gamma^2(1 + K_A/\gamma C)(1 + K_B/\gamma C) < \frac{\rho^2}{\beta^2}. \qquad (40)$$

Since one can hardly count on making k_0/k or k/k_0 less than 3.5,[1] and since in this case $\beta^2 = 10$, we may conclude that the first member of the preceding inequality must always be less than $^1/_{10}\,\rho^2$; that is, less than 10^{-7} for $\rho = {}^1/_{10}$ per cent., less than 10^{-6} for $\rho = {}^1/_3$ per cent., and less than 10^{-5} for $\rho = 1$ per cent. If, furthermore, either the acid or base is nearly completely ionized (K_A or $K_B = 1$) and the concentration C of the titrated solution is not greatly different from 0.1 normal, we may assign the medium value 10 to the product of the last three factors in the first member of (40), and write the inequality in the simple form:

$$\frac{K_w}{K_A K_B} < \frac{1}{100}\rho^2.$$

From this it follows that at 25°, where $K_w = 10^{-14}$, the product $K_A K_B$ must not have a smaller value than 10^{-6}, 10^{-7}, or 10^{-8} if an accuracy of $^1/_{10}$, $^1/_3$, or 1 per cent., respectively, is to be secured. These values therefore represent the practical limits below which the ionization-constant (K_A or K_B) of an acid or base may not fall if it is to be titrated at 25° with the stated accuracy, even with one of the most largely ionized bases or acids, such as sodium hydroxide or hydrochloric acid (for which K_B or K_A = approx. 1).

III. Titration of Two Monobasic Acids or of Two Monacidic Bases in the Presence of Each Other.

13. *Separate Titration of the More Ionized Acid.*—A special case that occurs not infrequently in practice is the titration of an acid HA in the presence of another, much less ionized acid HA′, or of a base BOH in the presence of another, much less ionized base B′OH. It is therefore of interest to determine the conditions under which such a titration can be

---

[1] That this is a reasonable estimate will be seen from the following considerations. It has already been pointed out in discussing equation (34) that the deviation of k_0/k or k/k_0 from unity is likely to arise mainly from the error in the value of K_I assumed in the calculation of the best value of α, and from the error in the experimental realization of the so-calculated value of α. Now there are probably few indicators for which we know the ionization-constant more closely than within one-half or twice its true value; and without taking unusual care in the titration to match the color of the indicator with a standard we can hardly realize any desired value of $(1 - \alpha)/\alpha$ nearer than within one-half or twice that value: and from the combination of these two errors a value of k_0/k or k/k_0 as large as 3.5 is not unlikely to arise. This becomes even more probable when the error likely to be involved in the ionization-constants of very weak bases or acids is also considered.

made without incurring a fractional error greater than any assigned value, especially for the case where a nearly completely ionized base BOH or acid HA is employed as the standard solution.

A general expression for the fractional error analogous to (31) can be readily derived for the case of the two acids in an entirely similar manner, as follows.

It will be noted that the following condition equations corresponding to (22), (23) and (24) hold true in this case:

$$(\Sigma B) = (B^+) + (BOH) + (BA) + (BA'). \qquad (41)$$

$$(\Sigma A) = (A^-) + (HA) + (BA). \qquad (42)$$

$$(B^+) + (H^+) = (A^-) + (A'^-) + (OH^-). \qquad (43)$$

Combining these equations, we get:

$$(\Sigma B) - (\Sigma A) = (BOH) - (HA) + (A'^-) + (BA') + (OH^-) - (H^+). \quad (44)$$

In this case we have to consider also the additional equilibrium equation:

$$(H^+)\,(A'^-) = K_{A'}(HA'). \qquad (45)$$

Since we may without serious error put (HA′) = (ΣA′) or = C' when only an inconsiderable proportion of the acid HA′ is converted into its salt, (45) may be written also in the form:

$$(A'^-) = C'K_{A'}/k. \qquad (46)$$

Dividing both members of (44) by (ΣB), substituting $(A'^-)/\gamma$ for $(A'^-) + (BA')$, eliminating (A'^-) by means of (46), writing C for (ΣB) and (ΣA), expressing the other quantities as before in terms of the appropriate constants, and transforming, we get:

$$\overline{FE} = \frac{(\Sigma B) - (\Sigma A)}{(\Sigma B)} = \frac{\gamma K_w(1 + K_B/\gamma C)}{kK_B} + \frac{C'K_{A'}}{\gamma Ck} - \frac{\gamma k(1 + K_A/\gamma C)}{K_A}. \qquad (47)$$

It will be seen that this equation differs from (31) only in the respect that it contains the additional term $+ C'K_{A'}/\gamma Ck$. (In this term C'/C is equal to the ratio of the quantities of two acids HA′ and HA originally present, and $K_{A'}$ is the ionization-constant of the acid HA′.)

Exact expressions for the best value and the limiting values of the indicator-function can therefore be written down simply by replacing in expressions (33) to (40) the quantity

$$\frac{\gamma K_w(1 + K_B/\gamma C)}{K_B} \text{ by } \frac{C'K_{A'}}{\gamma C} + \frac{\gamma K_w(1 + K_B/\gamma C)}{K_B}.$$

Instead of reproducing these somewhat complex exact expressions here, the simpler approximate expressions may be considered that are applicable: first, to the case where the first term in the last expression is smaller than one-tenth of the second term; and second, to the case where the first term is larger than the second term; so that the smaller of these two terms may be neglected without serious error.

In the first case, where

$$\frac{C'K_{A'}}{C} < \frac{\gamma^2 K_w(1 + K_B/\gamma C)}{10K_B}, \text{ or } < 10^{-14} \text{ at } 25° \text{ when } K_B = 1 \text{ and } C = 0.1,$$

the presence of the acid HA′ evidently has only a relatively small effect on the result of the titration, and no large error will be made by neglecting the term containing $K_{A'}$ and by employing equations (33) to (39), for computing the best value and the limiting values of the indicator-function. This merely signifies that at 25° the presence of an acid whose ionization-constant is less than about 10^{-14} can be disregarded (unless its concentration C' is much larger than that C of the acid to be titrated.)

In the second case, where

$$\frac{C'K_{A'}}{C} > \frac{10\gamma^2 K_w(1 + K_B/\gamma C)}{K_B}, \text{ or } > 10^{-12} \text{ at } 25° \text{ when } K_B = 1 \text{ and } C = 0.1,$$

a large error will not be made by neglecting in (47) the term containing K_w and K_B in comparison with that containing $K_{A'}$. When this is done equation (47) becomes:

$$\text{FE} = \frac{C'K_{A'}}{\gamma Ck} - \frac{\gamma k(1 + K_A/\gamma C)}{K_A}. \qquad (48)$$

Putting FE = 0 and solving for k, we get for the best value of the indicator-function:

$$k_0 = \frac{1}{\gamma}\left(\frac{C'K_{A'}K_A}{C(1 + K_A/\gamma C)}\right)^{\frac{1}{2}}. \qquad (49)$$

The expressions for the limiting values of k which will give a fractional error not greater than ρ are found, for any case in which the titration is practicable, to be as follows:

$$k < \frac{\rho K_A}{\gamma(1 + K_A/\gamma C)} \quad (50); \qquad \text{and } k > \frac{C'K_{A'}}{\rho\gamma C}. \qquad (51)$$

The following expression for FE in terms of k_0/k is also readily obtained from (48) and (49):

$$\text{FE} = \left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{C'K_{A'}}{CK_A}\right)^{\frac{1}{2}}\left(1 + \frac{K_A}{\gamma C}\right)^{\frac{1}{2}}. \qquad (52)$$

From this equation, if we represent by ρ the fractional error permissible in the titration and by β the smallest value of $(k_0/k) - (k/k_0)$ that one can hope to realize, we may obtain by substitution the following expression showing the limiting condition at which the titration ceases to be practicable:

$$\frac{C'K_{A'}}{CK_A}(1 + K_A/\gamma C) < \frac{\rho^2}{\beta^2}. \qquad (53)$$

Assuming $\beta = 3.5$ it follows from this expression for the case that $K_A = 1$

and C = about 0.1 that $C'K_{A'}/CK$ must be less than 10^{-8}, 10^{-7}, and 10^{-6} for accuracies in the titration of $^1/_{10}$, $^1/_3$, and 1 per cent., respectively; and for the case that $K_A < {}^1/_{10}C$ (when the parenthesis becomes substantially equal to unity), that $C'K_{A'}/CK_A$ must be less than 10^{-7}, 10^{-6}, and 10^{-5} for accuracies of $^1/_{10}$, $^1/_3$, and 1 per cent., respectively.

If the two acids were originally present in equivalent quantities ($C = C'$), these same statements are approximately true of the ratio $K_{A'}/K_A$.[1]

14. *Separate Titration of the More Ionized Base.*—The corresponding case involving the titration of a base BOH of ionization-constant K_B and concentration C in the presence of another much less ionized base B'OH of ionization-constant $K_{B'}$ and concentration C' with a nearly completely ionized acid HA can be similarly treated. The resulting expression for the fractional error corresponding to (47) is

$$FE = \frac{\gamma K_W(1 + K_B/\gamma C)}{kK_B} - \frac{\gamma k(1 + K_A/\gamma C)}{K_A} - \frac{kC'K_{B'}}{\gamma CK_W}. \qquad (54)$$

In the case where

$$\frac{C'K_{B'}}{C} < \frac{\gamma^2 K_W(1 + K_A/\gamma C)}{10K_A} \text{ or } < 10^{-14} \text{ at } 25^\circ \text{ when } K_A = 1 \text{ and } C = 0.1,$$

the influence of the base B'OH on the titration can without serious error be disregarded.

In the case where

$$\frac{C'K_{B'}}{C} > \frac{10\gamma^2 K_W(1 + K_A/\gamma C)}{K_A}, \text{ or } < 10^{-12} \text{ at } 25^\circ \text{ when } K_A = 1 \text{ and } C = 0.1,$$

the middle term in the second member of equation (54) is relatively small, and that equation assumes the approximate form:

$$FE = \frac{\gamma K_W(1 + K_B/\gamma C)}{kK_B} - \frac{kC'K_{B'}}{\gamma CK_W}. \qquad (55)$$

The best values and limiting values corresponding to this case are:

$$k_0 = \gamma K_W\left(\frac{C(1 + K_B/\gamma C)}{C'K_{B'}K_B}\right)^{\frac{1}{2}}. \qquad (56)$$

$$k < \frac{\rho\gamma CK_W}{C'K_{B'}} \quad (57); \qquad \text{and } k > \frac{\gamma K_W(1 + K_B/\gamma C)}{\rho K_B} \qquad (58)$$

It can also be readily shown that, as in the case of the two acids, the titration will be practicable with accuracies of $^1/_{10}$, $^1/_3$, and 1 per cent.

---

[1] Thus the ionization-constant for the first hydrogen of carbonic acid, according to Walker and Cormack, is 3 × 10^{-7}. Hence only the most completely ionized acids for which $K_A = 1$, such as HCl and HNO_3, can be titrated at 25° in the presence of an equal number of mols of H_2CO_3, and these only with an accuracy of about $^1/_2$ per cent., even where care is taken to secure a value of k not greater than about 3.5 k_0 and not less than about $^1/_{2.5}$ k_0. The best value k_0 for this case is calculated by equation (49) to be 2.1 × 10^{-4} (for $C = C'$ = about 0.1).

only when $C'K_{B'}/CK_B$ is less than 10^{-8}, 10^{-7}, and 10^{-6} when $K_B = 1$, and less than 10^{-7}, 10^{-6}, and 10^{-5} when $K_B < {}^1/_{10}\gamma C$.

15. *Titration of the Less Ionized Acid or Base.*—It is evident, in the titration of a mixture of two acids HA and HA′ with a largely ionized base, or of two bases BOH and B′OH with a largely ionized acid, that the more ionized acid HA or base BOH will first be converted into its salt, after which the titration of the less ionized acid HA′ or base B′OH will take place substantially as if it had been alone present.[1] The error in its titration, the conditions under which it is practicable, and the best value and limiting values of the indicator-function will therefore be determined by the considerations presented in Part II. Thus in accordance with expressions (39) it is necessary for the titration of HA′ that $k < \rho K_{A'}$, and for the titration of B′OH that $k > \dfrac{K_W}{\rho K_{B'}}$; and in accordance with equation (40) and the discussion following it, it is practically necessary that at 25° at 0.1 normal $K_{A'}$ or $K_{B'}$ be not smaller than 10^{-6}, 10^{-7}, and 10^{-8} for accuracies of $^1/_{10}$, $^1/_3$, and 1 per cent.

It is to be noted that an indicator-function which will give accuracy in the titration of HA′ or B′OH will also be suitable for the titration of the more ionized acid HA or base BOH; and that therefore the sum of the quantities of the two acids or bases can be accurately determined provided the conditions are such that the quantity of the less ionized acid or base can be so determined.

In order that, with the aid of two indicators, the quantity of each of the two acids or each of the two bases may be separately determined with any given accuracy, their ionization-constants must be sufficiently different to satisfy the requirement stated at the end of Sections 13 and 14; and yet, as just stated, the ionization-constant $K_{A'}$ or $K_{B'}$ of the less ionized acid or base must be large enough to satisfy equation (40), namely, at 25° and 0.1 normal it must be as large as 10^{-6}, 10^{-7} and 10^{-8} for accuracies of $^1/_{10}$, $^1/_3$ and 1 per cent. It follows from these two requirements that at 25° when $C = C' = 0.1$ normal, for an accuracy of $^1/_3$ per cent. (the greatest attainable under any conditions), the ionization-constant K_A or K_B of the more ionized acid or base must be as large as unity, and that $K_{A'}$ or $K_{B'}$ of the less ionized acid or base must be in the neighborhood of 10^{-7}; also that for an accuracy of 1 per cent., K_A or K_B may lie between 1 and 10^{-3} and $K_{A'}$ or $K_{B'}$ between 10^{-6} and 10^{-8} provided the ratio between them is as large as 10^5.

IV. Titration of Dibasic Acids with Monacidic Bases.

16. *General Formulation of the Theory.*—Thus far only monobasic acids and monacidic bases have been discussed. The case may now be

---

[1] The neutral salt BA present will not affect the result materially, since it is a salt of the acid HA and not of HA′, or of the base BOH and not of B′OH.

considered in which the acid has two replaceable hydrogens, as indicated by the symbol H_2A. In this case, the condition equations, corresponding to (22), (23), and (24) evidently are:[1]

$$(\Sigma B) = (B^+) + (BOH) + (BHA) + 2(B_2A). \qquad (59)$$

$$(\Sigma A) = (A^=) + (HA^-) + (H_2A) + (BHA) + (B_2A). \qquad (60)$$

$$(B^+) + (H^+) = (HA^-) + 2(A^=) + (OH^-). \qquad (61)$$

17. *Error in the Titration of the First Hydrogen.*—To derive an expression for the titration of the first hydrogen, we may first subtract (60) from (59) and substitute in the result for (B^+) its value given by (61), whereby we get:

$$(\Sigma B)-(\Sigma A) = (BOH) + (A^=) + (B_2A) - (H_2A) + (OH^-) - (H^+). \qquad (62)$$

It is now to be noted that, when (ΣB) is equal or nearly equal to (ΣA), as it is in even a rough titration of the first hydrogen, this equation represents the condition in which the acid H_2A has been nearly completely converted into its acid salt BHA. It is therefore true that $(A^=)$ is a relatively small quantity. We may therefore, when the difference between them is not involved, place $(B^+) = (HA^-)$, thus neglecting in this case the quantities $2(A^=) + (OH^-) - (H^+)$ in equation (61). We may therefore divide all the terms of equation (62) either by (HA^-) or by its substantial equivalent (B^+), whereby we get:

$$\frac{(\Sigma B)-(\Sigma A)}{(B^+)} = \frac{(BOH)}{(B^+)} + \frac{(A^=)+(B_2A)}{(HA^-)} - \frac{(H_2A)}{(HA^-)} + \frac{(OH^-)}{(B^+)} - \frac{(H^+)}{(HA^-)}. \qquad (63)$$

Other expressions for the ratios in the second member may be obtained from the following equations:

$$\frac{(B^+)(OH^-)}{(BOH)} = K_B \quad (64); \qquad \frac{(H^+)(HA^-)}{(H_2A)} = K_{A_1} \quad (65);$$

$$\frac{(H^+)(A^=)}{(HA^-)} = K_{A_2} \quad (66); \qquad (H^+)(OH^-) = K_w \quad (67);$$

$$(H^+) = k \quad (68); \text{ and } \quad (A^=) + (B_2A) = (A^=)/\gamma_2 \quad (69);$$

where k is the indicator-function defined as before by equation (14), and γ_2 is the ionization of the salt B_2A of the unibivalent type.[2]

---

[1] The assumption is here made that the concentration of the intermediate ion BA^- is negligible. There is as yet no evidence that such ions exist in appreciable quantity in the case of salts, at any rate up to moderate concentrations.

[2] Unibivalent salts differ from one another in ionization more than uniunivalent ones. The following average values are, however, sufficiently accurate for the purposes here under discussion:

Normal concentration.............	0.50	0.20	0.10	0.05	0.02	0.01
Ionization γ_2....................	0.50	0 64	0.72	0.76	0.85	0.88

Making obvious substitutions, writing $\gamma_1 C$ for (B^+) and (HA^-), multiplying both members by γ_1, and uniting the first and fourth and the third and fifth terms, equation (63) becomes:

$$\overline{FE} = \frac{(\Sigma B) - (\Sigma A)}{(\Sigma B)} = \frac{\gamma_1 K_w(1 + K_B/\gamma_1 C)}{kK_B} + \frac{\gamma_1 K_{A_2}}{\gamma_2 k} - \frac{\gamma_1 k(1 + K_{A_1}/\gamma_1 C)}{K_{A_1}}. \quad (70)$$

18. *Best Value and Limiting Values of the Indicator-Function for Titration of the First Hydrogen.*—It will be noticed that equation (70) differs from equation (31) only in the respect that it contains the additional term $(+\gamma_1 K_{A_2}/\gamma_2 k)$. By considering this term associated with the positive term preceding it, which also contains k in the denominator, and which therefore can be treated like it in deriving expressions for k, we may write down at once relations corresponding to (33) to (40). More specifically stated, this may be done by substituting in those equations for the quantity

$$\frac{K_w(1 + K_B/\gamma_1 C)}{K_B}, \text{ the quantity } \frac{K_w(1 + K_B/\gamma_1 C)}{K_B} + \frac{K_{A_2}}{\gamma_2}$$

It is therefore not necessary to write out these exact general expressions. We will, however, consider the two following cases: (1) that in which the second term in the last quantity is much smaller, and (2) that in which it is much larger than the first term; so that a serious error will not be made by neglecting the smaller of the two terms. It may be assumed that the error will be negligible when one term is as small as one-tenth of the other.

In the case where

$K_{A_2} < \frac{1}{10}\gamma_2(K_w/K_B)(1+K_B/\gamma_1 C)$, or $< 10^{-14}$ at 25° when $K_B = 1$ and $C = 0.1$, the acid may be treated as a monobasic acid, the ionization of its second hydrogen being disregarded.

In the case where

$K_{A_2} > 10\gamma_2(K_w/K_B)(1+K_B/\gamma_1 C)$ or $> 10^{-12}$ at 25° when $K_B = 1$ and $C = 0.1$, the approximate, but sufficiently accurate expressions for the best value and limiting values of the indicator-function corresponding to (33), (37), and (38) are as follows:

$$k_0 = \left(\frac{K_{A_1}K_{A_2}}{\gamma_2(1 + K_{A_1}/\gamma_1 C)}\right)^{\frac{1}{2}}. \quad (71)$$

$$k < \frac{\rho K_{A_1}}{\gamma_1(1 + K_{A_1}/\gamma_1 C)} \quad (72); \quad \text{and } k > \frac{\gamma_1 K_{A_2}}{\gamma_2 \rho}. \quad (73)$$

In the case, usual with dibasic acids, in which the first hydrogen is only moderately dissociated (thus where $K_{A_1} < {}^1/_{10}\, C$), equation (71) is substantially accurate in the still simpler form:

$$k_0 = \sqrt{K_{A_1}K_{A_2}}. \qquad (74)$$

It is evident therefore that, provided the second hydrogen is appreciably dissociated, it is the product $K_{A_1}K_{A_2}$ which mainly (equation (71)) or wholly (equation (74)) determines the best value of the indicator-function for the titration of the first hydrogen.[1]

In this case (where $K_{A_1} < {}^1/_{10}\,C$) the expressions for the limiting values permissible assume the following approximate, but sufficiently accurate forms:

$$k < \frac{\rho K_{A_1}}{\gamma_1}, \text{ and } k > \frac{\gamma_1 K_{A_2}}{\gamma_2 \rho}. \qquad (75)$$

Thus the smallest value which k may have is determined by the ionization-constant for the second hydrogen, and the largest value by that for the first hydrogen.

In analogy with equation (35), the expression for the fractional error in the titration of the first hydrogen of a dibasic acid may be written in the following form in the case where $K_{A_2} > 10(K_w/K_B)(1 + K_B/\gamma_1 C)$:

$$\overline{\text{FE}} = \gamma_1 \left(\frac{k_0}{k} - \frac{k}{k_0}\right) \left(\frac{K_{A_2}}{\gamma_2 K_{A_1}}\right)^{\frac{1}{2}} (1 + K_{A_1}/\gamma_1 C)^{\frac{1}{2}}. \qquad (76)$$

It is therefore in this case the quantity K_{A_2}/K_{A_1} (instead of $K_w/K_A K_B$) that mainly determines how large the value of k_0/k or k/k_0 may be without causing the fractional error in the titration to exceed any assigned value. Therefore column (3) of Table I in Section 11 will show the maximum values of k_0/k or k/k_0 permissible, if an accuracy of 0.1 per cent. is to be secured in the titration of the first hydrogen of a dibasic acid (for which $K_{A_1} < {}^1/_{10}\,C$ and $K_{A_2} > 10^2 K_w$) with a nearly completely ionized base, if it be understood that the figures in the columns headed $K_w/K_A K_B$ are in this case the values of K_{A_2}/K_{A_1}.

In analogy with expression (40), we may derive from (76) the following expression showing the condition that must be fulfilled in order that the titration may be practicable with any given accuracy ρ:

$$\frac{K_{A_2}}{K_{A_1}} \left(\frac{\gamma_1^2}{\gamma_2}\right) (1 + K_{A_1}/\gamma_1 C) < \frac{\rho^2}{\beta^2} \qquad (77)$$

Assuming as before that β_2 can hardly be made smaller than 10 and that

---

[1] Thus in the case of carbonic acid, for which the ionization-constants for the two hydrogens are $K_{A_1} = 3 \times 10^{-7}$ and $K_{A_2} = 3 \times 10^{-11}$, the best value for the indicator-function is $k_0 = (3 \times 10^{-7} \times 3 \times 10^{-11})^{\frac{1}{2}} = 3 \times 10^{-9}$. In the case of phosphoric acid, for which according to Abbott and Bray (THIS JOURNAL, 31, 760 (1909)) $K_{A_1} = 10^{-2}$ and $K_{A_2} = 2 \times 10^{-7}$, one finds by equation (71) for $C = 0.05$ that

$$k_0 = \left(\frac{K_{A_1}K_{A_2}}{1 + 10^{-2}/(0.86 \times 0.05)}\right)^{\frac{1}{2}} = 0.90(K_{A_1}K_{A_2})^{\frac{1}{2}} = 4.0 \times 10^{-5}.$$

(In the case of tribasic acids, the ionization of the third hydrogen is so much smaller than that of the second hydrogen that it does not affect appreciably the conditions determining the titration of the first hydrogen.)

$K_{A_1} < {}^1/_{10}C$, it follows (since γ_1^2/γ_2 = approx. 1) that the titration can not be made with an accuracy as great as ρ unless $K_{A_2}/K_{A_1} < {}^1/_{10}\rho^2$. Therefore K_{A_2}/K_{A_1} must be less than 10^{-7}, 10^{-6}, and 10^{-5} for accuracies of ${}^1/_{10}$, ${}^1/_3$, and 1 per cent. respectively.[1]

19. *Error in the Titration of the Total Hydrogen.*—An expression applicable to the titration of the total hydrogen may be obtained in a similar way. Namely, by multiplying equation (60) through by 2, subtracting the result from equation (59), and substituting for (B^+) the value of it given by equation (61), we get:

$$(\Sigma B) - 2(\Sigma A) = (BOH) - (HA^-) - (BHA) - 2(H_2A) + (OH^-) - (H^+). \quad (78)$$

Taking into account the fact that in this case (HA^-) is small, so that (B^+) may be placed equal to $2(A^=)$ when the difference between them is not involved, dividing through by (B^+) or its substantial equivalent $2(A^=)$, and putting $(HA^-) + (BHA) = (HA^-)/\gamma_1$ we get:

$$\frac{(\Sigma B) - 2(\Sigma A)}{(B^+)} = \frac{(BOH)}{(B^+)} - \frac{(HA^-)}{2\gamma_1(A^=)} - \frac{(H_2A)}{(A^=)} + \frac{(OH^-)}{(B^+)} - \frac{(H^+)}{2(A^=)}. \quad (79)$$

Substituting for the ratios in the second member their values as given by equations (64) to (68) and for (B^+) or $2(A^=)$ the quantity $\gamma_2 C$ (where C therefore represents the *equivalent* concentration of the salt), and multiplying through by γ_2, the ionization of the unibivalent salt, we get:

$$\frac{(\Sigma B) - 2(\Sigma A)}{(\Sigma B) \text{ or } 2(\Sigma A)} = \gamma_2\left(\frac{K_w}{kK_B} - \frac{k}{2\gamma_1 K_{A_2}} - \frac{k^2}{K_{A_1}K_{A_2}} + \frac{K_w}{k\gamma_2 C} - \frac{k}{\gamma_2 C}\right). \quad (80)$$

This equation evidently expresses the fractional error in the titration of the total hydrogen in the ordinary case in which no salt of the acid or base is originally present in the solutions.

Since equation (80) is a cubic with respect to k, a rigorous discussion of the best value and of the limiting values of the indicator-function would be attended with mathematical difficulties. It is therefore of importance to note that the third term in the parenthesis is in practice entirely negligible in comparison with the second term, whenever even a very rough titration is possible. This is true since the ratio of the third to the second term is $2\gamma_1 k/K_{A_1}$, since it may be shown (by substituting $2\gamma K_{A_2}$ for K_A in (37)) that $k/2K_{A_2}$ must be less than the fractional error, and since for all dibasic acids K_{A_1} is much larger than K_{A_2}. (Considered from the standpoint of the chemical composition as expressed by equation (78), this signifies that $2(H_2A)$ is negligible in comparison with (HA^-) in a solution in which the acid has been almost wholly converted into the salt B_2A or its ions.) Neglecting the third term in the parenthesis and writing $\overline{FE}$ for the first member, equation (80) becomes:

---

[1] Therefore in the case of carbonic acid for which $K_{A_2} = 10^{-4}\,K_{A_1}$ the titration of the first hydrogen is not possible with even a moderate degree of accuracy. But in the case of phosphoric acid, for which $K_{A_2} = 2 \times 10^{-5}\,K_{A_1}$ the titration of the first hydrogen should be possible with an accuracy of not far from 1 per cent by taking care to secure a value of the indicator-function as nearly as possible equal to the best value. In the case of nearly all the organic dibasic acids, the ionization-constants for the first and second hydrogens do not differ from each other sufficiently to make a titration of the former at all possible.

$$\overline{FE} = \frac{\gamma_2 K_W}{kK_B}(1 + K_B/\gamma_2 C) - \frac{\gamma_2 k}{2\gamma_1 K_{A_2}}(1 + 2\gamma_1 K_{A_2}/\gamma_2 C). \quad (81)$$

This will be seen to be identical with equation (31) expressing the error in titrating a monobasic acid, except that it contains $2\gamma_1 K_{A_2}$ in place of K_A, and γ_2 in place of γ. It will also be noted that in the titration of a dibasic acid it is the constants for the base and for the second hydrogen which determine the error, that for the first hydrogen having dropped out.

20. *Best Value and Limiting Values of the Indicator-Function for Titration of the Total Hydrogen.*—In view of the close correspondence of equations (81) and (31) just referred to, all the conclusions drawn from the latter in regard to the best value and the limiting values of the indicator-function for the titration of monobasic acids can be made to apply directly to the titration of the total hydrogen of dibasic acids by substituting $2\gamma_1 K_{A_2}$ for K_A and γ_2 for γ, in expressions (33) to (40), in Table I, and in the discussions of those expressions and of that table. It is therefore unnecessary to consider in detail the conditions relating to the titration of the total hydrogen.

V. Titration of Diacidic Bases with Monobasic Acids.

21. *Error in the Titration of the First Hydroxyl.*—By a method entirely analogous to that just described for dibasic acids expressions may be obtained for the error in the titration of both the first and total hydroxyl of a diacidic base $B(OH)_2$ with a monobasic acid HA, the ionization-constants for the first and second hydroxyls being represented by K_{B_1} and K_{B_2} and defined by the equilibrium equations:

$$\frac{(BOH^+)(OH^-)}{B(OH)_2} = K_{B_1} \quad (82); \qquad \frac{(B^{++})(OH^-)}{(BOH^+)} = K_{B_2}. \quad (83)$$

The so-obtained expression for the first hydroxyl is:

$$FE = \frac{(\Sigma B) - (\Sigma A)}{(\Sigma B) \text{ or } (\Sigma A)} = \frac{\gamma_1 K_W(1 + K_{B_1}/\gamma_1 C)}{kK_{B_1}} - \frac{\gamma_1 k(1 + K_A/\gamma_1 C)}{K_A} - \frac{\gamma_1 k K_{B_2}}{\gamma_2 K_W} \quad (84)$$

22. *Best Value and Limiting Values of the Indicator-Function for Titration of the First Hydroxyl.*—It will be seen that equation (84) corresponds

closely with (70), and differs from (31) only in the respect that it contains the additional term ($-\gamma_1 k K_{B_2}/K_w\gamma_2$). By a treatment entirely analogous to that described in Section 18 expressions may be obtained for the best value and the limiting values of the indicator-function. The following are the forms applicable to the case where

$K_{B_2} \times 10(K_w/K_A)(1+K_A/\gamma_1 C)$ or $> 10^{-12}$ at 25° when $K_A = 1$ and $C = 0.1$:

$$k_0 = \left(\frac{\gamma_2 K_w^2}{K_{B_1}K_{B_2}}\right)^{\frac{1}{2}}(1 + K_{B_1}/\gamma_1 C)^{\frac{1}{2}} = \text{appr.} \frac{K_w}{\sqrt{K_{B_1}K_{B_2}}} \text{ when } K_{B_1} < \frac{1}{10}C. \quad (85)$$

$$k < \frac{\rho\gamma_2 K_w}{\gamma_1 K_{B_2}} \quad (86), \qquad \text{and } k > \frac{\gamma_1 K_w(1 + K_{B_1}/\gamma_1 C)}{\rho K_{B_1}} \quad (87)$$

$$\text{or } k > \frac{\gamma_1 K_w}{\rho K_{B_1}} \text{ when } K_{B_1} < \frac{1}{10}C. \quad (87a)$$

$$\overline{FE} = {}_1\left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{K_{B_2}}{\gamma_2 K_{B_1}}\right)^{\frac{1}{2}}(1 + K_{B_1}/\gamma_1 C)^{\frac{1}{2}}. \quad (88)$$

$$\frac{K_{B_2}\gamma_1^2}{K_{B_1}\gamma_2}(1 + K_{B_1}/\gamma_1 C) < \frac{\rho^2}{\beta^2}. \quad (89)$$

23. *Titration of the Total Hydroxyl.*—For the error in this titration the following expression analogous to equations (31) and (81) may be obtained by a similar method of procedure:

$$\overline{FE} = \frac{\gamma_2 K_w}{2k\gamma_1 K_{B_2}}(1 + 2\gamma_1 K_{B_2}/\gamma_2 C) \quad \frac{\gamma_2 k}{K_A}(1 + K_A/\gamma_2 C). \quad (90)$$

This will be seen to differ from equation (31) only in the respects that it contains $2\gamma_1 K_{B_2}$ in place of K_B, and γ_2 in place of γ. The conclusions drawn from that equation therefore all apply, after making these substitutions, to the titration of the total hydroxyl of a diacidic base.

VI. Summary.

24. *Summary.*—It seems desirable to sum up the conclusions reached in this article which are of most direct application to the problems of volumetric analysis.

The equilibrium relations of the two differently colored structural forms in which all indicators probably exist, and the equilibrium conditions under which such a pair of tautomeric substances can show sharply differentiated colors in acid and alkaline solution were first discussed (see Section 2). It was shown that, provided these conditions are fulfilled, the indicator can be treated in titrations as if it were a single acid or base having an ionization-constant which, though really a function of three equilibrium-constants, can be directly determined either from the color-changes exhibited by it in solutions of various hydrogen-ion concentration, or by any of the other methods commonly employed—for example, by measurement of the conductivity of the indicator acid or base or by a study of the hydrolysis of its salt.

The well-known principle of the theory of indicators was then formulated (in Section 3), according to which the proportion of the indicator acid converted into its salt, or of the indicator base liberated from its salt, is determined solely by its ionization-constant (K_{IA} or K_{IB}) and by the hydrogen-ion concentration (H^+) in the solution; and a series of lecture experiments illustrating this were described in Section 4. Defining the end-point of the titration as the condition where a definite proportion (α) of the indicator, as shown by the color, is so transformed, the equilibrium prevailing at the end-point is then expressed by the equations:

$(H^+) = K_{IA}(1 - \alpha)/\alpha\gamma = k$, for an acid indicator; or

$(H^+) = (K_w/K_{IB})(\gamma(1 - \alpha)/\alpha) = k$, for a basic indicator;

where $K_w = (H^+)(OH^-)$, and γ represents the ionization of the indicator salt, which may be assumed to be equal to that of other salts of the same type.

The symmetry in the equilibrium relations of acid and basic indicators and the impossibility of distinguishing them by their behavior in titrations was pointed out; and the term apparent ionization-constant (K_I) was introduced, this being defined for acid and basic indicators by the equations $K_I = K_{IA}/\gamma$ and $K_I = \gamma K_w/K_{IB}$, respectively, where γ represents the ionization of the indicator salt in any solution in which its color serves as a measure of its concentration We then have for either an acid or basic indicator: $(H^+) = K_I(1 - \alpha)/\alpha = k$.

Throughout the article the letter k is written in place of the lengthy expression preceding it in this equation; and it is designated the indicator-function. This fundamental quantity was fully discussed in Section 5, the fact being emphasized that it depends on two factors, the ionization-constant of the indicator and the fraction of it transformed at the end-point. The limits within which the fraction transformed can be varied in practice were considered, it being pointed out that the experimental determination of these limits for each indicator would supplement in an important way that of its ionization-constant In the absence of such experimental data, it was suggested as a reasonable estimate that in the case of sufficiently soluble one-color indicators, like *p*-nitrophenol, the fraction transformed might be varied from 0.1 to 25 per cent., corresponding to a variation of k from 1000 K_I to $3K_I$. When, however, the indicator has a limited solubility S, the largest value of k that can be secured is equal to $K_I(S - I)/I$, where I represents that concentration of the transformed part of the indicator which gives the depth of color suitable for the end-point. Attention was called to the facts that in the case of two-color indicators, like methyl orange, the range was much smaller, since the fraction transformed must have a considerable value in order that its color may not be entirely obscured by the color of the untransformed part of the indicator; and that, on the other hand, such indicators could sometimes be employed at both ends of their transformation, being in one case say 10 per cent. transformed in the direction from acid to alkaline and in the other case 10 per cent. transformed in the other direction, thus giving two values of k equal to about $10K_I$ and $^1/_{10}K_I$, respectively.

It was shown in Section 6 that, if the indicator itself is not to require for its neutralization an appreciable proportion of the base or acid used in the titration, its concentration (ΣIn) in the titrated solution must be less than $\rho C/\alpha$ for an acid indicator, or less than $\rho C/(1 - \alpha)$ for a basic indicator, where C represents the concentration of the salt, ρ the fractional error permissible in the titration, and α the fraction of the indicator transformed in the direction from acid to alkaline.

Through formulation of the equilibrium and condition equations involved and the combination of these, the following practically exact expression was derived in Sections 7 and 8 for the fractional error $\overline{\mathrm{FE}}$[1] incurred in the titration of any monobasic acid HA of ionization-constant K_A and of any monacidic base BOH of ionization-constant K_B when the indicator-function has any value k, the salt in the titrated solution having an equivalent concentration C and an ionization γ_1:

$$\overline{\mathrm{FE}} = \frac{\gamma K_w}{k K_B}(1 + K_B/\gamma_1 C) - \frac{\gamma k}{K_A}(1 + K_A/\gamma_1 C). \qquad (31)$$

It was shown in Section 9 that, when a neutral salt BA of the acid and base is originally present in the solution to be titrated, the fractional error in the titration is equal to that calculated by equation (31) multiplied by the ratio which the sum of the quantity of that salt and of the quantity of acid or base used in the titration bears to the latter quantity. This also holds true when a neutral salt (BA′ or B′A) is present which is a salt of a different acid or base (HA′ or B′OH) provided the latter is of the largely ionized type.

In later sections were derived expressions for the fractional error in the titration of combinations of other types of acids and bases, as follows:

For the total hydrogen of a dibasic acid H_2A with a monacidic base BOH, replace in (31) K_A by $2\gamma_1 K_{A_2}$ and γ_1 by γ_2. (81)

For the total hydroxyl of a diacidic base $B(OH)_2$ with a monobasic acid HA, replace in (31) K_B by $2\gamma_1 K_{B_2}$ and γ_1 by γ_2. (90)

For the first hydrogen of a dibasic acid H_2A with a monacidic base BOH:

$$\overline{\mathrm{FE}} = \frac{\gamma_1 K_w}{k K_B}(1 + K_B/\gamma_1 C) - \frac{\gamma_1 k}{K_{A_1}}(1 + K_{A_1}/\gamma_1 C) + \frac{\gamma_1 K_{A_2}}{\gamma_2 k}. \qquad (70)$$

---

[1] Meaning thereby the difference between the quantity of acid or base originally present and the quantity of standard base or acid added when the end-point has been reached, divided by either of these quantities. The percentage error is, of course, equal to 100 $\overline{\mathrm{FE}}$.

For the first hydroxyl of a diacidic base $B(OH)_2$ with a monobasic acid HA:

$$\overline{\overline{\mathrm{FE}}} = \frac{\gamma_1 K_w}{kK_{B_1}}(1 + K_{B_1}/\gamma_1 C) - \frac{\gamma_1 k}{K_A}(1 + K_A/\gamma_1 C) - \frac{\gamma_1 k K_{B_2}}{\gamma_2 K_w}. \quad (84)$$

In these expressions K_{A_1} and K_{A_2} represent the ionization-constants for the first and second hydrogens of the acid as defined by the equations $(H^+)(HA^-)/(H_2A) = K_{A_1}$ and $(H^+)(A^-)/(HA^-) = K_{A_2}$, K_{B_1} and K_{B_2}; represent the ionization-constants for the first and second hydroxyls of the base correspondingly defined; C represents the equivalent concentration of the salt in the titrated solution; and γ_1 and γ_2 represent the degrees of ionization in the titrated solution of the salts of the uni-univalent and unibivalent types. Average values of these degrees of ionization at various concentrations will be found in tables given in Sections 8 and 17.

For the titration of a more ionized acid HA in the presence of a less ionized acid HA′ with a monacidic base BOH:

$$\overline{\overline{\mathrm{FE}}} = \frac{\gamma_1 K_w}{kK_B}(1 + K_B/\gamma_1 C) \quad \frac{\gamma_1 k}{K_A}(1 + K_A/\gamma_1 C) + \frac{C' K_{A'}}{\gamma_1 C k}. \quad (47)$$

For the titration of a more ionized base BOH in the presence of a less ionized base B′OH with a monobasic acid HA:

$$\overline{\overline{\mathrm{FE}}} = \frac{\gamma_1 K_w}{kK_B}(1 + K_B/\gamma_1 C) - \frac{\gamma_1 k}{K_A}(1 + K_A/\gamma_1 C) - \frac{k C' K_{B'}}{\gamma_1 C K_w}. \quad (54)$$

The C'/C occurring in the last terms of these equations is equal to the ratio of the quantities of the two acids HA′ and HA, or of the two bases B′OH and BOH, originally present in the solution to be titrated; and $K_{A'}$ and K_A, or K_B and $K_{B'}$, are the ionization-constants of these two acids or bases.

By these expressions the fractional error can be readily calculated in any case where the values of the ionization-constants involved and of the indicator-function are known. The error can evidently be reduced by securing an appropriate value of the indicator-function, which may be done by choosing a suitable indicator and taking care that the proper fraction of it is transformed at the end-point. Other sections of the article are therefore devoted to the derivation of expressions for the best value of the indicator-function and for the limiting values permissible in the different cases, and to a consideration of the conditions, under which the titration ceases to be practicable with any indicator.

By placing in each of the seven equations just considered the first member $\overline{\overline{\mathrm{FE}}}$ equal to zero, and solving the equation for k, expressions were obtained for the value which the indicator-function k must have in order that the titration may be perfect. The expressions for the "best values" (k_0) of k so obtained are for the seven cases as follows:

For the titration of a monobasic acid and a monacidic base:

$$k_o = \left(\frac{K_w(1+K_B/\gamma_1 C)}{K_B}\right)^{\frac{1}{2}} \left(\frac{K_A}{1+K_A/\gamma_1 C}\right)^{\frac{1}{2}}. \qquad (33)$$

For the titration of the total hydrogen of a dibasic acid with a monobasic acid, replace in equation (33) K_A by $2\gamma_1 K_{A_2}$ and γ_1 by γ_2.

For the titration of the total hydroxyl of a diacidic base with a monobasic acid, replace in equation (33) K_B by $2\gamma_1 K_{B_2}$ and γ_1 by γ_2.

For the titration of the first hydrogen of a dibasic acid with a monacidic base, when $K_{A_2} > 10(K_w/K_B)\ (1 + K_B/\gamma_1 C)$:

$$k_o = \left(\frac{K_{A_1}K_{A_2}}{\gamma_2(1+K_{A_1}/\gamma_1 C)}\right)^{\frac{1}{2}}. \qquad (71)$$

For the titration of the first hydroxyl of a diacidic base with a monobasic acid, when $K_{B_2} > 10(K_w/K_A)\ (1 + K_A/\gamma_1 C)$:

$$k_o = \left(\frac{\gamma_2 K_w^2}{K_{B_1}K_{B_2}}\right)^{\frac{1}{2}} (1+K_{B_1}/\gamma_1 C)^{\frac{1}{2}}. \qquad (85)$$

For the titration of a more ionized acid HA in the presence of a less ionized one HA′, when $(K_{A'}C'/C) > 10(K_w/K_B)\ (1 + {}_BK/\gamma_1 C)$:

$$k_o = \frac{1}{\gamma_1}\left(\frac{C'K_{A'}K_A}{C(1+K_A/\gamma_1 C)}\right)^{\frac{1}{2}}. \qquad (49)$$

For the titration of a more ionized base BOH in the presence of less ionized one B′OH, when $(K_{B'}C'/C) > 10(K_w/K_A)\ (1 + K_A/\gamma_1 C)$:

$$k_o = \gamma_1 K_w \left(\frac{C(1+K_B/\gamma_1 C)}{C'K_{B'}K_B}\right)^{\frac{1}{2}}. \qquad (56)$$

The applicability of the last four equations is not greatly limited by the restriction that the ionization-constant for the hydrogen that is *not* to be titrated must be greater than $10(K_w/K_{A \text{ or } B})\ (1 + K_{A \text{ or } B}/\gamma C)$; for this quantity has at 25° (where $K_w = 10^{-14}$) a value of only about 10^{-12} when the titration is made, as it usually is, with an almost completely ionized univalent base or acid (for which K_B or $K_A = 1$), such as sodium hydroxide or hydrochloric acid. (This restriction and these statements in regard to it apply also to the corresponding equations presented below.) If K_{A_2} or K_{B_2} is smaller than $^1/_{100}$ of this quantity (thus smaller than 10^{-14} at 25°) the dibasic acid or diacidic base may be treated as a monobasic or monacidic one; and if $(K_{A'}C'/C)$ or $(K_{B'}C'/C)$ is smaller than $^1/_{100}$ of this quantity, the presence of the less ionized acid or base can be disregarded. In the intermediate case more complex formulas than those given above must be used, in regard to which reference may be made to Sections 18, 22, 13, and 14.

By placing in each of the seven equations for the fractional error the first member $\overline{FE}$ equal to $\pm\rho$ and solving for k, expressions can be directly obtained for the maximum and minimum values which the indicator-function k may have without giving rise to a fractional error numerically greater than any assigned value ρ. The expressions so obtained are:

For the titration of a monobasic acid with a monacidic base, or the reverse:

$$k < \frac{pK_A}{\gamma_1(1+K_A/\gamma_1 C)} \quad (37), \text{ and } k > \frac{\gamma_1 K_w(1+K_B/\gamma_1 C)}{pK_B}. \quad (38)$$

For the titration of the total hydrogen of a dibasic acid, replace in (37) K_A by $2\gamma_1 K_{A_2}$ and γ_1 by γ_2; and for the titration of the total hydroxyl of a diacidic base, replace in (38) K_B by $2\gamma_1 K_{B_2}$ and γ_1 by γ_2.

For the titration of the first hydrogen of a dibasic acid with a nearly completely ionized base:

$$k < \frac{pK_{A_1}}{\gamma_1(1 + K_{A_1}/\gamma_1 C)} \quad (72); \quad \text{and } k > \frac{\gamma_1 K_{A_2}}{\gamma_2 p} \quad (73).$$

For the titration of the first hydroxyl of a diacidic base with a nearly completely ionized acid:

$$k < \frac{\gamma_2 p K_w}{\gamma_1 K_{B_2}} \quad (86); \quad \text{and } k > \frac{\gamma_1 K_w(1 + K_{B_1}/\gamma_1 C)}{pK_{B_1}} \quad (87).$$

For the titration of an acid HA in the presence of another acid HA′, with a nearly completely ionized base:

$$k < \frac{pK_A}{\gamma_1(1 + K_A/\gamma_1 C)} \quad (50); \quad \text{and } k > \frac{C'K_{A'}}{p\gamma_1 C} \quad (51).$$

For the titration of a base BOH in the presence of another base B′OH, with a nearly completely ionized acid:

$$k < \frac{p\gamma_1 C K_w}{C'K_{B'}} \quad (57); \quad \text{and } k > \frac{\gamma_1 K_w(1 + K_B/\gamma_1 C)}{pK_B} \quad (58).$$

By these expressions the practical limits between which the indicator-function must lie can be readily calculated for any given combination of acid and base. It will be observed that in the first three cases, where the total acid or base present is to be titrated, the upper limit for k is determined by the ionization-constant of the acid and the lower limit by that of the base; that, in the case of the titration of the first hydrogen of a dibasic acid or of one monobasic acid in the presence of another, the upper limit is determined by the ionization-constant for the hydrogen that is to be titrated, and the lower limit by that for the hydrogen that is not to be titrated; and that the reverse is true in the case of the titration of the first hydroxyl of a diacidic base, or of one monacidic base in the presence of another.

It has been shown that, although theoretically there is a value of the indicator-function which would make a perfect titration possible for any combination of acid and base, yet in practice, since that best value k_0 can be only approximately realized, it ceases to be possible to make the titration with reasonable accuracy when the ionization-constants of the base and acid assume too small values. The following expressions were derived in order to show how great the ratio of the actual value k to the best value k_0 may become without causing the fractional error in the titration to exceed any assigned value:

For the titration of a monobasic acid and a monacidic base;

$$\text{FE} = \gamma_1\left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{K_W}{K_A K_B}\right)^{\frac{1}{2}}(1 + K_B/\gamma_1 C)^{\frac{1}{2}}(1 + K_A/\gamma_1 C)^{\frac{1}{2}}. \qquad (35)$$

For the titration of the total hydrogen of a dibasic acid or the total hydroxyl of a diacidic base, replace in this equation γ_1 by γ_2 and K_A by $2\gamma_1 K_{A_2}$, or γ_1 by γ_2 and K_B by $2\gamma_1 K_{B_2}$, respectively.

For the titration of the first hydrogen of a dibasic acid:

$$\text{FE} = \gamma_1\left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{K_{A_2}}{\gamma_2 K_{A_1}}\right)^{\frac{1}{2}}(1 + K_{A_1}/\gamma_1 C)^{\frac{1}{2}}. \qquad (76)$$

For the titration of the first hydroxyl of a diacidic base, replace in this equation K_{A_2} by K_{B_2} and K_{A_1} by K_{B_1}. (88)

For the titration of one monobasic acid HA in presence of another, less ionized one HA′,

$$\text{FE} = \left(\frac{k_0}{k} - \frac{k}{k_0}\right)\left(\frac{C'K_{A'}}{CK_A}\right)^{\frac{1}{2}}(1 + K_A/\gamma_1 C)^{\frac{1}{2}}. \qquad (52)$$

For the titration of one monacidic base BOH in presence of another less ionized one B′OH, one should replace $K_{A'}$ by $K_{B'}$ and K_A by K_B in this equation.

Since the factors of the form $(1 + K/\gamma_1 C)^{\frac{1}{2}}$ never have a value very different from unity, how small k_0/k or k/k_0 must be to prevent the error FE from exceeding any assigned value depends mainly on how small the value is of $\frac{K_W}{K_A K_B}$, $\frac{K_W}{2K_{A_2}K_B}$, $\frac{K_W}{2K_A K_{B_2}}$, $\frac{K_{A_2}}{K_{A_1}}$, $\frac{K_{B_2}}{K_{B_1}}$, $\frac{C'K_{A'}}{CK_A}$, or $\frac{C'K_{B'}}{CK_B}$.

The numerical values of k_0/k or k/k_0 corresponding to a fractional error of 0.1 per cent., to a series of values of $K_W/K_A K_B$ or of any other of these seven quantities, and to different values of $(1 + K/\gamma_1 C)$ have been calculated and tabulated on page 836. This table shows that as any of these seven quantities increases, greater care must be taken to bring the actual value k of the indicator-function closer to the best value k_0, and when any of them becomes as large as 10^{-8}, the ratio k_0/k or k/k_0 must be given a value so small as to approach the practically attainable limit; namely, a value less than 7.4 when K_A or $K_B = 1$ and $C = 0.5$, and one less than 2.7 when K_A or $K_B = 1$ and $C = 0.05$. The table, as illustrated by this example, also shows that the smaller the concentration C of the titrated solution, the smaller is the limiting value of k_0/k or k/k_0 at which the titration is still possible with a given accuracy, and therefore that it is advantageous to titrate in a solution as concentrated as possible whenever the titration is sensitive to error and a strong base or acid is involved in it.

It was also pointed out, since the actual value of the indicator-function must be made to approach the best value more closely as K_w/K_AK_B, $K_w/2K_{A_2}K_B$ or $K_w/2K_AK_{B_2}$ increases, and since K_w increases very rapidly with rising temperature (thus from 10^{-15} at 0° to 10^{-14} at 25° and 10^{-13} at 65°), that it is advantageous to make the titration at as low a temperature as possible, provided the total acid or base present is to be titrated.

The following expressions, showing the maximum values which any of the seven quantities above referred to may have without causing the titration to become impracticable, were obtained from the equations for FE by denoting the minimum value of $(k_0/k - k/k_0)$ which one can hope to realize in practice by β and representing the fractional error permissible in the titration by ρ, and transforming:

For the titration of a monobasic acid and monacidic base:

$$\frac{K_W}{K_AK_B}\cdot\gamma_1^2(1+K_A/\gamma_1C)(1+K_B/\gamma_1C)<\frac{\rho^2}{\beta^2}. \qquad (40)$$

For the titration of the first hydrogen of a dibasic acid:

$$\frac{K_{A_2}}{K_{A_1}}\left(\frac{\gamma_1^2}{\gamma_2}\right)(1+K_{A_1}/\gamma_1C)<\frac{\rho^2}{\beta^2}. \qquad (77)$$

For the titration of one monobasic acid HA in the presence of another less ionized one HA′:

$$\frac{C'K_{A'}}{CK_A}(1+K_A/\gamma_1C)<\frac{\rho^2}{\beta^2}. \qquad (53)$$

For the titration of the other combinations the same substitutions are to be made in these expressions as in the previous cases.

It was shown in Section 12 that the smallest value of k_0/k or k/k_0 that one can ordinarily hope to realize may be fairly estimated to be in the neighborhood of 3.5. Since under this assumption β^2 is equal to 10, we may conclude that the first members of the preceding inequalities must not have a larger value than 10^{-7}, 10^{-6}, and 10^{-5} if the error (ρ) in the titration is not to exceed $^1/_{10}$, $^1/_3$, and 1 per cent., respectively.

By the first of these inequalities one can also calculate the minimum value which the product K_AK_B may have under various conditions. It is evident that this minimum value will be smaller, the greater the concentration C of the titrated solution and the lower the temperature (owing to the variation of K_w with the latter). It may also be pointed out that under ordinary conditions (say at 25° with the concentration 0.1 normal) the minimum value which K_A or K_B may have is about 10^{-8}, 10^{-7}, or 10^{-6} if the acid or base is to be titrated with an accuracy of $^1/_{10}$, $^1/_3$, or 1 per cent. with one of the nearly completely ionized bases or acids. The same statements apply to the product $2K_{A_2}K_B$ in the case of a dibasic acid, and to the product $2K_AK_{B_2}$ in the case of a diacidic base; also to the values of $2K_{A_2}$ and $2K_{B_2}$.

The more important of the foregoing considerations relating to the best value and the limiting values of the indicator-function may be expressed in the form of simple practical rules which, though only approximately correct, have sufficient accuracy for almost all purposes. These rules may be derived from the equations for k_0 and from the inequalities containing k and ρ by putting γ equal to unity, by putting also the expressions of the form $1 + K/\gamma C$ equal to unity when they refer to acids or bases that are not largely ionized, and by assigning to expressions of the form $\gamma(1 + K/\gamma C)/K$ the medium value[1] 10 and to K_A or K_B the value unity when they refer to the most completely ionized acids or bases. The rules are as follows:

In order that a not largely ionized acid or base may be titrated with one of the most largely ionized bases or acids with a fractional error not greater than ρ, it is essential that the indicator-function k have a value which is greater than the "minimum value" and less than the "maximum value" given in the following table; and in order to assure the fulfilment of this requirement, it is advisable in any titration sensitive to error to aim to secure a value of the indicator-function as nearly as possible equal to the "best value," whose square is given in the table.[2]

TABLE 2.—APPROXIMATE EXPRESSIONS FOR THE MAXIMUM, MINIMUM, AND BEST VALUES OF THE INDICATOR-FUNCTION.

Titration, with a largely ionized base or acid, of	Square of best value.	Maximum value.	Minimum value.	Function for limit of titratability
A monobasic acid	$10K_WK_A$	ρK_A	$10K_W/\rho$	$10K_W/K_A$
A monacidic base.........	$^1/_{10}K_W/K_B$	$^1/_{10}\rho$	$K_W/(\rho K_B)$	$10K_W/K_B$
The total hydrogen of a dibasic acid.............	$10K_W2K_{A_2}$	$\rho 2K_{A_2}$	$10K_W/\rho$	$10K_W/2K_{A_2}$
The total hydroxyl of a diacidic base.............	$^1/_{10}K_W/2K_{B_2}$	$^1/_{10}\rho$	$K_W/(\rho 2K_{B_2})$	$10K_W/2K_{B_2}$
The first hydrogen of a polybasic acid..........	$K_{A_1}K_{A_2}$	ρK_{A_1}	K_{A_2}/ρ	K_{A_2}/K_{A_1}
The first hydroxyl of a polyacidic base	$\frac{K_W^2}{K_{B_1}K_{B_2}}$	$\frac{\rho K_W}{K_{B_2}}$	$\frac{K_W}{\rho K_{B_1}}$	K_{B_2}/K_{B_1}
One monobasic acid (HA) in the presence of another (HA')............	$\frac{K_AK_{A'}C'}{C}$	ρK_A	$\frac{K_{A'}C'}{\rho C}$	$\frac{K_{A'}C'}{K_AC}$
One monacidic base (BOH) in the presence of another (B'OH)...........	$\frac{K_W^2C}{K_BK_{B'}C'}$	$\rho\frac{CK_W}{C'K_{B'}}$	$\frac{K_W}{\rho K_B}$	$\frac{K_{B'}C'}{K_BC}$

---

[1] When $K = 1$ as it is approximately for such acids as HCl and HNO_3 and such bases as NaOH and KOH at 0.1 normal, the value of $\gamma(1 + K/\gamma C)/K$ varies from about 3 when the titrated solution is 0.5 normal, to about 21 when it is 0.05 normal.

[2] For the significance of the various K's and C's in this table see the third and fourth pages of this Summary. For an example illustrating the use of the table, see the foot-note at the end of the article.

The table also contains in the last column that function of the ionization-constants whose value determines the limit beyond which the titration becomes impracticable. This limit depends also on how small a value of $(k_0/k - k/k_0)$ it is possible to realize. If we represent by β the minimum value of the latter quantity attainable, the following rule in regard to the limit may be stated:

In order that the titration of a not largely ionized acid or base with one of the most completely ionized bases or acids may be made with a fractional error not greater than ρ, it is essential that the quantity given in the last column of the table have a value less than that of the ratio ρ^2/β^2. If we adopt the estimate that the value of k_0/k or k/k_0 may be made as small as 3.5, but not smaller without taking unusual precautions, then $\beta^2 = 10$ approximately; and we may conclude that the titration ceases to be practicable with an accuracy ρ when any of the functions of the ionization-constants given in the preceding list become greater than $^1/_{10}\rho^2$; thus greater than 10^{-7} for an accuracy of $^1/_{10}$ per cent., greater than 10^{-6} for an accuracy of $^1/_3$ per cent., and greater than 10^{-5} for an accuracy of 1 per cent.

VII. Appendix.

25. *Values of the Ionization-Constants of Indicators.*—The application of the principles developed in this article to the various practicable titrations involves the use of a series of indicators with ionization-constants varying in value by gradations from about 10^{-3} to 10^{-11}. Unfortunately, our knowledge of the ionization-constants of the numerous available indicators is at present for the most part inexact, and needs to be supplemented by further careful investigations. Extensive preliminary studies of indicators in this direction were first made by Friedenthal,[1] Salessky,[2] Fels,[3] and Salm,[4] who have published tables showing roughly the hydrogen-ion concentration at which a large number of indicators undergo change in color, in connection with which it may be recalled that the ionization-constant of an indicator is equal to the hydrogen-ion concentration at which it is one-half transformed into its salt. A more careful investigation by the colorimetric method has been made by Salm[5] with the object of obtaining better values of the constants for several of the more important indicators. A quantitative study of phenolphthalein has also been

made colorimetrically by McCoy,[1] Hildebrand,[2] and Wegscheider;[3] and the ionization-constant for *p*-nitrophenol has been determined by the ordinary conductivity method by Bader,[4] Hantzsch,[5] Holleman,[6] and Lundén.[7]

The following table contains the values of the apparent indicator-constant K_I (as defined at the end of Section 3) derived from these quantitative investigations, the data being those of Salm, except in the case of phenolphthalein where the geometrical mean of the values obtained by him, McCoy, and Hildebrand,[8] is given, and except in the case of *p*-nitrophenol where the ratio of the mean value[9] (excluding Bader's) derived from the various conductivity investigations to 0.83 (the value of γ at 0.1 normal) is adopted. In the case of the basic indicators, the value given is that which the constant would have if the indicator were regarded as an acid.

TABLE 3.—IONIZATION-CONSTANTS OF INDICATORS.

Dimethylaminoazobenzene...	7×10^{-4}	Alizarin..................	9×10^{-9}
Methyl orange..............	5×10^{-4}	Cyanin....................	2×10^{-9}
p-Nitrophenol.	9×10^{-8}	Phenolphthalein...........	2×10^{-10}
Rosolic acid	1×10^{-8}		

It is to be borne in mind that it is not the ionization-constant itself, but the product obtained by multiplying it by $(1 - \alpha)/\alpha$, where α is the fraction of the indicator transformed into its salt at the end-point, that is directly involved in the applications of the theory to volumetric analysis. It is therefore important to know also the limits between which the fraction transformed and therefore this product, designated throughout this article the indicator-function k, can in practice be varied, by adding different quantities of the indicator. In accordance with the considerations of Section 5 and the experiments communicated in the foot-notes thereto, the following values may be provisionally given as representing

[1] *Am. Chem. J.*, 31, 503 (1904).

[2] *Z. Elektrochem.*, 14, 351 (1908).

[3] *Ibid.*, 14, 510 (1904).

[13] Since barium and calcium hydroxides, like the tri-ionic salts, apparently do not dissociate in stages with formation of the intermediate ions $BaOH^+$ or $CaOH^+$, they can be regarded as monacidic bases.

A comprehensive list of the ionization-constants for organic monobasic acids, for the first hydrogen of organic polybasic acids, and for organic monacidic bases, is given in Kohlrausch and Holborn's "Leitvermögen der Electrolyte" (pp. 176–94); and a more nearly complete one will be found in Lundén's monograph on "Affinitäts-messungen an schwachen Säuren und Basen" (pp. 81–102) in Ahrens' *Sammlung chemischer und chemisch-technischer Vorträge.* Values for the specific acids and bases will also be found under them in Beilstein's and in Meyer and Jacobson's "Handbücher der organischen Chemie." The facts must not, however, be overlooked that the values given in all these books except Lundén's are 100 times the true ionization-constants, which have been employed throughout this article; and that in the case of dibasic acids the values given are ordinarily those for the first hydrogen, while it is those for the second hydrogen that are involved when the total acid is to be titrated. Values for the constants for the second hydrogen of many dibasic acids will be found in an article in THIS JOURNAL by Chandler.[1]

With the aid of Table 2, given near the end of the summary, and the data presented or referred to in this section and the preceding one, the conditions for realizing a satisfactory titration of any particular slightly ionized acid or base may be readily derived; or, if the titration is not practicable, the fact that such is the case may be determined.[2]

BOSTON, May 1910.

---

[1] THIS JOURNAL, 30, 713 (1908).

[2] A concrete example may facilitate the application of these considerations by analysts. Suppose that butyric acid is to be titrated with sodium hydroxide. We find by reference to the summaries of Kohlrausch and Holborn or Lundén or to Meyer and Jacobson's text-book that the ionization-constant K_A for this acid is 1.5×10^{-5}. Referring to the first row of Table 2, we find that the best value of the indicator-function k for the titration of a monobasic acid by a largely ionized base is equal to $10K_WK_A$; therefore for this acid at 25° where $K_W = 10^{-14}$, it is $10 \times 10^{-14} \times 1.5 \times 10^{-5}$ or 1.2×10^{-9}. Reference to Table 3, in Section 25, shows that this value may be secured by using phenolphthalein (for which K_I is 2×10^{-10}) and causing it to be about 14 per cent. transformed into its salt at the end-point (since $k = K_I(1 - \alpha)/\alpha = 2 \times 10^{-10} \times 0.86/0.14 = 1.2 \times 10^{-9}$), and reference to Table 4 in Section 25 shows that it is practicable to secure with phenolphthalein this fraction transformed (since it corresponds to a value of k equal to $6K_I$).

The succeeding expressions in the first row of Table 2 show also that the maximum and minimum values which the indicator-function must have, if an accuracy ρ is to be secured, are $K_A\rho$ and $10K_w/\rho$, respectively; so that in this case if an accuracy of 0.1 per cent. ($\rho = 0.001$) is to be secured, the value of the indicator-function must be between the limits 1.5×10^{-8} and 10^{-10}. This shows that the attained value of the indicator-function must not be greater than 10 times the best value just calculated or smaller than one-tenth of that best value.

[CONTRIBUTIONS FROM THE RESEARCH LABORATORY OF PHYSICAL CHEMISTRY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, NO. 49.]

THE THEORY OF THE DETERMINATION OF TRANSFERENCE NUMBERS BY THE METHOD OF MOVING BOUNDARIES.

BY GILBERT N. LEWIS.

Received May 2, 1910.

In spite of the very important rôle that the transference numbers of electrolytes have played in chemical theory, since Hittorf developed sixty years ago the method of determining these quantities by analysis of the electrode solutions, few really accurate transference numbers have been obtained. This is doubtless due to the very great patience and experimental skill demanded by the Hittorf method. The much simpler method of moving boundaries which was first conceived by Lodge has been so far developed, especially by the recent experiments of Denison and Steele,[1] that it yields results showing a degree of reproducibility rarely attained by the analytical method. It is therefore desirable to subject this method to a careful scrutiny in order to see the precise relation between the transference numbers obtained by its means and those determined by the classical method of Hittorf.

On account of certain discrepancies between the values obtained by the two methods it has frequently been surmised that these differences might be due to the existence of complex ions and that a comparison of the results of the two methods might therefore give some information as to the nature of the ions present in solution. The fallacy of this view has recently been clearly demonstrated by Lash Miller,[2] who emphasizes the fact that the direct method gives transference numbers that, when properly interpreted, are from every point of view identical with those obtained by the analytical determination of the amount of substance transferred from one electrode to the other during electrolysis.

There are, however, two distinct analytical methods of determining transference numbers. In the first, which gives the ordinary or Hittorf transference number, the ratio of the amount of salt to a given amount of water at each electrode is determined before and after electrolysis. This obviously shows the actual transference of the salt only in case the water itself is not transported by the current. The second method, which gives the so-called "true transference number," was first devised by Nernst,[3] and depends upon the use of some reference substance in solution which does not wander with the current, and with respect to which rather than to the water the salt content at each electrode is determined. The practicability of this method has recently been demonstrated by the experiments of Buchböck[1] on hydrochloric acid and especially by the very accurate investigation of the alkali chlorides by Washburn.[2]

[2] *Z. physik. Chem.*, 69, 436 (1909).

[3] *Göttingen Nachricht*, 56, 86 (1900).

If in any case there is a difference between the true and the Hittorf transference numbers, it is not at once obvious which, if either, of these values may be exactly calculated from the experiments on moving boundaries. For normal sodium and potassium chlorides the true and Hittorf numbers are accurately known and these salts have been investigated by Denison and Steele with the moving boundary method. The transference numbers of the anion obtained by the three methods are given in the following table:

	Hittorf.[3]	True [3]	D. and S.
KCl (normal)	0.515	0.505	0.508
NaCl (normal)......	0.631	0 613	0.614

The close agreement between the true transference numbers and those obtained by Denison and Steele was observed by Washburn, and led him to conclude that the method of moving boundaries gives immediately the true transference numbers. This view moreover has been accepted by Denison in a recent paper.[4]

We shall see, however, that the agreement is entirely accidental, and is due to the neglect of a correction which must always be made when the method of moving boundaries is employed, and which, although never entirely ignored by previous writers, has hitherto been neglected in practice. In order to show the nature and magnitude of this correction let us consider the accompanying figure, which represents (diagrammatically) the conditions of Denison and Steele's experiments. The apparatus consists essentially of two electrode chambers, a straight tube AB, and two small tubes E and F into which the liquid rises to a certain height. Assume that the transference number of normal sodium chloride solution is sought A column of this solution is introduced into the center tube, and bounded by two solutions in one of which (LiCl) the cation has a smaller mobility than the sodium ion, and in the other of which ($NaC_2H_3O_2$) the anion has a smaller mobility than the chloride ion. Under these circumstances a current sent through the cell, in the direction shown by the arrows, sharpens the boundaries A and B and causes them to move in opposite directions, say to A′ and B′. Denison and Steele would now consider AA′ proportional to the mobility of sodium, and BB′ to that of chlorine, whence $\frac{AA'}{AA' + B'B}$ and $\frac{B'B}{AA' + B'B}$ are the transference numbers of cation and anion respectively.

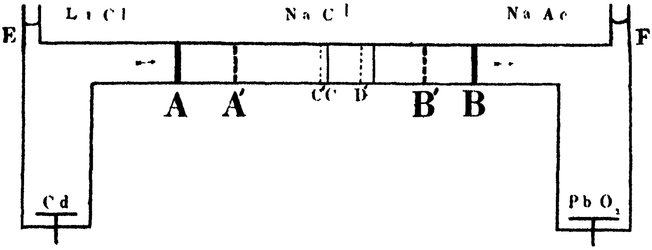
[2] *Technology Quart.*, 21, 288 (1908); THIS JOURNAL, 31, 322 (1909); *Z. physik. Chem.*, 66, 513 (1909).

[3] These values for the normal solutions have been obtained by interpolating between the values obtained by Washburn for 1.25 *N* solutions and the accepted values at infinite dilution.

[4] *Trans. Faraday Soc.*, 5, 165 (1909).



The positions and motions of the boundaries are referred to marks on the glass tube or read by a telescope which is stationary with respect to the apparatus, and it is therefore obvious that any flow of the solution bodily through the tube would vitiate the results. Thus if during the experiment liquid were poured into the tube F and allowed to flow out at E, the boundary B would move more and the boundary A less than before, and entirely different transference numbers would be obtained. A like effect would be produced if the tube F were closed, and hydrogen gas evolved at the cathode. Here also there would be a considerable flow of solution through the middle portion of the apparatus. This is of course an extreme case and it is not difficult to find electrodes which permit no evolution of gas. Nevertheless there will always be a certain volume change at each electrode, and therefore to each of Denison and Steele's transference numbers a correction must be applied which depends both upon the salt investigated and upon the kind of electrode used.[1]

In order to illustrate the mode of calculation of this correction and to obtain an idea of its order of magnitude, let us determine the volume changes at each electrode in a typical experiment of Denison and Steele's, in which a normal solution of sodium chloride is electrolyzed with a cadmium anode and a cathode composed of a paste of lead and lead peroxide. Assume now that the tube E in the apparatus is closed and the tube F is open, and that one faraday of electricity passes, whereby the sodium boundary moves from the point A (on the glass tube) to the point A′ and the chloride boundary from B to B′. The solution between A′ and B′ will remain unchanged. Now let C be the original position of what we may call an *average* water particle, and CC′ the change in position of this particle due to flow of liquid caused by a volume change at the cadmium electrode; or, if this idea of the average water particle seems too indefinite, let C and C′ be two points such that there is the same amount of water to the left of C′ after the experiment as there was to the left of C at the beginning. It will now be obvious from our definition that if we measure the positions of A and B from the point C and the positions A′ and B′ from the point C′ we shall be referring the transference of salt to a given quantity of water[1] and thus obtain exactly the Hittorf transference numbers, which are, for the cation, $N_C = \frac{AA' + C'C}{AA' + B'B}$ and for the anion, $N_A = \frac{B'B - C'C}{AA' = B'B}$.

---

[1] The transference numbers obtained from moving boundaries without this correction are analogous to those obtained by the Hittorf method when the amounts of salt transported are referred, not to given weight of water, but, incorrectly, to the contents of a given volume of the apparatus.

To calculate the distance C′C, when one faraday passes, we must find the volume change occurring during electrolysis to the left of our "average water particle." In this calculation we may use a principle which, although not absolutely correct, is sufficiently so for our present purpose. This principle states that the volume of an aqueous solution differs from the volume of pure water which it contains, by a quantity that is proportional to the number of equivalents of the solute present. The proportionality constant is called the apparent equivalent volume of the solute. Thus in the present case the distribution of lithium chloride is changed by the electrolysis, since its concentration between A and A′ will in general be different from that immediately to the left of A.[2] But the total amount of lithium chloride in the portion to the left of C will be unchanged and the volume therefore due to lithium chloride will remain unchanged. The only changes that will affect the volume considered are (1) the disappearance of one equivalent of metallic cadmium, which occupied 6.5 cc.;[3] (2) the formation of one equivalent of cadmium chloride in solution where it has the apparent volume of 12.0 cc.; and (3) the loss of N_C equivalent of sodium chloride, N_C being the Hittorf transference number, for the cation, of sodium chloride. We have given above the value of N_C for normal sodium chloride as about 0.37. The apparent equivalent volume of this salt is 18.0 cc. The total increase of volume, which is the volume between C and C′, is then $12.0 - 6.5 - (0.37 \times 18.0) = -1.2$ cc.

If now the tube E is open and F closed, the flow through the tube is determined by the volume changes in the right-hand portion of the apparatus. Here one equivalent each of lead peroxide (6.7 cc.) and of water (9.0 cc.), and N_A (=0.63) equivalents of sodium chloride with apparent equivalent volume 18.0 cc. have disappeared, one each of lead (4.6 cc.) and sodium hydroxide (—4.1 cc.) have been formed.[1] The total increase in volume is therefore $4.6 - 4.1 - 6.7 - 9.0 - (0.63 \times 18) = -26.6$ cc. In the previous case, where the tube E was closed, we found the volume change hardly greater than the probable error of the calculation, but in the present case, with F closed, the change of 26.6 cc. means a very considerable flow of solution through the tube from left to right.

---

[1] See also Lash Miller, *Loc. cit.*

[2] See Kohlrausch, *Ann. d. Physik*, 62, 237 (1897).

[3] All data concerning equivalent volumes are taken or calculated from the tables of Landolt and Börnstein.

As a matter of fact Denison and Steele left both E and F open. This complicates the matter, but if we assume that both tubes were of the same diameter, then, since the solutions in the two tubes have about the same density, the volume change will be distributed evenly, and the flow of solution will be the mean of the two values we have just calculated, 1.2 in one direction and 26.6 in the other. This is 12.7 cc. or in round numbers 13 cc. flow from left to right.

We have seen that the Hittorf transference numbers are to be calculated by the equations $N_C = \frac{AA' + C'C}{AA' + B'B}$, $N_A = \frac{B'B - C'C}{AA' + B'B}$ while the Denison and Steele transference numbers, which we may represent by N'_C and N'_A are $\frac{AA'}{AA' + B'B}$ and $\frac{B'B}{AA' + B'B}$. Hence $N_A = N'_A - \frac{C'C}{AA' + B'B}$. Now since the tube A B has a uniform bore the quantities AA′, B′B, C′C may represent volumes as well as distances. We will replace C′C then by v, which will denote the total flow of olution from cathode to anode when one faraday passes. It is obvious that AA′ + B′B, the total distance moved by both boundaries during the passage of one faraday, is simply equal to the volume containing one equivalent of salt, which is the reciprocal of the equivalent concentration, c. The above equation therefore becomes,

$$N_A = N'_A - vc.$$

In the above case of normal sodium chloride, $c = 1$, $v = -0.013$ (in liters), N'_A was found to be 0.614, hence N_A, the Hittorf number obtained from Denison and Steele's value, is 0.627.

In the case of normal potassium chloride we may make a similar calculation. Here N_A is about 0.51 and the apparent equivalent volumes are 28.5 cc. for potassium chloride and 6.6 cc. for potassium hydroxide. Proceeding as before we find that the increase of volume is —8.3 cc.

---

[1] Denison and Steele added a trace of acetic acid near the cathode and of alkali near the anode. These substances, if present at the electrodes, would make the reactions somewhat different from those given above. It seems, however, most probable that these substances were used up in the immediate neighborhood of the electrodes by the preliminary current which was always passed through before the readings were begun, and I have assumed this to be the case.

on the left side, and —18.3 cc. on the right. Assuming again that tubes E and F are both open and of the same size, the flow of liquid, v, through the apparatus amounts to —5.0 cc., that is, in the same direction as for sodium chloride. We must therefore add 0.005 to Denison and Steele's value to find the Hittorf transference number for the anion, and thus obtain 0.513 for the latter.

These two transference numbers, 0.627 for normal sodium chloride, and 0.513 for normal potassium chloride obtained by the moving boundary method are close to those found by the analytic method, namely 0.631 and 0.515.

The uncertainty as to the exact conditions of Denison and Steele's experiments makes it impossible to go further into these corrections; but we see at least that they are so large as to render it necessary in the future to carry out moving boundary experiments in such a way that the flow of liquid through the apparatus may be exactly determined. In general it would seem advisable that only one of the tubes, represented by E and F in our figure, be open at a time. The calculation of the correction would then be simplified. Moreover successive experiments with E open and with F open would give independent data, and thus furnish a mutual check. It would also be well to measure the total volume change in the apparatus after the passage of a given amount of current and compare with the calculated.

Denison and Steele found that their transference numbers were much nearer those obtained by the Hittorf method, when they passed from normal to tenth normal solutions. The reason for this is evident from our equation,

$$N_A = N'_A - vc.$$

Since the quantity v is nearly independent of the concentration, the difference between the Denison and Steele and the Hittorf numbers is only one-tenth as great in tenth normal as in normal solutions. Nevertheless the difference even in tenth normal solution may in some cases amount to 1 per cent. or more, and in most cases is larger than the apparent experimental error of the moving boundary method.

So far we have made no assumption concerning the hydration of the ions, and our conclusions are equally valid whether or not water is itself carried with the current. But suppose now that in that portion of the apparatus lying between A and B there is present in solution a small amount of a non-electrolyte which is known not to migrate with the current, and let this substance extend to the point D where its boundary is recognizable by optical methods, or otherwise. Assume that the ions of the electrolyte under investigation are hydrated and that more water is carried by the cation than by the anion. As a result water will be carried during electrolysis, through the non-electrolyte, towards the cathode, and while the point C, which we have defined above, moves to C′, the boundary D will move a greater distance to D′. A little consideration will show that the difference between the volumes C′C and D′D is a direct measure of the volume of water carried by the current, and furthermore that the *true* transference numbers of the electrolyte are given at once by the expressions, $\frac{AA' + D'D}{AA' + B'B}$ for the cation, and $\frac{B'B - D'D}{AA' + B'B}$ for the anion. In this case it is not even necessary to calculate the volume changes at the electrodes, for these are measured directly by the movements of the boundary D.

The only experimental difficulty in such an experiment as we have just proposed would be found in keeping the boundary D sufficiently sharp for accurate reading; for this boundary is not automatically sharpened by the electrolysis as in the case of the boundaries A and B. The difficulty seems, however, by no means insurmountable and this device should furnish a very simple method of investigating ionic hydration, and true transference numbers.[1]

We have seen that the analytical method of Hittorf is capable of yielding the true transference numbers when a stationary non-electrolyte is employed, as in the experiments of Buchböck and Washburn. Another familiar method of obtaining transference numbers consists in the determination of the electromotive force of cells with and without transference. I have shown in another place[2] that by the use of a stationary non-electrolyte it is possible to determine ionic hydrations and thus true transference numbers. These methods together with the one outlined above suggest that any method of determining the Hittorf transference numbers may with some modification be made to yield true transference numbers, but only by the employment of a non-electrolyte which does not migrate with the current.

Summary.

It is shown that the transference numbers of Denison and Steele are subject to a considerable correction on account of volume changes at the electrodes, the correction being larger, the more concentrated the solution. When this correction is applied the method of moving boundaries gives, theoretically and practically, the Hittorf transference numbers, and not the true transference numbers.

---

[1] Evidently when the amount of water carried by the current has been determined by some other method the true transference number may be obtained directly from the Denison and Steele values. It is to be noted that either the true or the Hittorf number is obtained from Denison and Steele's by making a correction for the volume changes at the electrodes. In the first case the volume change includes the volume of the water carried, in the second case it does not.

[2] THIS JOURNAL, 30, 1355 (1908); *Z. Elektrochem.*, 14, 509 (1908).

A method is proposed for obtaining true transference numbers from moving boundary experiments through the aid of a non-electrolyte which does not migrate with the current.

THE PHOSPHATES OF CALCIUM. IV.[1]

BY FRANK K. CAMERON AND JAMES M. BELL.

Received May 12, 1910

Owing to the increasing importance of the phosphates of calcium in the fertilizer industry, a knowledge of their behavior in water and in solutions becomes increasingly important. Some years ago two papers[2] were published from this laboratory, in which it was shown that at 25° the solutions, resulting from the mixture of the phosphates of calcium with water, always contain a greater ratio of P_2O_5/CaO than does the original solid. Thus the effects observed are not merely solubility effects but there is also an hydrolysis. So, each of the phosphates of calcium may exist in equilibrium with a series of solutions, in which the ratios of P_2O_5/H_2O and CaO/H_2O vary between rather wide limits.

It was found that at 25° solid monocalcium phosphate could exist in equilibrium with solutions containing over 320 grams phosphoric anhydride per liter. Below this concentration the stable solid was dicalcium phosphate. In the former analyses of these solids, only the ratio P_2O_5/CaO was determined, no estimation having been made of the amount of water of crystallization. The solids analyzed were always contaminated with the adhering mother liquor. In the determination of the above ratio this contamination is not a very serious source of error, as the mother liquor was present in small quantity compared with the crystals, and as the mother liquor was always much poorer both in phosphoric anhydride and in calcium oxide than were the crystals. Further, any determination of the amount of water would have been subject to an enormous error, as the percentage of water in the crystals is small, and that in the adhering liquid was very large. Consequently, the composition of the solid phase was taken as $CaHPO_4.2H_2O$, the ordinary dihydrate of dicalcium phosphate.

That this assumption seemed to be confirmed was indicated in a paper published subsequently by Bassett.[3] In this paper it was announced that above 30° the solid dicalcium phosphate dihydrate changed into the anhydrous salt. At 30° there is an invariant point, the five phases being the two forms of dicalcium phosphate (anhydrous and dihydrate), monocalcium phosphate monohydrate, solution and vapor. Also it was announced that 80° was the maximum temperature at which the dihydrate could exist, the five phases being the two hydrates of dicalcium phosphate, tricalcium phosphate, solution and vapor. Under these conditions there is a transition interval for the reaction

---

[1] Published by permission of the Secretary of Agriculture.

[2] Cameron, Seidell and Bell, THIS JOURNAL, 27, 1503, 1512 (1905).

[3] *Z. anorg. Chem.*, 53, 34 (1907).

$$CaHPO_4.2H_2O \rightleftarrows CaHPO_4 + \text{solution}$$

between 30° and 80°. Thus according to this publication the stable hydrate of dicalcium phosphate below 30° was the dihydrate, or possibly some higher hydrate.

Later Bassett[1] corrected his early temperature measurements, this transition interval being given as from 21° to 36°. This work would indicate that at 25° the anhydrous salt would be the stable form in equilibrium with the more concentrated solutions. And, as the temperature 25° is nearer 21° than 36°, it would be supposed that the dihydrate would exist over a much greater range of concentration than does the anhydrous salt. This supposition is, however, not confirmed by Bassett's results at 25°, for he finds that $CaHPO_4.2H_2O$ exists in equilibrium with solutions *below* 0.5 per cent. phosphoric anhydride. Above this value up to 23 per cent. phosphoric anhydride in solution, the solid phase is $CaHPO_4$. Thus the transformation at 25°

$$CaHPO_4.2H_2O \rightleftarrows CaHPO_4 + 2H_2O$$

has the same vapor pressure as an aqueous solution containing approximately 0.5 per cent. phosphoric anhydride and 0.2 per cent. lime. It is obvious that this vapor pressure cannot be much below that of pure water. This result does not appear to be in accord with the following statement of Bassett.[2] "Ein solcher Versuch wurde begonnen, gab aber kein Resultat *wegen des ausserordentlich geringen Wasserdampfdruckes von* $CaHPO_4.2H_2O$."[3]

Owing to the confusion regarding the relative stability of the hydrated and the anhydrous dicalcium phosphate, the following experiments were made at 25°. Solutions of phosphoric acid of varying concentration were prepared, the total volume of these solutions being 180 cc. To each mixture weighed quantities of potassium chloride (about 5 grams) were added and Kahlbaum's tricalcium phosphate in sufficient quantity to give a permanent precipitate. The reasons for the addition of potassium chloride should be further explained. As has been stated above, an analysis of the solid phase with the adhering mother liquor is useless to determine the water present in a solid. Also, the residue method of Schreinemakers[4] and Bancroft[5] fails, because the line joining the two points (representing $CaHPO_4.2H_2O$ and $CaHPO_4$) is almost parallel with the tie lines, and consequently very slight errors of analysis of the solution or of the solid residue might give erroneous results regarding the composition of the solid phase. A modification of this method, the "tell-tale" method,[1] was employed. This differs from the method of residues in this way. By the method of residues lines joining the points representing solution and residue are joined and produced. Where three or more such lines pass through a point, the point represents the composition of the solid phase. By the "tell-tale" method, it becomes possible to calculate the quantity of liquid adhering to the crystals, and consequently to calculate how far to produce this tie line. Where the different tie lines met at a large angle, the first method has been used generally, but where tie lines meet at a very small angle, the second method is to be preferred. One condition to be fulfilled in this latter case, is that the "tell-tale" substance must be present only in the liquid phase. That the condition was satisfied here was indicated by the analysis of the liquid phase, for almost exactly the calculated quantity of chloride was found per unit of solution. Consequently this quantity is a measure of the quantity of solution adhering to the solid. Also from an analysis of the liquid the quantity of all the components present in the adhering liquid may be estimated. By subtracting these from the quantities found by analysis in the total residue, the composition of the solid may be found. In every case the quantity of water was determined by difference and so all the errors of experiment are heaped on these values. In spite of the fact that a slight error in the chloride determinations is multiplied many times in the corresponding quantities of water and that the water in the solid is the difference between two large values, the results by this method give fairly concordant values for the composition of the solid phases. The following table gives the results of the analyses:

TABLE.

	Solution.					Residue.				
No	Total	CaO.	P_2O_5.	KCl.	H_2O	Total	CaO	P_2O_5	KCl	H_2O.
112	25 014	0 052	0.152	0.685	24.125	9.162	1 934	2.336	0 099	4.793
115	24.528	0 103	0.290	0.659	23.476	10.531	2.439	3.033	0 091	4 968
119	26 196	0 249	0.685	0.703	24.559	8.463	1 609	2 054	0.102	4 698
122	15.701	0.252	0.741	0.409	14.299	7 278	1 774	2.271	0 053	3.180
126	5.469	0.161	0.500	0.134	4.674	11.627	2 719	3 561	0.094	5.253
127	3.656	0 158	0 585	0 090	2.823	21.495	5 745	8 134	0.189	7.427
130	5.254	0.287	1 355	0.106	3 506	14 797	2 095	6 051	0.157	6.494

The calculations of the compositions of the solid phase for one mixture (No. 126) follow. The ratios of the components in the residue, the solution and the solid are as follows:

---

[1] Bancroft, *J. Physic. Chem.*, 9, 558 (1905); later called the "tell-tale" method by Kenrick, *J. Physic. Chem.*, 12, 693 (1908).

	KCl.	CaO.	P_2O_5.	H_2O.
Residue	1	28.93	37.87	55.88
Solution	1	1.20	3.73	34.88
Solid	.	27.73	34.14	21.00

The values for the solid are the differences between the corresponding values for the solution and residue. In molecular ratios the values for the solid are

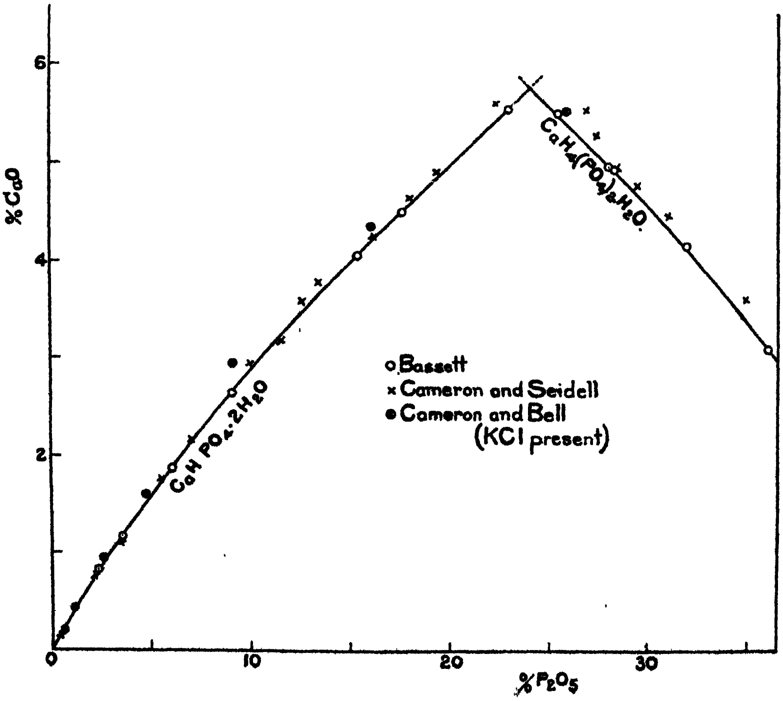
$$2.06\ CaO : 1.00\ P_2O_5 : 4.86\ H_2O.$$

The following table gives the molecular ratios calculated similarly for the solids in each of the other mixtures:

TABLE.

No.	CaO.	P_2O_5	H_2O.	Composition of solids.
112	2.11	1	4.39	
115	1.94	1	4.51	$2CaO.P_2O_5.5H_2O$ or $CaHPO_4.2H_2O$
119	2.03	1	4.66	
122	2.02	1	4.78	
126	2.06	1	4.86	
127	1.99	1	1.72	
130	1.04	1	2.55	$CaO.P_2O_5.3H_2O$ or $CaH_4(PO_4)_2.H_2O$

It is evident from these results that the stable solid phase up to a concentration of about 15 per cent. P_2O_5 is $CaHPO_4.2H_2O$. One result



(No. 127) indicates that there is a lower hydrate of $CaHPO_4$. It is probable that this is the anhydrous salt and that the single point (No. 127) gives the conditions at 25° for the transition

$$CaHPO_4.2H_2O \rightleftarrows CaHPO_4 + 2H_2O.$$

As the KCl present in solution influences the vapor pressure of the solution, concentrations of calcium oxide and phosphoric anhydride in each case are somewhat lower than for the corresponding solution where no potassium chloride is present.

These results also show the effect of potassium chloride in concentrations of about 25–30 grams per liter upon the system $CaO–P_2O_5–H_2O$. In the accompanying diagram are given the results of Bassett, of Cameron and Seidell, and of the present paper where potassium chloride is present. These last results lie above the curves drawn through the former points. Thus the effect of the potassium chloride is to increase the lime in solution.

In this paper it has been shown that:

1. The presence of potassium chloride in solution containing calcium oxide and phosphoric anhydride increases slightly the lime content of solutions in equilibrium with dicalcium phosphate and monocalcium phosphate.

2. By the "tell-tale" method the composition of the solid phases was found to be $CaHPO_4.2H_2O$ and $CaH_4(PO_4)_2.H_2O$ with a region between, which was not explored, where the composition of the solid was probably $CaHPO_4$.

3. This result is in accord with Bassett's last determination of the transition interval of $CaHPO_4.2H_2O \rightleftarrows CaHPO_4 + 2H_2O$ but is not in accord with his direct determination of the compositions of the solid phases.

BUREAU OF SOILS,
U. S. DEPT OF AGRICULTURE,
WASHINGTON, D. C.

BASIC NITRATE OF YTTRIUM.

BY C. JAMES AND L. A. PRATT.

Received May 7, 1910.

Of all the methods that have been published for the separation of yttrium and erbium, the classic procedure of Bahr and Bunsen[1] still serves best. It was therefore considered that a study of the system Y_2O_3, N_2O_5, H_2O would be highly interesting.

The only basic nitrate mentioned by Bahr and Bunsen was given the formula (recalculated) $2Y_2O_3.3N_2O_5.9H_2O$, which was derived from the analysis of the air-dried salt. It is highly probable that their compound was contaminated with normal nitrate from adherent mother liquor.

---

[1] *Ann.*, 137, 1 (1866).

In order to study the system Y_2O_3, N_2O_5, H_2O, it was necessary to prepare a comparatively large amount of pure yttrium oxide, since yttrium nitrate is extremely soluble.

The Preparation of Yttria Material.—The crude yttria earths were first submitted to a long fractional crystallization by the bromate method.[1] By this procedure samarium, gadolinium, terbium, dysprosium and holmium separated in the least soluble portions. The middle fractions contained yttrium, together with a little erbium and holmium, while the most soluble portion carried nearly all the erbium and all the thulium, ytterbium, lutecium and scandium.

The middle fractions were then precipitated as the hydroxide and well washed with boiling water. The hydroxides were next converted into the nitrates and the latter subjected to fractional decomposition. This was carried out by evaporating the solution and fusing until a portion had decomposed. The evolution of red fumes was allowed to proceed until the surface acquired a peculiar steely appearance. This point was easily ascertained by experience. The decomposition was not allowed to continue until the mass became creamy.

In order to find the best method of obtaining the solution of the melt, several plans were tried. It was discovered that the simplest way was to pour the fused mass into cold water. Great care was required in order to prevent spattering. The result of this operation was a nicely granulated product, which rapidly disintegrated upon boiling.

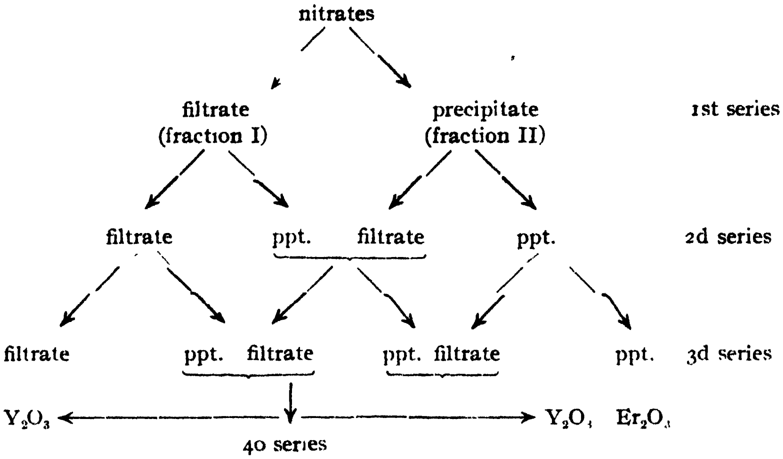
Under the best conditions the entire mass went into solution; especially was this true of the yttrium end of the series. Upon cooling, the basic nitrates separated out in a crystalline form. At the opposite end—the least basic portion—of the fractions there always remained an insoluble basic nitrate, unless the decomposition was stopped at an earlier stage, *i. e.*, when there was a copious evolution of red fumes.

In case a precipitate remained, it was highly important that it should be well agitated by thorough boiling. After cooling, the precipitate was filtered off (Fraction II), redissolved in nitric acid and again fused. The filtrate (Fraction I) was also boiled down, and fused. This second series gives two filtrates and two precipitates. The filtrate from Fraction II was mixed with the precipitate from Fraction I with the result that the second series contained three fractions. The diagram below will readily show the manner in which the work was carried out.

About 40 series of operations were carried out, yielding two kilos of yttrium nitrate. The nitrate was dissolved in water, heated and precipitated by means of oxalic acid. The resulting oxalate was filtered off, well washed, dried and ignited.

---

[1] THIS JOURNAL, 30, 182.



The white oxide obtained in this way was dissolved in an excess of nitric acid, and twice crystallized from this solvent.

A saturated solution of the nitrate was then prepared by using 1 kilogram of the salt. The spectroscope showed only very faint bands of erbium and holmium when viewed through a layer 12.5 cm. thick and the solution was perfectly colorless. Therefore, it was considered sufficiently pure for the study of the basic nitrates.

Some of the remaining fractions of yttrium, which still contained a little erbium and holmium, were put through a modified chromate method. This yielded a further supply of yttrium oxide of such a purity that, when converted into a concentrated solution of the nitrate, it showed no absorption bands through a layer of about 5 cm.

Twenty-two solutions were prepared, in regularly increasing concentrations of yttrium nitrate, from great dilution to a saturated solution. These solutions together with an excess of yttrium oxide were placed in bottles of 100 cc. capacity, and rotated in a thermostat at 25°. After an interval of three months, several of the solutions were analyzed. During the analysis, it was observed that the solid phase, in those solutions having a fairly high concentration of yttrium nitrate, was composed of fine crystals. These bottles cleared in a comparatively short time so that the supernatant liquid could be readily drawn off. In the bottles, where the concentrations were not so great, the solid phases settled with difficulty, and had more the appearance of a hydroxide. After four and a half months of rotation, the system was found to be in equilibrium. The solutions were withdrawn, and the yttrium, present as the hydroxide and the total yttrium determined.

Several difficulties were encountered in carrying out these analyses, and different methods were tried in order to reduce errors to a minimum. The following methods gave the most accurate and rapid results:

A weighed amount of mother liquor was, after considerable dilution, titrated to the neutral point with standard nitric acid (approximately $^1/_{10}$ normal) using methyl orange as the indicator. From this, the amount of yttrium oxide, present as hydroxide, was easily calculated. Checks, which were run on several of the solutions, proved that dependence could be placed upon the results obtained.

In order to determine the total yttrium, the solutions, which had previously been titrated, were diluted to 200 cc. Aliquot portions of these diluted solutions were warmed, and treated with a slight excess of an oxalic acid solution. After being allowed to stand for some time, the precipitate was filtered off, dried, and carefully ignited to the oxide in a weighed platinum crucible.

The data obtained from the analyses of the solutions are given in Table I and shown graphically in Fig. 1.

Bottle No. 21 contained an excess of both basic yttrium nitrate and yttrium nitrate. Bottle No. 22 contained only an excess of yttrium nitrate, which gave for the solubility of this compound at 25° 141.6 grams per 100 grams of water.

For the analysis of the solid phase, the sample was withdrawn, freed, as far as possible, from adhering mother liquor, by pressing between filter paper, after which it was quickly transferred to a weighing bottle and carefully mixed. A known amount was then ignited in a weighed platinum crucible for total yttrium. In another portion of the same sample the yttrium oxide as yttrium hydroxide was estimated by dissolving a weighed amount in an excess of standard nitric acid, and titrating back to neutrality with a sodium carbonate solution of known ratio. In this case methyl orange was again used as the indicator.

---

[1] This result undoubtedly contains a slight error, but, unfortunately, the bottle was emptied before it could be checked.

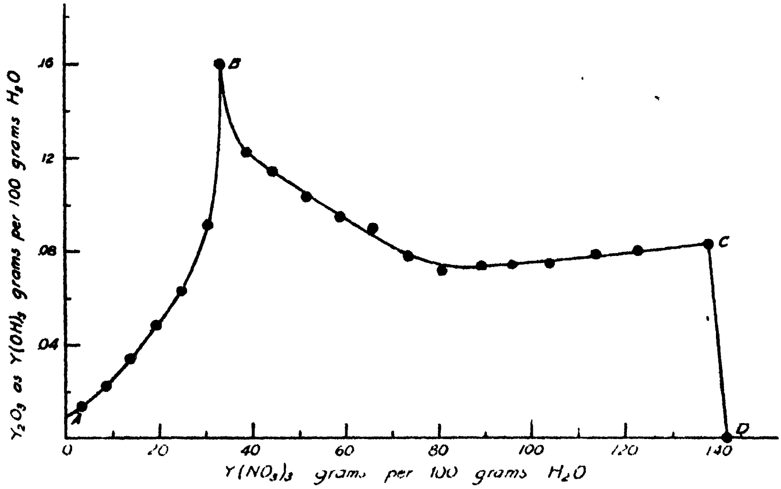

Fig. 1.

The results are given in Table II, and plotted on the triangular diagram in Fig. 2.

TABLE II.

Point.	Solutions.		Point.	Solids.		Bottle No
	Y_2O_3.	N_2O_5.		Y_2O_3.	N_2O_5.	
E	1.26	1.79	E′	49 55	13.29	1
F	3.19	4 55	F′	45.20	12.96	2
G	5.04	7.18	G′	42 97	13.74	3
H	6.61	9.42	H′	47.82	14.56	4
I	9.65	13.74	I′	41.67	16.22	6
J	11.54	16.42	J′	39.78	26.98	8
K	12.69	18.08	K′	38.09	26.93	9
L	15 23	21.75	L′	38.21	27.89	11
M	16.36	23.39	M′	38.39	28.12	12
N	17.38	24.83	N′	38.19	28.70	13
O	18.37	26.28	O′	38.44	29.19	14
P	19.38	27.73	P′	37.83	29.58	15

It will be seen that the lines (EE′, FF′ and GG′, etc., of Fig. 2) joining points represented on curve AB of Fig. 1 do not intersect at a common point; also the solids, upon examination, showed a great resemblance to yttrium hydroxide. Therefore the precipitates along this line can only be solid solutions. Lines joining any points along the curve BC (Fig. 1) meet at a common point x, which corresponds to a definite hydrated basic nitrate of yttrium possessing the formula $3Y_2O_3.4N_2O_5.20H_2O$.

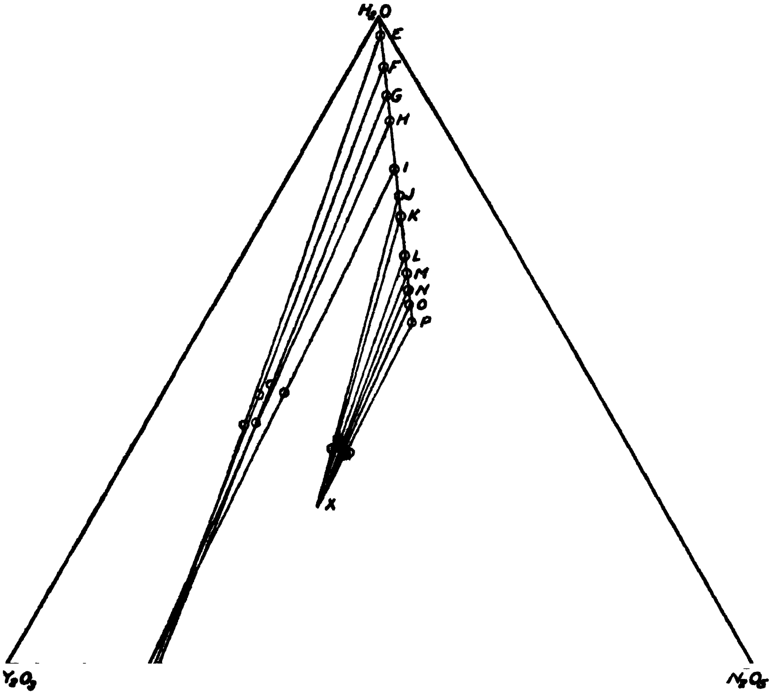

Fig 2.

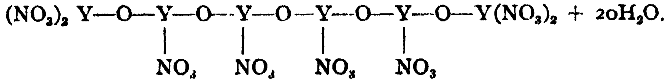
The basic nitrate consisted entirely of small crystals, which were rapidly decomposed by water. The compound, however, was not affected by continued washing with absolute alcohol, and, since the normal nitrate is very soluble in this liquid, it could be entirely separated from the basic nitrate. The solids from several bottles along the curve BC were filtered upon a Hirsch funnel, washed with absolute alcohol, air-dried, and analyzed. The results obtained were as follows:

Calculated	Y_2O_3..............	46.10	N_2O_5.....	29.40	H_2O	24.50
Found (bottle 10)	Y_2O_3..............	46.09	N_2O_5.....	29.55	H_2O (diff.)	24.36
Found (bottle 11)	Y_2O_3..............	45.96	N_2O_5.....	29.67	H_2O (diff.)	24.37
Found (bottle 13)	Y_2O_3..............	45.82	N_2O_5.....	29.67	H_2O (diff.)	24.51

The basic compound from still another bottle was dissolved in yttrium nitrate solution, and recrystallized after filtering. The mother liquor was separated by suction, the crystals washed with absolute alcohol, and air-dried. The analytical results obtained agreed well with the above as may be seen:

Y_2O_3............... 45.82 N_2O_5............. 29.67 H_2O........... 24.51

For this compound the authors offer the following complex formula:



$$(NO_3)_2\,Y{-}O{-}\underset{\overset{|}{NO_3}}{Y}{-}O{-}\underset{\overset{|}{NO_3}}{Y}{-}O{-}\underset{\overset{|}{NO_3}}{Y}{-}O{-}\underset{\overset{|}{NO_3}}{Y}{-}O{-}Y(NO_3)_2 + 20H_2O.$$

From the foregoing work the following conclusions are drawn:

First, that the basic compound mentioned by Bahr and Bunsen does not exist. Their results were undoubtedly due to adherent normal nitrate.

Secondly, the only basic nitrate that does exist at 25° is the one corresponding to the formula $3Y_2O_3.4N_2O_5.20H_2O$.

Thirdly, this compound is stable in air and can exist in contact with water containing more than 33 grams of yttrium nitrate to 100 grams of water.

THE RATE OF EXTRACTION OF PLANT FOOD CONSTITUENTS FROM THE PHOSPHATES OF CALCIUM AND FROM A LOAM SOIL.

By James M. Bell.

Received March 28, 1910.

In a recent paper[1] entitled "Ein Beitrag zur Düngemittel und Bodenanalyse," E. A. Mitscherlich, R. Kunze, K. Celichowski, and E. Merres, have investigated the rate of solution of two phosphates of calcium and the rate of extraction of lime from a loam soil, by water saturated with carbon dioxide. The conclusion was reached that the usual equation expressing the rate of solution does not accord with their data. In this equation, *viz.*:

$$dy/dt = k(A - y) \qquad (1)$$

which when integrated becomes

$$\log (A - y) = \log A - kt \qquad (2)$$

A represents the concentration of the solution when final equilibrium is reached. In applying these equations, however, the authors have mistaken the significance of A; since the value of A used by them was the total quantity of the salt which was originally mixed with the carbonated water, and not that portion of salt which the liquid was capable of dissolving. Only when the quantity of salt added to the water is just sufficient for saturation is the above procedure valid. Since in the experiments, two different original ratios of dicalcium phosphate to water were employed, *viz.*: 1 : 750 and 1 : 1500, at least in one case (and probably in both) a wrong value was assigned to A. In the case of tricalcium phosphate four different ratios of salt to water were employed, *viz.*: 1 : 1500, 1 : 2000, 1 : 3000, and 1 : 6000. So that in three of the four series, and probably also in the fourth, incorrect values were assigned to A.

---

[1] *Landw. Jahrb.*, 39, 299 (1910).

As the above equations under these conditions failed to accord well with the data, a modified form of equation (2) has been proposed by the above authors,

$$\log (A - y) = \log A - ct^n \ldots\ldots\ldots\ldots (3)$$

in which A represents the total quantity of the salt and c and n are constants. It seems to me proper, therefore, to recalculate the results, in order to determine whether equations (1) and (2) are really out of accord with the data.

Before discussing the recalculated results, several features of solution phenomena should be recalled. It is obvious that the rate of solution of any substance depends upon its exposed surface. Where the substance is in grains of widely different sizes, it is not possible to deduce any *rational* equation representing the rate of solution of such an aggregation of particles. And further, if any *empirical* equation is found to conform with the data for material in one mechanical condition, that equation will not, in general, describe the rate of solution of material which is chemically the same but mechanically different. Consequently experiments on rate of solution have usually been carried out with large crystals of low solubility, the surface changing but slightly during the course of the experiment. It is apparent also that an aggregation of crystals of uniform size and of low solubility may be considered as of constant surface during the solution.

In the experiments of Mitscherlich, Kunze, Celichowski, and Merres powdered material was probably used, but no statement is made as to its mechanical condition. The data indicate that the surface exposed must have altered considerably, for in the experiments with dicalcium phosphate over half of the phosphoric anhydride was extracted, and in the experiments with tricalcium phosphate, at least 45 per cent. of the phosphoric anhydride was extracted. Consequently, even if the proper value of A (the total quantity of phosphoric anhydride in solution at equilibrium) had been used in the calculations, the usual equation for rate of solution might have failed because of the great changes in the extent of surface.

In the tables the first figures give the concentration of the solution one hour after the salt and water were mixed. In my recalculated results, this has been taken as the starting point of the reaction, for the following reasons: In every case more phosphoric anhydride passed into solution within the first hour (within which no determinations were made) than in the remaining time of the reaction (23-47 hours). Thus, calculated on the basis of 45.55 per cent. phosphoric anhydride in dicalcium phosphate, in one case the increase was from 20.16 per cent. after 1 hour to only 23.03 per cent. after 47 hours more, and in the other case the variation was between 35.09 per cent. and 39.67 per cent. Similarly for tricalcium phosphate with 43.22 per cent. phosphoric anhydride, the increases for four experiments were as follows: From 14.92 per cent. after 1 hour to 19.83 per cent. after 47 hours more; from 17.24 per cent. after 1 hour to 24.69 per cent. after 24 hours; from 20.99 per cent. after 1 hour to 34.55 per cent. after 48 hours; and from 21.46 per cent. after 1 hour to 42.14 per cent. after 24 hours. Thus, for most of the cases, the solution has been very close to equilibrium, and the extent of surface has probably changed but little. For the last two cases given (Tables V and VI) however, the changes in surface have been considerable. In the recalculated results this surface factor has been assumed constant, a legitimate assumption in all but two cases (Tables V and VI). Even in these two cases, in spite of this objection to the application of the usual equation, it will be seen that the equation describes the facts at least as well as the empirical equation proposed by the above authors.

TABLE XXI.—RATE OF SOLUTION OF LIME FROM A LOAM SOIL BY WATER SATURATED WITH CO_2. RATIO OF SOIL TO WATER, 1 : 10. TEMP. 30° C.

	Original.		Recalculated.			
t.	y found.	y calc. from eqn. (16)	$T = t - 2$	$Y = y - 0.1087$.	Y calc. from eqn. (17).	y calc. = $Y + 0.1087$.
2	0.1087	0.1069	0	0	0	0.1087
4	0.1199	0.1232	2	0.0112	0.0107	0.1194
8	0.1342	0.1378	6	0.0257	0.0264	0.1351
11.5	0.1461	0.1450	9.5	0.0374	0.0360	0.1447
16	0.1520	0.1511	14	0.0433	0.0436	0.1523
24	0.1572	0.1578	22	0.0485	0.0512	0.1599
32	0.1631	0.1620	30	0.0544	0.0544	0.1631

$$\log (0.18 - y) = (0.2553 - 1) - 0.315\sqrt[3]{t} \dots\dots \quad (16)$$

$$\log (0.057 - Y) = \log 0.057 - 0.045T \dots\dots \quad (17)$$

From the above tables it is evident that the results calculated by the usual velocity equation are in as good accord with the observed values, as are the results calculated by the empirical equation (3) proposed by the above authors.

Finally it should be observed that A, which is the maximum quantity of phosphoric anhydride which the liquid can extract, is not identical in Tables I and II, or in Tables III to VI. If the phenomenon being measured were one of solution only, this would of course, be a legitimate objection to these calculations. But it has been shown that when water acts on dicalcium phosphate or tricalcium phosphate a decomposition results, the solution having a higher ratio, $P_2O_5 : CaO$, than the remaining solid.[1] The same sort of hydrolysis undoubtedly takes place when carbonated water is used as a solvent. With a hydrolysis whose extent depends on the original ratio of salt to water, the quantity of phosphoric anhydride in solution at equilibrium depends on the quantity of salt originally employed, and hence A will vary with the conditions of the experiments.

---

[1] Cameron and Bell, *Bull.* 41, Bureau of Soils, U. S. Dept. Agr.

In this paper it has been shown that notwithstanding the conditions militating against the use of the ordinary equation for rate of solution, *viz.*: the variable extent of surface and the fact that the phenomenon observed is not one of solution only but also of hydrolysis, this equation describes the data at least as well as the empirical equation proposed by Mitscherlich, Kunze, Celichowski, and Merres.

The usual equation for rate of solution also describes very well the extraction of lime from a loam soil by carbonated water.

NOTES.

Red Lines for a Balance Scale.—Having occasion recently to purchase a balance, it occurred to me that, as color contrast is an aid to vision, it might be of assistance in reading the variations of the needle on a balance scale, and I therefore instructed the makers to equip the balance with an ivory scale having *red* lines, instead of the usual black ones.

This was done, and the result has justified my anticipations. The contrast between the black needle and the red lines on a white background is restful and pleasing to the eyes, and enables a close weighing with less eye-strain than with the black lines.

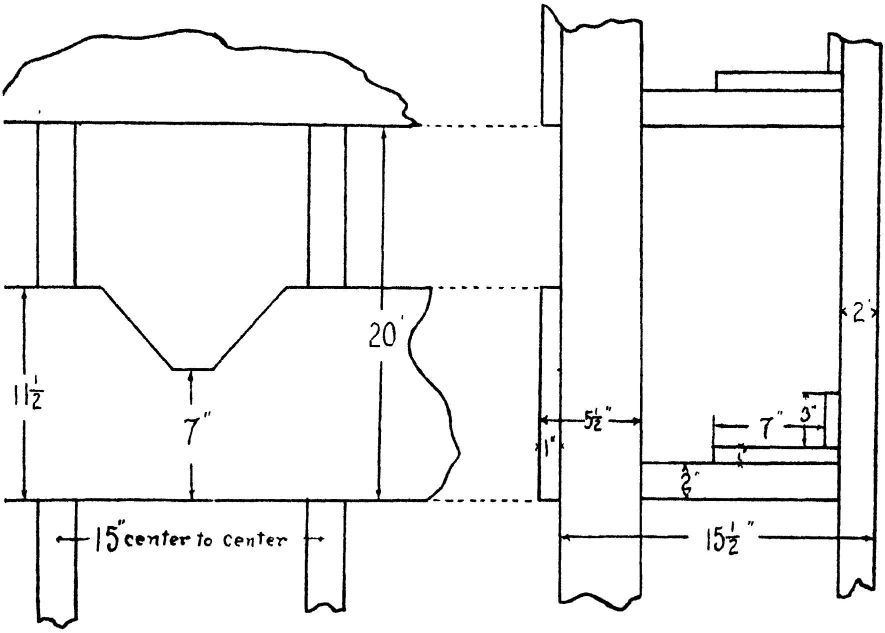
No extra expense was incurred in making the change from black lines to red, and I would recommend such innovation to those contemplating the purchase of a balance. C. M. CLARK.

Rack for Holding Reagents in Bulk.[1]—The bottle rack that we designed for our building to store the common stock solutions in five-gallon quantities is a framework of two-inch square material. Each row holds thirteen bottles, which are held apart, both in front and back, by uprights of the same material. For each bottle there is, therefore, a frame compartment. The bottles are kept from the wall by a three-inch board, nailed to the floor of each shelf at the rear of the rack. Along the front of each tier runs a board with a "V" shaped cut in the middle of each compartment on the sides of which the bottles rest. This prevents them from rolling. It also allows the bottles to be placed in the rack on their sides, at an angle which gives the maximum room for the solution and uses up the minimum amount of space. A glass siphon runs to the lowest portion of the bottle through a notched cork or rubber stopper, and is closed at the outer end by means of a rubber tube and a pinch clamp. Smaller bottles can thus be neatly and quickly filled without lifting the heavy, cumbersome stock bottles.

The solutions are made concentrated, according to a formula, and then the bottle is placed in the rack, and the siphon inserted. A rubber tube leading from the distilled water tap is then connected to the lower end of the siphon and the bottle filled. The strong current of water entering at the deepest part of the solution acts as sufficient stirrer to thoroughly mix the solution and secure uniform density.

---

[1] Published by permission of Dr. Charles Baskerville, Director of the Chemical Laboratory, College of the City of New York.



In this way a large number of bottles can be compactly stored and the solutions are easy of access. The framework structure allows the bottles to be cleaned without removing them from the rack, as they are exposed on all sides. All dirt can be brushed down into the inclined lead-lined drip trough at the base of the rack and flushed off. J. Lorenz Sporer.

[Contribution from the Bureau of Chemistry, U. S. Dept. of Agriculture.]

IS THE HYDROLYSIS OF CANE SUGAR BY ACIDS A UNIMOLECULAR REACTION WHEN OBSERVED WITH A POLARISCOPE?

By C. S. Hudson.

Received May 9, 1910.

It may be recalled that in 1908 Julius Meyer[1] expressed the view that the hydrolysis of cane sugar by acids is accompanied by two simultaneous reactions, the mutarotation of glucose and fructose, and published experiments which seemed to show that the hydrolysis when observed with the polariscope deviates slightly from the unimolecular order during the first 3 or 4 per cent. of the reaction. In the same year the author[1] showed that the hydrolysis of cane sugar by the enzyme invertase is certainly accompanied by these mutarotation reactions, but claimed that the acids catalyze the mutarotations so greatly that they are not of detectable influence in the hydrolysis of cane sugar by acids. Meyer's experiments, which seemed to show such an influence, were criticized on the ground that the possible errors in them were greater than Meyer had estimated and even greater than the deviation from the unimolecular order which he recorded. Essentially the same criticism has also been made by Bodenstein.[2] In a reply to these objections Meyer[3] has lately insisted on the great accuracy of his experiments and claims that he did indeed detect the mutarotation reactions during the hydrolysis of cane sugar by acids.[4] If the question were only a difference of opinion regarding the accuracy of Meyer's experiments the discussion could well be closed because all three parties are agreed on the principal point, namely, that the hydrolysis of cane sugar is not the simple reaction that it has heretofore been supposed to be, but is accompanied by two other important reactions. But Meyer goes further than this and claims[5] that he first proved experimentally the existence of these subsidiary reactions, and on account of this claim, which appears to me quite unwarranted, the following further criticism of Meyer's experiments is made. In it I will seek to show that Meyer has repeated portions of his measurements and found them to be entirely erroneous, that Armstrong and Caldwell made measurements similar to Meyer's four years in advance of him and found numbers which are different even in sign from Meyer's, that the deviation which Meyer claims he found is opposite in sign from that predicted by the very theory which he was testing, that certain obvious precautions which are necessary for the accuracy that Meyer attempted to reach were overlooked, and that his latest measurements contain certain self-evident errors of great size.

---

[1] *Z. physik. Chem.*, **62**, 59–88 (1908).

In Meyer's first article the mutarotation of fructose was found to have the velocity coefficients 0.017 at 18° and 0.027 at 25°. In response to a letter from me he has measured these values again and now finds 0.18 at 18° and 0.32 at 25°, values which are tenfold greater than his former ones. Although he thus admits that one set of his measurements was entirely incorrect, he insists that another set of a similar though not identical kind, namely that in which the minute deviation was supposedly detected, contains no error greater than about one-tenth of 1 per cent. The experiments were made under the same conditions, and great accuracy is claimed for one set and great error admitted for the other; comment would hardly seem necessary.

[4] In replying to my criticism Meyer has made an arithmetical error (p. 119) in which he confuses 3 per cent. with three-tenths of 1 per cent. and this difference refutes his own argument. It will be sufficient time to discuss the bearing of this portion of the reply after he publicly corrects this error. He has also confused α- and β-fructose on pp. 117 and 122.

[5] *Z. physik. Chem.*, 72, 117 (1910).

In 1904 Armstrong and Caldwell[1] made polariscopic measurements to test whether the hydrolysis of cane sugar by acids follows the unimolecular order and came to the conclusion that it does not, and that the velocity-coefficient of the reaction *increases* slightly during the inversion instead of remaining constant as is required by the theory. Meyer's measurements lead him to the conclusion that the velocity-coefficient *decreases* during the inversion. Meyer has not mentioned this work of Armstrong and Caldwell, nor the older work of O'Sullivan and Tompson,[2] who were the first to show that the mutarotation of glucose accompanies the inversion of cane sugar by invertase, nor the work of the author,[3] which shows that the mutarotation of both glucose and fructose follows slowly on the hydrolysis by invertase. It would seem that he should at least discuss the cause of the disagreement between his detection of the *decreasing* coefficient and Armstrong and Caldwell's of an *increasing* one, particularly in view of the fact, which I shall immediately explain, that a *decreasing* coefficient is not in agreement with the theory which Meyer was testing.

Meyer supposes that the mutarotation of glucose and fructose following the inversion of cane sugar would cause the reaction as measured by the polariscope to show a decreasing coefficient, and as he found a decreasing one in his experiments he claims that he has proved experimentally the correctness of the theory. The mutarotation of fructose proceeds so much faster than that of glucose that the influence of the former may be neglected in comparison with that of the latter. The glucose which is first formed is known to be α-glucose, of specific rotation 110°, and it subsequently passes to the stable mixture of α- and β-glucoses, of specific rotation 52°. If now the mutarotation of glucose is comparable in rate with the inversion of cane sugar, the glucose resulting from the hydrolysis will contain an excess of α-glucose and have a specific rotation higher than the stable mixture, 52°. As it is assumed in calculating the velocity-coefficient of the hydrolysis from the polariscopic readings that the glucose has the specific rotation 52°, the presence of an excess of α-glucose, due to the comparative slowness of the mutarotation reaction, must cause the inversion to appear slower than it really is. During the further progress of the inversion the excess of α-glucose diminishes and therefore the polariscopic readings in the late stages of the reaction give a true measure of the extent of the hydrolysis. Such a reaction, in which there is an error of this kind causing it to apparently go slower in its initial stages than it really does, must give an *increasing* velocity-coefficient during its progress. Meyer found however a *decreasing* coefficient, which is thus quite at variance from the theory which he claims he has proved by detecting such a coefficient. It would seem to the author that this point should be a conclusive objection to Meyer's claim that he proved the existence of the mutarotation reactions in the hydrolysis of cane sugar.

[1] *Proc. Roy. Soc. London*, 74, 195–201 (1904).

[2] *J. Chem. Soc.*, 57, 834–931 (1890).

[3] THIS JOURNAL, 30, 1160–6, 1564–83 (1908); 31, 655–64 (1909).

It is to be objected to the experiments of both Meyer and Armstrong and Caldwell that a source of considerable error was not considered, namely the fact that the specific rotation of fructose increases with its concentration; thus in the hydrolysis of a 20 per cent. cane sugar solution the fructose increases in concentration from zero to about 10 per cent., which involves according to the measurements of Hammerschmidt[1] and others, an increase of 2 per cent. in the specific rotation of fructose. If the progress of the inversion is calculated from the polariscopic readings under the assumption that the specific rotation of fructose remains constant during the reaction, the velocity coefficient must be expected to increase. The changing concentrations of glucose and cane sugar also involve similar corrections, but they are small in comparison with that for fructose. This error would affect the velocity coefficient in the same manner that the mutarotation of glucose would, and until it is accurately investigated it cannot be claimed that an *increasing* coefficient proves the occurrence of the mutarotation during the hydrolysis of cane sugar by acids; and of course the claim of Meyer, who found a *decreasing* coefficient, is quite unreasonable.

Lastly, as an illustration of the inaccuracies which occur in Meyer's measurements, and in refutation of his insistence that both Bodenstein and the author have done him the injustice of underestimating the accuracy of his work, it may be mentioned that he records[2] as the final rotations of two fructose solutions of the same concentration, prepared from the same sample, and measured in tubes of the same length, —14.40° at 25° and —14.41° at 18°. It is well known that fructose has one of the largest temperature coefficients of rotation ever found, namely 0.007° per degree of rotation per degree rise of temperature.[3] Other observers, including Dubrunfaut, Zecchini, Dafert, Hönig and Jesser, Jungfleisch and Grimbert, Wiley, Borntraeger, and Ost,[4] have invariably detected a change of rotation for such solutions of (14.40) (0.007) (7) = 0.69°, or over half a degree, but Meyer did not find any appreciable difference at the two temperatures. With this error of half a degree plainly visible in his published work it is impossible to agree with him that such readings as 40.45° and 40.41° differ beyond his experimental error; and yet the deviation from the unimolecular order which he found the inversion of cane sugar by acids to show, depends on the reality of the difference between such measurements.[1]

The rates of the inversion of cane sugar and the mutarotation of glucose at different temperatures and acid strengths have been measured by various investigators, and it is possible to calculate from them the deviation which is to be expected from the unimolecular order due to the mutarotation of the glucose. The author has made such a calculation and finds the deviation to be, under the most favorable conditions of temperature and acidity, a very small quantity only about a tenth of 1 per cent. It agrees in magnitude and sign with the deviation which Armstrong and Caldwell found and it is quite possible that the mutarotation reaction is responsible for a portion of their deviation, but the change in the specific rotation of fructose which has been mentioned, causes a deviation in the same direction and the two possible causes of the deviation leave the matter still in doubt as to whether Armstrong and Caldwell's deviation is due to mutarotation, change of rotation of fructose, or a true exception to the law of mass-action, which latter view is the one that Armstrong and Caldwell hold. But there can be no reasonable further doubt regarding the cause of Meyer's deviation—it was due to experimental errors alone, and is opposite in sign to the deviation predicted by theory.

A REVIEW OF DISCOVERIES ON THE MUTAROTATION OF THE SUGARS.[2]

By C. S. Hudson.

Received May 9, 1910.

Dubrunfaut[3] discovered in 1846 that the specific rotation of a freshly prepared cold solution of crystalline glucose decreases from an initial value of about 110° to become constant at 52°. This phenomenon he named *birotation* but later discoveries have shown the name to be inappropriate and the better term *mutarotation*, which was introduced by Lowry[4] in 1899, has generally replaced it, though the word *multirotation* is also in use. In addition to glucose the following crystalline sugars have been found to show mutarotation: lactose,[1] galactose,[2] arabinose,[3] maltose,[4] xylose,[5] fructose,[6] fucose,[7] rhamnose,[8] mannose,[9] rhodeose,[10] gentiobiose,[11] melibiose,[12] perseulose,[13] and several rare synthetic sugars. All of these sugars reduce Fehling's solution and combine with phenylhydrazine, proving that they are aldoses or ketoses and contain the carbonyl group; on the other hand such sugars as sucrose, raffinose, gentianose, and stachyose, and the polysaccharides starch, inulin, mannan, etc., and the glucosides salicin, amygdalin, helicin, arbutin, etc., none of which show the characteristic reactions for the carbonyl group, do not exhibit mutarotation. This proves that the mutarotation is in some way dependent upon the carbonyl group.

After Dubrunfaut's great discovery the next important observation on mutarotation was made by E. O. Erdmann[14] in 1855, who noticed that lactose occurs in two crystalline modifications, one having a higher rotation (86°) than that of the stable solutions (52°), and the other a lower rotation (36°), and each form showing mutarotation towards the same final rotation (52°). Erdmann measured the rates at which each form changes in rotation to that of the stable solution, but did not notice that the rates are the same in value and that this fact is of much theoretical significance. Many years later, after the principles of chemical dynamics became better known, the author[15] showed that these equal rates prove that the two changes of rotation are not different reactions but are opposite parts of one balanced reaction. In this way the mutarotation of lactose, and what is true of this sugar is doubtless true of all which show mutarotation, was proved to belong to the great class of balanced reactions.[16]

In 1859 Anthon[17] noticed that crystalline glucose forms its saturated solutions in cold water very slowly even when the mixing is vigorous; this fact was discovered for lactose by Mills and Hogarth[18] in 1879. It is now known that this slowness of the process of solution is caused by the same slow balanced chemical reaction, involving the carbonyl group, which causes the mutarotation, and that it is a general property of all the aldehyde and ketone sugars.[1]

The first attempt to find the physical law which governs the rate of the mutarotation was made by Mills and Hogarth[2] in 1879, but the result was only an empirical formula and must be regarded as unsatisfactory. It is to Urech[3] that we owe the first real progress in this line. He showed by a series of experiments during 1882–5 that the mutarotation follows the law of unimolecular reactions. It is interesting, and to some minds instructive, to note that this correct beginning in the physico-chemical study of the long unsolved mutarotation reaction was coincident in time with the beginning of the modern theory of solutions and chemical dynamics. There can be little doubt that Urech's experiments, which are the starting point of all exact work on mutarotation, were suggested by the advances that were being made at that time in the study of chemical dynamics by the new physico-chemical school.

In 1888 Brown and Morris[4] and Arrhenius[5] observed that the freezing temperatures of glucose solutions remain unchanged during the process of mutarotation, which proves that the reaction which causes mutarotation is not a polymerization or dissociation of the sugar. More recently Roth[6] has detected a slight change in freezing temperature of concentrated solutions of anhydrous glucose on standing but this is doubtless due to hydration and does not alter the conclusion from the work of Brown and Morris and Arrhenius, because a polymerization or dissociation would also affect the freezing point of dilute solutions, and the investigators are all agreed that such an effect is not discernible.

In 1890 O'Sullivan and Tompson[7] noticed that the invert sugar which is produced by the hydrolytic action of the enzyme invertase on sucrose shows mutarotation; this fact was later investigated by E. F. Armstrong[8] and has been precisely studied lately by the author.[9] These researches have shown that the glucose which is liberated from sucrose is α-glucose and the fructose is a hitherto unknown form of this hexose, α-fructose; these facts show that sucrose has the constitution α-glucose $<>$ α-fructose. The new form of fructose has not as yet been obtained crystalline. This method for determining the constitution of the polysaccharides by studying the mutarotation of the sugars which are formed by their enzymotic hydrolysis was first used by E. F. Armstrong[2] in his correlation of the α- and β-methylglucosides with the α- and β-glucoses. In applying the method to other substances such as cane sugar where two mutarotating sugars are formed at the same time it is necessary to extend the theoretical considerations; a mathematical theory of the modified method of Armstrong and an experimental demonstration of it has recently been published by the author.[1]

In 1895 Charles Tanret[2] discovered a new form of crystalline glucose which was found to have a specific rotation lower than that of the stable solution (52°), though its value increased to this on standing. This discovery is the complement to Dubrunfaut's and the two must cause chemists the world over to be grateful to French science, because more fruitful single discoveries in the chemistry of the carbohydrates have hardly been made. Tanret found the final rotation of glucose solutions to be the same whether the solution is made from the higher or the lower initially rotating form. He interpreted his results as proving that three forms of glucose exist, one of high rotation, one of low, and the third the form to which each of these changes in aqueous solution. About the same time Tanret isolated similar new crystalline forms of rhamnose, galactose and arabinose, and obtained Erdmann's lower rotating form of lactose practically pure. Tanret's striking discoveries immediately caused new interest to be taken in the problem of mutarotation. In 1899 Lowry[1] advanced the view that the mutarotation of glucose is caused by a balanced reaction between the highest and lowest rotating forms of the sugar, a view which may be expressed by the equation *α-glucose* $\rightleftarrows$ *β-glucose*. This explanation is essentially different from any that preceded it and later investigations have proved it to be entirely correct. On the other hand, Lowry did not support this hypothesis with any direct proof and it remained without such proof for several years. In 1902[3] the author published the same view as an explanation of the mutarotation of lactose, being at that time unacquainted with the publication of Lowry. The explanation may be expressed by the equation α-lactose $\rightleftarrows$ β-lactose, and experimental evidence for the view was given by measurements on the heats of solution of the three forms of lactose, which showed that the stable form to which α- and β-lactose change in solution is not a chemical individual, as Tanret had supposed, but is a mechanical mixture of α- and β-lactoses. In 1903 the author[4] measured the slow maximum rate of solution of α-lactose and showed that the slowness of dissolving, which had been discovered by Mills and Hogarth,[1] is caused by the balanced reaction which produces the mutarotation. By quantitative measurements the hypothesis of the balanced reaction was tested and proved, and the explanation which these measurements gave of the mutarotation of lactose was immediately accepted by such an authority as Nernst.[5] In the same year Lowry[6] published similar experiments on glucose and proved the suggestion which he had advanced in 1899. These questions of priority are here stated for the reason that E. F. Armstrong[7] has recently claimed for Lowry the discovery of the balanced reaction which causes the mutarotation, a claim which in the opinion of the author is entirely too broad.

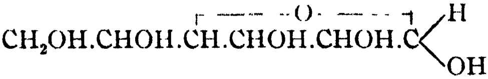
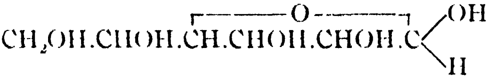
[7] "The Simple Carbohydrates and Glucosides," p. 8.

A very fruitful idea was advanced by Lippmann[1] in 1895 in the suggestion that the lactonic formula for glucose predicts two possible forms of the sugar on account of the asymmetry of the end carbon atom, the two structures being



$$CH_2OH.CHOH.\overbrace{CH.CHOH.CHOH.C}^{O}\begin{smallmatrix}H\\OH\end{smallmatrix}$$

and



$$CH_2OH.CHOH.\overbrace{CH.CHOH.CHOH.C}^{O}\begin{smallmatrix}OH\\H\end{smallmatrix}.$$

This suggestion, after a slight development by Simon,[2] was made more probable by Armstrong's discovery,[3] that the α- and β-forms of methyl glucoside are hydrolyzed by enzymes to give methyl alcohol and the α- and β-forms of glucose respectively. As the methyl glucosides show no aldehyde reactions the lactonic formulas have always been chosen for them, the hydroxyl of the end carbon atom in the structures shown above being replaced by the group OCH_3. Armstrong's discovery indicates that similar structures probably apply to the forms of glucose. This suggestion received final proof in 1909 when the author[4] showed that certain numerical relations which can only be explained by the assumption of such lactonic structures for the two forms of the sugar, hold all through the sugar group. If the rotation of the end carbon atom is B for one structure it must be $-B$ for the other, and if A is the rotation of the remaining asymmetric carbon atoms, which are common to both structures, the total rotation of the one structure is $A + B$, and of the other structure $A - B$, the difference between the two total rotations being then $2B$. This rotation B applies to all the aldoses because they contain the same end asymmetric carbon, therefore the difference between the molecular rotations of the α- and β-forms of all the aldose sugars should be a constant quantity if the sugars have the two isomeric lactonic structures. The molecular rotatory powers of the two forms of lactose, glucose, arabinose and galactose were found indeed to differ by the quantities 17600, 16000, 16200, and 15700, which are sufficiently alike to show that the theory is correct and that the two forms of each of the mutarotating sugars have the stereomeric lactonic structures. Certain other similar conclusions from the same theory were also found to agree with the rotatory powers of the sugars and their glucosidic derivatives.

The catalytic action of various substances on the mutarotation reaction has been investigated by various chemists.[5] These researches have shown that only acids and alkalies have a strong action. Osaka[6] made the first quantitative study of the relation between acidity or alkalinity and catalytic action and found that the catalysis is proportional to the concentration of the hydroxyl ions and proportional to the square root of that of the hydrogen ions. Later the author[1] showed that the proportionalities are somewhat different from this and that the rate of the mutarotation of glucose is related to the acidity and alkalinity of the solution by the expression *rate* = $A + B(H^{\cdot}) + C(OH')$, where A, B, and C are constants at constant temperature. This formula has lately been used as the basis of a new method for measuring the electrolytic dissociation of water.[2] A satisfactory explanation of the fact that acids and alkalies are enormously powerful catalysts of the mutarotation while all other substances are without comparable action is lacking.

The sugars glucose, lactose, galactose, rhamnose, melibiose, arabinose, maltose, xylose and some others occur as monohydrates and these have generally been regarded as hydrated aldehydes without lactonic structure and thus intermediate forms between the two lactonic α- and β-forms of the sugars. The freshly prepared solutions of these monohydrates are identical in properties with such solutions of one of the anhydrous lactonic forms of the sugars and it is therefore to be concluded that the equilibrium between this lactonic form, whichever it may be, and the monohydrate is established instantly. For most of the sugars the lactonic form which is thus in instantaneous equilibrium with the monohydrate is the α-form, but for one sugar at least, maltose, it is the β-form. The mutarotation reaction may then be considered to be the slow change of the monohydrate into the other lactonic form by a reversible reaction, or in the form of an equation,

$$\alpha\text{-sugar} + H_2O \underset{(1)}{\rightleftharpoons} \text{monohydrate} \underset{(2)}{\rightleftharpoons} \beta\text{-sugar} + H_2O.$$

For most of the sugars the reaction 1 is instantaneous in comparison with 2, which is therefore the mutarotation reaction, but for maltose the relations are reversed. Why the monohydrate should change instantly to the α-form for some sugars, but to the β-form for others is entirely unknown and is a most interesting problem.

The mutarotation reaction is general to all the aldehyde and ketone sugars. It may indeed be called the fundamental reaction of the sugar group. While its cause remained unknown during the half century following its discovery, the last decade has brought a full explanation of it. The principal facts regarding it have been accurately measured and correlated. On the other hand the application of these facts to the elucidation of the chemical and biological reactions of the sugars, in every one of which mutarotation plays a part, has just begun, but it is even now apparent that the unfolding chemistry of the polysaccharides is to be largely a development of the mutarotation reaction.

STUDIES IN VAPOR PRESSURE: I. A METHOD FOR DETERMINING UNDER CONSTANT CONDITIONS THE BOILING POINTS OF EVEN MINUTE QUANTITIES OF LIQUIDS AND OF NON-FUSING SOLIDS.[1]

BY ALEXANDER SMITH AND ALAN W. C. MENZIES

Received June 11, 1910.

For solids which do not melt, no method of determining the boiling point ("vaporizing point") that is at once simple and accurate is available. The chemist, when he encounters such a material, is thus deprived of both of his favorite methods for the characterization of substances. The crude plan of heating the substance in a deep crucible, placed in a draft cupboard, and taking the temperature of the vaporizing solid[2] is highly inconvenient, is very wasteful of material and, as we shall see, is not accurate.

The measurement of the boiling point of a liquid, as usually made by means of a distilling flask and thermometer, is open to several objections. One of these is that, even if the whole of the mercury thread of the thermometer is immersed in the vapor, the apparatus is not such that the other conditions can be exactly specified and constantly fulfilled. Varying results are therefore obtainable with the same substance by different observers, or even by the same observer. Thus, it is a familiar fact that use of a larger flame will raise the apparent boiling point. Again, use of a sand bath, a metal bath, or a wire gauze may cause superheating of the thermometer by radiation.

---

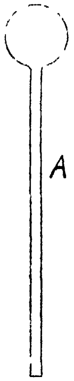
[1] Read before the American Chemical Society, Dec. 30, 1909.

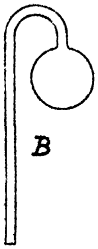
[2] V. Meyer and Harris, *Ber.*, 27, 1482.

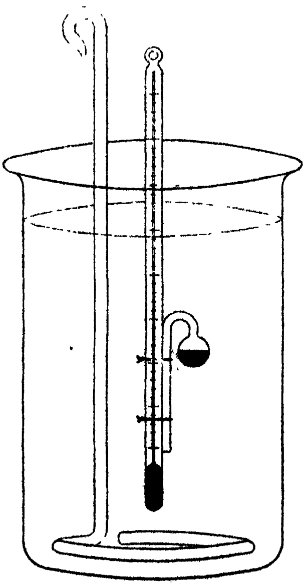
On the other hand, many liquids are easily superheated, and boil irregularly in consequence.

When the liquid boils regularly, use of a small flame, playing on the naked bulb of the flask and touching the latter only below the level of the surface of the liquid, gives the most constant and easily reproducible results. But trial will show that at least five minutes' continuous boiling is required before the thermometer reaches the true temperature. Unless the liquid is distilling over very slowly during this time, a considerable supply of the material is thus required, and must be prepared. Even if the boiling point were to be determined in a vessel attached to a reflux condenser, at least 10–20 cc. of the liquid would be required to wet the condenser and leave a sufficient amount of the liquid to cover the flame.

Surrounding the bulb of the thermometer with cotton[1] may protect the instrument from contact with superheated vapor arising from a "bumping" liquid, and so overcome one of these objections. But cotton is a bad conductor, and the air it contains is very slowly expelled, so that its use will be found to triple the time elapsing before the thermometer reading reaches the true boiling point. Its employment involves the provision of a slightly larger supply of the substance than would ordinarily be required.







Use of the apparatus here described enables one to avoid all these objections. The method automatically provides that constancy of conditions required for securing unvarying results. It enables one, also, to determine the boiling point of a solid as easily as that of a liquid. The whole operation takes no more time, and but little more of the substance than the measurement of a melting point, made with a like degree of accuracy.

The Apparatus.—A small bulb, with a wide capillary tube 3–4 cm. long and not less than 1 mm. in width

---

[1] Sydney Young, Stoichiometry (London, 1908), 141.

(figure, A) is prepared as for organic combustion of a liquid. The capillary is bent close to the bulb (figure, B), and a small amount (0.03-0.1 g.) of the liquid, or of the pulverized solid, is introduced (the latter most easily before bending). To exclude moisture, liquids may be distilled directly into a crucible or small test tube placed in a Brühl receiver, suitably desiccated. The bulblet stands stem downwards in, or hangs on the edge of, thec rucible. When the receiver is partially exhausted, and air is again admitted, the liquid enters the bulb. The bulblet, after being charged, is attached with thread or asbestos cord above the bulb of the thermometer. Use of wire is apt to cause breakage of the latter. The whole is then fixed in a beaker (preferably of tall form) filled with a transparent liquid, and provided with a glass stirrer, all just as for a melting-point determination (figure).

The Bath Liquid.—For substances boiling below 100°, the beaker may usually be filled with water, or a strong solution of calcium chloride. For substances boiling below 200°, sulphuric acid, and for those boiling as high as 280–300° melted paraffin wax (m. p. about 53°) may be employed. With substances boiling between 220° and 450° (or higher) we have used a eutectic mixture of potassium and sodium nitrates.[1] To extend the range downwards (to 120°), lithium nitrate may be added, but above 250° the lithium nitrate damages the thermometer and beaker by slowly attacking the glass and rendering it opaque. The composition of the mixtures is as follows:

$NaNO_3$.	KNO_3.	$LiNO_3$.	M. p.
18.18	54.54	27.27	120°
45.5	54.5	...	218°

When the nitrate baths are used, the melt is poured into an iron or porcelain dish and not allowed to solidify in the glass beaker. To secure a transparent liquid from a formerly turbid one, the outside of the solidified mass may be washed before being again used. The whole apparatus stands over a metal tray (*e. g.*, a "drip-pan"), which, in case of accidental breakage, catches the molten salts.

The Manipulation.—The apparatus being in order, the bath is heated and, as the boiling point is approached, is stirred vigorously. At first, a few bubbles of air are expelled in consequence of expansion. When the boiling point is reached, all the air in the submerged bulblet is quickly displaced and, provided the substance is not soluble in the bath liquid, bubbles of the vapor of the substance rise to the surface in a rapid and regular stream. On removing the flame, a fall in temperature by a small fraction of a degree interrupts the stream sharply, and a re-elevation by the same amount restores it. Since all solids have air and moisture adhering to their surfaces, and liquids are likely to contain oxygen and nitrogen and traces of water dissolved in them, a gentle stream of bubbles is allowed to pass off for a few moments before the temperature is allowed to fall preliminary to the final temperature reading. This reading is taken when, with very slowly falling temperature, accompanied by vigorous stirring, the stream of bubbles ceases. This applies only to the case of mutual insolubility of the substance and bath liquid: the procedure in the contrary case will be described presently.

---

[1] Carveth, *J. Physic. Chem.*, 2, 207; see also Scudder, This Journal, 25, 161.

The whole process should be repeated until constant readings are secured. To prevent the entrance into the bulb of the liquid from the bath, the thermometer and bulblet are finally raised out of the liquid. The barometric height (reduced to mercury at 0°) is recorded, as usual, along with the observed temperature. A necessary correction will be discussed later.

If the substance is soluble in the bath liquid, the temperature at which vapor ceases to issue cannot be observed sharply. The temperature reading is therefore taken when the bath liquid has ascended the capillary to a predetermined point, 5–10 mm. from the opening. The position of this point may be fixed by noting some mark on the thermometer or binding threads. When the substance is very soluble in the bath liquid, as alcohol is in water, the bubbles of vapor dissolve, instead of rising to the surface, and only the few bubbles of air are seen. When, in such a case, the flame is removed, and the bath liquid enters the capillary, the section of the latter is so small that the surface layer of the liquid within it quickly becomes saturated with the vapor of the substance. Hence the vapor cannot any longer dissolve nearly as fast as fresh vapor can be evolved from the substance in the bulblet. The level reached in the capillary is therefore unaffected by the tendency to absorb the vapor, and is fixed solely by the vapor pressure of the substance, which is slowly diminishing as the temperature falls.

The fact that the bath liquid may have considerable vapor pressure of its own—as, for example, when the boiling point of benzene is being determined with water as the bath liquid—has no influence on the observed boiling point. Such an influence would be observed only if the vapor of the water were able to diffuse up the capillary so as to reach the surface of the substance contained in the bulblet, and this it has no opportunity to do when the methods are used as directed. In particular the second method, involving ascent of the bath liquid into the capillary, should not be used with insoluble vapors. When thus no process of solution is occurring, the vapor of the substance is stationary and very slowly condensing. A little of the vapor of the bath liquid, if the latter has any appreciable vapor pressure, may then diffuse backwards into the bulblet. When, in such circumstances, the reading is made too deliberately, the dilution of the vapor in the bulb may lead to the reading of a temperature 0.05–0.1° too low.

Even when the vapor of the substance interacts chemically with the material in the bath, the boiling point will usually be still determinable. Thus, we have obtained serviceable boiling points of calomel with a bath of melted nitrates, although the vapor causes a slow precipitation of mercuric oxide; and of ammonium chloride, although the vapor interacts with the nitrates, giving rise to a continuous formation of nitrous oxide. In the latter instance, the temperature at the point of minimum gas-evolution was taken.

Correction for Immersed Depth.—Since the pressure, due to the height of the liquid in the beaker over the opening of the capillary in the first method, or over the point to which the liquid ascends in the capillary in the second, will raise the boiling point above that shown in an open flask, a correction of the barometric reading for this effect is required. The depth from the surface to the end of the capillary, or to the mark opposite the point to which the liquid ascended, is measured by means of a scale held in front of the beaker. This distance (in mm.) is multiplied by the specific gravity of the liquid at the temperature used and divided by the specific gravity of mercury at 0° (13.59). The result is added to the barometric reading. For ordinary purposes this distance and the specific gravity of the liquid do not need to be known with great accuracy. An error even remotely approaching 0.2 mm. of mercury in the pressure, representing an error of 2.7 mm. in the measurement of immersed depth when water is the bath liquid, could not possibly be

Sulphuric acid (92.75%)		Paraffin (M. p. 53°).		Two nitrates (Na and K).		Three nitrates (Na, K and Li).

..	...	..	...	..	...	300	1.870

made. Yet such an inconceivable error would usually involve a difference of only 0.01° in the boiling point.

The above table of specific gravities[1] may be used in making the correction. For intermediate temperatures, the value is obtained by linear interpolation.

Precautions for Special Accuracy: *Stirring, Thermometry, Capillarity.*—(1) It is necessary that temperature changes near the boiling point should proceed very slowly, and that uniform distribution of temperature be secured by violent stirring.

(2) The thermometer must be accurate, or its errors known. The usual correction for exposed thread must be made. Use of short thermometers, with a range of only 50–60° each, and of a deep beaker, will permit complete immersion of the whole thread and render this correction unnecessary. The accuracy of the readings is ordinarily limited only by the accuracy of the thermometers used.

(3) Since the tendency to capillary rise in the narrow tube contributes an added pressure, and slightly elevates the boiling point, a capillary less than 1 mm. in diameter should not be employed.

It might be expected that this pressure, due to capillary ascension, would involve an appreciable error, but this is not the case. It is true that water has an exceptionally high capillary constant—at 0° nearly 31 mm. for a tube 1 mm. in diameter, and at 100° about 25 mm. In the single case, therefore, in which the substance and the bath liquid are both pure water, this pressure amounts to 1.7 mm. of mercury, and raises the boiling point 0.06°. But the capillary constants of other liquids are usually much smaller. Thus, the ascents in a tube 1 mm. in diameter are: paraffin oil (at 100°) 10.8 mm. (= 0.6 mm. Hg), sulphuric acid (at 100° 9.8 mm. (= 1.3 mm Hg). With the nitrates, however, *when pure*, the ascent is very high. Thus the ascent of the two nitrates in a tube 1 mm. in diameter is 23.4 mm. at 270° (= 3.3 mm. Hg). When water is the bath liquid, and some other substance is contained in the bulb, then the capillary ascension of the water contaminated with the distillate is not that of water alone, but very nearly that of the substance. Thus, when the substance is one miscible with water, such as alcohol, the capillary ascent, assuming 50 per cent. alcohol within the capillary, is 10.4 mm. (= 0.7 mm. Hg). When the substance is one immiscible with water, the ascent, as is well known, is greatly reduced by the oily matter in the liquid and the tube. In the case of benzene and water, for example, at 0°, it is only about 14 mm. (= 0.9 mm. of Hg). The ascent of the nitrates is likewise reduced. Thus, when the tube is wet with an organic substance which does not mix with the salts, the elevation is of the order of the smallest of the foregoing values. Thus the correction, if any be made on this account, represents only about 1 mm. of mercury, which would raise the boiling point on an average about 0.04°. The temperature readings must therefore be accurate to less than 0 04° to justify the use of this correction. When correction on this account is desired, the capillary rise may be measured to the nearest mm. by severing the bulb from the capillary tube, wetting the interior of the latter with the substance, and dipping the tube in the bath liquid.

---

[1] These specific gravities were determined in this laboratory by Mr. F. B. Plummer, to whom we desire to express our indebtedness. The values are accurate to within one unit in the third place of decimals. The following formulas summarize the results, and give values correct to the second decimal place within the limits of temperature specified:

Sulphuric acid (92.75%, 30–200°), 1.818–0.000906 (t — 30).
Paraffin (m. p. 53°, 60–230°), 0.778–0.000612 (t — 60).
Two nitrates (230–390°), 1.968–0.00075 (t — 230).

Examples.—The following sample boiling points (not corrected for capillarity) show: (1) that the correspondence of the results given by the submerged bulblet method (column 6) with those given by the distilling flask method[1] (col. 7), both obtained with the same thermometer, is satisfactory; (2) that this correspondence is as good whether the substance is very soluble or is insoluble in the bath liquid (col. 2); (3) that the correspondence is equally good whether the bath liquid has itself a high or a low vapor pressure at the temperature concerned; (4) that the correspondence in the case of solids is also satisfactory so far as data for comparison are obtainable:

Substance.	Bath liq.	Immersed depth.	Density of bath liq.	V. p. increase for 1°.	B. p. subm bulblet.	B. p. dist. flask.
Benzene	Water	113	0.97	24	79.01°	79.00°
"	H_2SO_4	104	1.77	..	79.04	79.00
"	Min. oil	60	0.9	..	79.35[2]	79.33[2]
Ether	$CaCl_2$ sol.	70	1.47	27	33.87	33.85
"	Water	73	0.99	..	33.91	33.85
Alcohol	Water	60	0.97	31	77.56	77.55
Camphor	Paraffin	45	0 69	20	208.00	207.65
Naphthalene	3 Nitrates	68	1.93	17	217.68	217.73
Calomel	2 Nitrates	59	1.85	..	383.2	[382.5]
Com. am. carbonate	Olive oil	57	0.88	..	58.5	[58.5]

For the sake of comparison, the results for liquids by the submerged bulblet (col. 6), being obtained under greater pressure than those in the open flask (col. 7), are reduced to the existing atmospheric pressure by means of the known vapor pressure changes for 1° (col. 5).

The value for calomel in col. 7 is taken from vapor pressure measurements made by ourselves, using a platinum resistance thermometer.

---

[1] Naked flask, flame below the level of the liquid, and boiling continued to constant reading.

[2] These observations were made at a different barometric pressure from the preceding ones.

Since a mercury thermometer, even when nitrogen-filled under pressure, and calibrated by comparison with a resistance thermometer, is accurate only ±1° at temperatures above 300°, this correspondence is satisfactory. V. Meyer (*loc. cit.*), using an open crucible, found the temperature of the vapor 357° (corr.), the error by his method being therefore 25.5°.

The vaporizing temperature of commercial ammonium carbonate is necessarily variable, since the substance is not of constant composition. The value in col. 7 is the mean of two values (59.6° and 57.6°, respectively) taken from Naumann's[1] and Isambert's[2] measurements of the vapor pressures of ammonium carbamate, and is therefore not strictly comparable.

Probably because the liquid is heated equally from all sides, and not merely from below, no tendency to "bumping" was observed.

Impure and Decomposing Liquids.—The submerged bulblet method will not only give the boiling point of a pure liquid, but has, in addition, the advantage of showing promptly when a mixture, and not a pure liquid, is being handled. If a second reading, following a second brief period of boiling for the removal of the volatile substances possibly present, shows a divergence from the first reading, the boiling or distilling operation can be repeated again and again. Since at most only two drops of material have been taken, as much as half of the sample can be boiled away in two or three minutes, and another observation made. If a continuously changing series of boiling points is observed, then the substance is impure (either originally, or in consequence of rapid decomposition). These operations are essentially fractionations, involving, however, only minute amounts of material and an insignificant expenditure of time.

To illustrate the behavior of a mixture, equal volumes of benzene and commercial toluene were taken, and 0.03 cc. of this mixture was used. The successive boiling points, with sulphuric acid as bath liquid, were 91.1°, 92.7°, 94.0°, 96.1°, 98.7°. After five observations, about half the contents of the bulblet still remained.

Characteristics of the Submerged Bulblet Method.—The chief features of the method are:

(1) That it is applicable to non-fusing solids, for the determination of the boiling points of which no simple and accurate method has been known.

(2) That a minimum of material[3] (at most 0.1 g.), and a minimum of time are consumed.

---

[1] *Ber.*, 4, 782.

[2] *Compt. rend.*, 97, 1212.

[3] For other methods requiring but little material cf. Sivolobov, *Ber.*, 19, 765; Mulliken, "Identification of Pure Organic Compounds," Vol. I, p. 282 (1904); Schleiermacher, *Ber.*, 24, 944.

(3) That the conditions are definite and easily reproducible with exactness, and that, in particular, it is impossible for the liquid, the vapor, and the thermometer to differ in temperature. The boiling points ascertained are therefore more accurate, and more exactly comparable than are those obtained by the usual method.

(4) That with impure or decomposing liquids a fractional distillation in miniature may quickly be carried out and the impureness recognized.

(5) That when the dissolved or occluded gases, or volatile substances which are always present, can be removed by boiling, the removal may be accomplished and a satisfactory boiling point secured.

(6) That by taking the boiling point of a mixture of the two, the identity or non-identity of two liquids of almost identical boiling points may often be ascertained without sacrifice of an appreciable amount of material. This method will apply, however, only when the two substances are of chemically dissimilar natures, and not usually to very similar substances.[1]

(7) That the method may be adapted to finding boiling points at normal pressure (760 mm.), and under reduced pressure (see next two papers).

[COMMUNICATION FROM THE LABORATORIES OF GENERAL AND PHYSICAL CHEMISTRY OF THE UNIVERSITY OF CHICAGO.]

A COMMON THERMOMETRIC ERROR IN THE DETERMINATION OF BOILING POINTS UNDER REDUCED PRESSURE.

BY ALEXANDER SMITH AND ALAN W. C. MENZIES.

Received June 11, 1910.

In very accurate work, when the thermometer is immersed in a bath of liquid, a correction is introduced on account of the apparent elevation of the temperature, due to compression of the bulb. The converse effect, namely, a dilatation of the bulb, causing an apparent lowering in the temperature, when the thermometer bulb is immersed in a vapor under reduced pressure, may be equally well known. Having had occasion, however, to study a large part of the literature of boiling points and vapor pressures, we have not happened to observe any mention of this source of error, or any case in which a correction was applied on account of it.[2] This source of error would appear therefore to be neglected by many chemists. Yet in the magnitude of its effects it usually far exceeds the correction for compression, since evacuation involves the removal of a pressure equivalent to a head of about 30 feet of water, while the compression involves usually the addition of only a few inches. The following observations show that, in point of fact, the effect cannot be ignored in any but the roughest work.

---

[1] Young, Stoichiometry (London), 1908), 264.

[2] Since the above was written, a single, inconspicuous instance has been noticed.

Experiments.—Eleven thermometers (mercury in glass) of various makes were selected. Seven were graduated in tenths of a degree, and were capable of being read to hundredths. Two (Nos. 9 and 10) were graduated in fifths, and two (Nos. 1 and 11) in hundredths of a degree. The thermometers, fitting tightly through rubber stoppers, were partially enclosed in test tubes, provided with side tubes. The tubes were supported in a thermostat, the temperature of which remained constant ±0.005. After the reading of each thermometer became constant, the test tube was exhausted to 20 mm. through the side tube, and the new reading, after constancy was reached, was taken. Air was then re-admitted, and the readings were repeated, to ascertain that no permanent change in the value at one atmosphere pressure (or more exactly 748 mm.) had occurred.

The results are given in the table. The diameters of the bulbs are outside measurements (mm.). The thickness of the glass of the bulbs differed considerably, but could not, of course, be measured. Nos. 9 and 10 were members of a set of Anschütz thermometers. No. 4 was of Jena normal glass, by Götze:

	Bulb.		
No.	Length	Diam.	Change.
1	58	5.0	0.144°
2	28	6.5	0.16
3	25	5.0	0.13
4	20	5.5	0.10
5	20	5.0	0.13
6	9	5.5	0.11°
7	9	5.5	0.11
8	10	5.0	0.10
9	10	4.2	0.14
10	10	4.2	0.17

The change in apparent temperature (dilatation) varied from 0.10 to 0.17°. Considering the very great differences in the sizes of the bulbs, it was surprising that the changes did not cover a wider range. Evidently the amount of the effect cannot be predicted from the dimensions of the bulb.

When intermediate pressures were used, the change, as might be expected, was found to be a linear function of the pressure.

Only one of the eleven thermometers suffered a permanent distortion. In this case (No. 11) the bulb measured 35 x 9.5 mm. The successive values of the change were 0.260°, 0.177°, 0.162°, 0.162° (constant).

Conclusions.—(1) In vacuum distillation, if the temperatures are to be reasonably correct, special investigation of the behavior of each thermometer is required. In view of the behavior of our eleven thermometers, which showed no relation to the size of the bulb, an error much greater than 0.2° might be involved in the case of an individual instrument.

(2) In measurements of vapor pressures, by methods in which the bulb of the thermometer is immersed in the vapor, an error of 0.15°

or more may exist in the temperature readings. The absence of any correction on this account vitiates many of the published data. Specific instances will be noted in later papers dealing with vapor pressures.

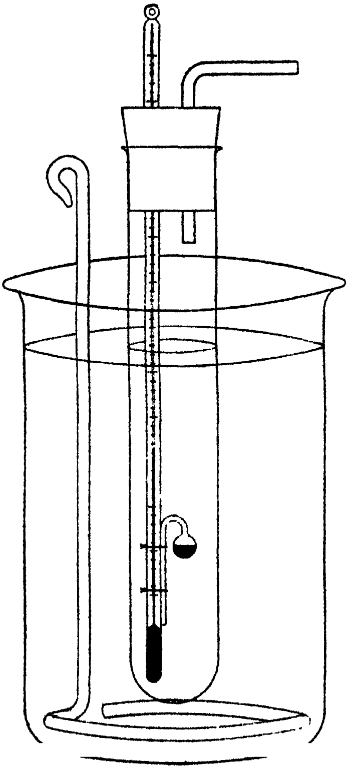
[COMMUNICATION FROM THE LABORATORIES OF GENERAL AND PHYSICAL CHEMISTRY OF THE UNIVERSITY OF CHICAGO.]

STUDIES IN VAPOR PRESSURE: II. A SIMPLE DYNAMIC METHOD, APPLICABLE TO BOTH SOLIDS AND LIQUIDS, FOR DETERMINING VAPOR PRESSURES, AND ALSO BOILING POINTS AT STANDARD PRESSURES.

BY ALEXANDER SMITH AND ALAN W. C MENZIES.

Received June 11, 1910.

The principle of the submerged bulblet method of determining boiling points, described in the preceding paper, may be adapted to the measurement of vapor pressures. The necessary apparatus may be set up from materials found in any laboratory, and a series of measurements of considerable accuracy may be made, all with the expenditure of very little time.



The Apparatus.—The bulblet, with attached capillary tube not less than 1 mm. in diameter, is charged with a small amount (about 0.1 g.) of the solid or liquid substance, and is attached to the thermometer by means of thread or asbestos cord, just as for the boiling-point determination. Instead, however, of being then immersed directly in the open bath, it is enclosed in a test tube (see figure). The L-shaped tube leads to the manometer, connections with the atmosphere and with a pump being provided by means of T-tubes. A large bottle between the pump and manometer is useful for regulating the pressure. Stopcocks on the tube leading to the pump and on that opening to the air permit the pressure to be lowered or raised at will. For pressures below that of the atmosphere, a water-pump, and for pressures above that of the atmosphere a small compression pump (*e. g.*, a bicycle pump) may be used. With only a rubber stopper closing the test tube, the pressure cannot be carried far above that of the atmosphere. But this apparatus will serve well when direct observation of the boiling point at standard pressure (760 mm.) is desired.

The test tube contains the same liquid as the surrounding bath. What was said in the first paper in regard to suitable bath liquids (p. 899), and in regard to the choice of thermometers (p. 902) applies here. The bath may be stirred by hand.

The Manipulation.—It will be sufficient to describe the mode of operation when pressures below that of the atmosphere are being observed. After the temperature has become constant at the desired point, and time has been allowed for equalization of the temperatures within and without the test tube, the pressure is reduced by cautiously opening the stop-cock on the tube leading to the pump. When the pressure has fallen to, or just below, the vapor pressure of the solid or liquid, a continuous stream of bubbles issues from the capillary. In a few moments, the vapor of the substance has displaced the air in the bulb, and usually also all the oxygen, nitrogen, or moisture dissolved in the substance, or adhering to the substance or the glass. The stop-cock on the tube leading to the pump is now closed, and that admitting air is slightly opened. The pressure is allowed slowly to rise until the stream of bubbles ceases. Use of the stop-cock alone does not permit of fine adjustment. Admission of air, a very little at a time, is best effected by grasping and closing the rubber tube at two places with the fingers. The volume of air in the enclosed section of the tubing bears only a small ratio to the total volume of the apparatus, including the bottle. By opening and closing the two constrictions alternately, first that next to the apparatus, then that nearer to the end which is open to the atmosphere, air is admitted in minute amounts at a time, and the pressure is raised very gradually. When the stream of bubbles suddenly ceases, the pressure of the air in the apparatus is equal to that of the vapor. The pressure at this moment is read on the manometer. This method applies when the substance and bath liquid are mutually insoluble. When they are mutually soluble, the bath liquid is allowed to ascend to a predetermined point, 5–10 mm. from the mouth of the capillary, just as in the boiling-point determination (p. 900).

To make sure that the dissolved or adhering gases and moisture are all expelled, the pressure is lowered, and the boiling out and subsequent operations are repeated. If consecutive measurements do not finally give constant values at the same temperature, the substance is impure, either because of original impurity or of decomposition during the heating. When a satisfactory reading has been obtained, the temperature is raised 5° or 10° and the same operations are carried out at the new temperature. If an open manometer is used, the barometric height (reduced to mercury at 0°) is taken also, and the reading of the manometer (likewise reduced to 0°) is subtracted from it.

A correction for the pressure, due to the depth from the surface of the bath down to the mouth of the capillary, or to the point to which the liquid ascends, is required. The details of this correction are identical with those described in the paper on boiling points (p. 901).

Sample Determination: Water.—To illustrate the adaptability of this form of the submerged bulblet method to securing quickly and easily a series of measurements of moderate accuracy, the results with water may be given. The test tube and bath were filled with mineral oil. Elaborate precautions to insure accuracy were purposely avoided. The manometer consisted of a piece of glass tubing fastened rigidly to an ordinary wooden meter scale. It stood in a vessel of mercury. Correction was made for capillarity in the manometer (+1.7 mm.), and the readings of the manometer and barometer were reduced to mercury at 0°. The correction for the immersed depth of the bulblet was made. One of a set of short Anschütz thermometers graduated in fifths of a degree was used, and the thread was completely immersed. Comparison with a standard thermometer showed no errors over 0.05°, and the readings were therefore assumed correct. The following were the observed readings, after correction:

Temp.	V. p. S and M.	V. p. H & H.	Diff. mm.	Temp.	V. p. S and M.	V. p. H & H.	Diff. mm.
49.0	88.0	[87.8]	+0.2	80.0	355.4	355.1	+0.3
60.7	155.3	154.1	+1.2	85.5	441.5	442.2	—0.7
67.8	213.8	212.2	+1.6	90.0	526.5	525.8	+0.7
73.6	273.5	272.5	+1.0	95.3	640.5	641.1	—0.6

The columns H & H contains the values published by Holborn and Henning,[1] which are the most trustworthy available. The algebraic sum of the differences divided by the number of observations gives the divergence of the curve as a whole from that of H & H. This divergence is 0.46 mm, and the corresponding divergence of the temperature is 0.07°.

This arrangement was used successfully in preliminary measurements of the vapor pressures of mercury and of non-fusing solids like the mercurous halides at 280–370°.

Three Additional Sources of Error, and the Corrections Therefor.—The irregularity of the individual observations cited above is due to the crudeness of the manometer, chosen intentionally to avoid the use of any special apparatus. Aside from this, however, there are three other sources of error for which, if desired, correction may be made.

---

[1] *Ann. Physik*, [4] 26, 882 (1908).

. One of them is the error due to neglecting the pressure caused by capillary ascension of the bath liquid in a tube 1 mm. in diameter. As we have shown,[1] this involves an error of only about 1 mm. of mercury pressure, or usually about 0.04° in temperature. In the case of the paraffin oil used in the foregoing determinations, this error was only 0.5–0.6 mm. Unless, therefore, the temperature is being read with unusual precautions, this correction may be ignored.

The second source of error lies in the fact to which attention is called in a separate communication,[2] namely, that a thermometer bulb placed in a partial vacuum undergoes dilatation and gives low readings.

The amounts of these two corrections, and the effect of taking account of them, is shown with the same data in the following table:

Temp.	V. p. S and M.	Temp. corr. for dilatation	V. p. change per 1°.	Corr. for dilatation in mm.	Corr. for capil. in mm.	S and M corr.	Diff. from H & H.
49.0°	88.0	0.13°	4.5	—0.6	+0.6	88.0	+0.2
60.7	155.3	0.11	7.1	—0.8	+0.6	155.1	+1.0
67.8	213.8	0.10	9.2	—0.9	+0.6	213.5	+1.3
73.6	273.5	0.09	11.5	—1.0	+0.6	273.1	+0.6
80.0	355.4	0.08	14.6	—1.2	+0.5	354.7	—0.4
85.5	441.5	0.06	17.3	—1.0	+0.5	441.0	—1.2
90.0	526.5	0.04	20.0	—0.8	+0.5	526.2	+0.4
95.3	640.5	0.02	23.4	—0.5	+0.5	640.5	—0.6

By these corrections, the divergence from the standard values is reduced from 0.46 mm. to 0.16 mm., or, in temperature, from 0.07° to 0.03°.

It will be seen that these two corrections work in opposite directions. On this account, when the present apparatus is used for securing a series of approximate vapor pressures, and for the applications to be mentioned presently, they may be neglected. When accurate vapor pressure measurements are required by a dynamic method, a modified, less simple form of the apparatus, to be described in a later paper, may be employed with advantage. In this apparatus, one of these corrections (that for dilatation) disappears, and the other is therefore to be taken into account.

The pressures may be still further corrected for the value of the gravity constant at the place of observation. In this laboratory the correction is —0.25 mm. per 760 mm. This correction, if applied, reduces the average divergence of the curve of pressures observed from the standard curve to 0.06 mm., or about 0.01°. This final result shows that by the method results of remarkable accuracy are obtainable.

Application to the Determination of Boiling Points of 760 mm., and under Reduced Pressure.—The present, almost universal custom of publishing boiling points at whatever atmospheric pressure happens to exist at the time, aggravated in the majority of cases by omission to state what that pressure was, raises some question as to the carefulness of the whole investigation, and, besides, tends to defeat the purpose for which ostensibly such data are given, namely the identification of substances. Thus, even when the barometric height is only 16 mm. distant from 760 mm., the boiling point of alcohol is 0 5° in error and that of naphthalene no less than 1°. It is extremely desirable that uniformity should be observed, and that all boiling points of stable substances should be ascertained at the normal pressure of 760 mm., and published in that form. The submerged bulblet method just described renders this operation so easy that the added value of the data is worth far more than the little extra trouble involved.

[2] See preceding paper, THIS JOURNAL, 32, 906.

When the substance is unstable at its boiling point, and has been purified by distillation under a reduced pressure, the boiling point at this pressure is published, and in such cases the value of the pressure is usually given. Commonly, to promote quiet boiling, a fine stream of air enters the boiling liquid through a capillary. Examination of the literature shows conclusively, however, that boiling points determined in this way are utterly untrustworthy.

This was clearly exhibited, for example, in connection with the controversy[1] over the question of whether such a boiling point was identical with the temperature at which the substance exercised a vapor pressure equal to that used in the distillation. Employing a vacuum distillation apparatus of the standard type, but more carefully constructed than the forms commonly used, G. W. A. Kahlbaum[2] found the boiling points to be sometimes higher and sometimes lower. The differences were, indeed, finally demonstrated to be in part due to the fact that the vapor pressure observations which he chose for comparison were inaccurate.[3] In at least one conspicuous case (butyric acid), also, the material was very impure.[4] But the greater part of the differences was due simply to the form of this particular apparatus, which was never devised for obtaining exact boiling-point-pressure readings. The original, and still, practically, the only purpose of the apparatus is to secure efficient purification by fractionation *in vacuo*. Any form which will achieve this end may be used, and is used.

To illustrate the striking differences between boiling points in a distillation apparatus and the true boiling points under various pressures, as determined in an apparatus especially devised for this purpose, a few typical values are given below. In the columns headed K appear Kahlbaum's[1] boiling points. The substances, in these instances, could not have been seriously impure. Under R & Y and Y are given the boiling points as ascertained by Ramsay and Young and by Young, respectively, and these results are confirmed by other published data.

The especial unfitness of the distillation apparatus at low pressures, where the temperature is below that of the room, is shown particularly in the cases of alcohol and benzene. Here, heat reaches the thermometer by radiation faster than it can be removed by a vapor of low heat capacity, and the temperatures are all much too high. Kahlbaum[6] states that wrapping cotton round the bulb, whether this cotton is previously moistened with the substance or not, does not, in these cases, bring about better correspondence of the results.

Quite recently, Von Rechenberg[7] has called attention to another error due to the fact that the large amount of vapor passing through the distillation apparatus gives a steep pressure gradient between the flask and the pump. When the manometer is distant from the flask, the observed pressure may be as much as 12 mm. below that existing in the flask. When air is admitted freely through a capillary to prevent "bumping," the steepness of this gradient is higher than it would otherwise be.

It seems, therefore, to be desirable that the boiling points (and corresponding pressures) of substances isolated by vacuum distillation should always be determined by a measurement made especially for the purpose. The submerged bulblet method described above furnishes a simple apparatus, and gives results of the requisite degree of accuracy. It is free from the error due to the air entering through the capillary. This method involves in reality a distillation *in vacuo*, but the extremely small amount of actual vapor transference occuring completely obviates the source of error noted by Von Rechenberg. The method avoids the error at low temperatures due to superheating of the thermometer by radiation, as the latter is immersed in a bath liquid of great heat capacity. It eliminates also, for the same reason, all the variability in the conditions, and therefore in the results, to which, as we have seen,[1] the distilling flask method is liable.

[5] *Ibid.*, 55, 485.

[6] *Ber.*, 19, 947.

[7] *J. prakt. Chem.*, 79, 475. For further discussion of this subject see Kraffts, *Ibid.*, 2, 80, 242 (1909); Hansen, *Ibid.*, 80, 449; Krafft, *Ibid.*, 80, 469; and the reply of von Rechenberg, *Ibid.*, 80, 547. Also Siepermann, *Ibid.*, 81, 190; and Hansen, *Ibid.*, 81, 282.

For data which are to be published, ready comparability would be secured by choosing a list of predetermined pressures, such as 5, 10, 20, 50, 75, 100, 200 mm., etc., up to 760 mm., the particular pressures being selected from this list with reference to the stability of the substance. The simplest way to accomplish this is to make several vapor-pressure readings in the desired region, to prepare a temperature-pressure curve from the data, and to read off the temperature at the exact pressures selected.

Reduction of Boiling Points to 760 mm. by Calculation.—It does not seem to be widely known that the observed boiling point at existing atmospheric pressure may be reduced to the value at 760 mm. by calculation alone, and usually without serious error. A rule given by Landolt,[2] which appears to be the only one that is familiar, is to the effect that the boiling point changes 0 043° for each mm., or, what is the same thing, 1° for every 23.3 mm. Now the following changes in pressure for 1° at the boiling point show this statement to be too inexact for practical use: Benzene, 24 mm.; ether, 27 mm.; alcohol, 30.3 mm.; naphthalene, 17 mm.; mercury, 13.6 mm.; water, 27.2 mm. Landolt's rule in reality overlooks the fact that the change in pressure per 1° is not constant, but varies inversely with the boiling point on the absolute scale. The following rule, based on the Clausius-Clapeyron law, and identical with, but simpler in form than that of Young,[3] gives results of accuracy sufficient for many purposes: *Divide 8500 by the boiling point on the absolute scale* (observed at about one atmospheric pressure), *and the quotient is the change in pressure (in mm.) for 1° change in boiling point.*

The constant varies, changing by about 1 per cent. for every 10 mm. below or above 760. The above value (8500) can be used, therefore, only for observed boiling points near to 760 mm. This value applies to most substances, but for alcohols, acids, water, and other substances containing the hydroxyl group the value 10200 must be used instead. The following data illustrate the degree of approximation attained by the use of this rule:

[CONTRIBUTIONS FROM THE RESEARCH LABORATORY OF PHYSICAL CHEMISTRY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, NO. 52.]

THE CONDUCTANCE AND IONIZATION OF POTASSIUM TRI-IODIDE, AND THE EQUILIBRIUM BETWEEN IODINE, IODIDE, AND POLYIODIDES IN AQUEOUS SOLUTION.

BY W. C. BRAY AND G. M. J. MACKAY.

Received June 13, 1910

This investigation was undertaken in order to determine the equivalent conductance of the tri-iodide ion, I_3^-; for a knowledge of this quantity is needed in the study of the equilibrium between iodine, iodide, and polyiodides in aqueous solution. Our own experimental work deals only with dilute solutions; but so much experimental evidence relating to this equilibrium in more concentrated solutions is available that it has seemed worth while to consider the results of several of these investigations from a single point of view. Accordingly, after presenting our own results, we have attempted to calculate the proportion of iodide, tri-iodide, and higher polyiodide present in a normal KI solution saturated with iodine.

The only careful determination of the conductance of tri-iodide ion, Λ_{I_3}, is that of Burgess and Chapman,[2] who calculated, from transference experiments, that $\Lambda_{I_3}/\Lambda_I = 0.566$. If we accept the value $\Lambda_I = 76.5$ at 25°, as given below, then Λ_{I_3} is found to be 42.5. We have recalculated these results[3] and have found the same mean value for Λ_{I_3}, although the separate values do not agree perfectly with the original calculations. These experiments are, it is true, open to the objection that concentration changes are referred to a constant volume of solution instead of to a definite weight of water. But we have estimated, on the assumption that the partial volume of 1 gram of dissolved iodine (as explained below) is 0.2376 cc. and that of 1 gram dissolved potassium iodide is 0.283 cc., that the error introduced in this way is less than 0.2 per cent.

---

[1] Constant here 10200, for the others 8500.

[2] Burgess and Chapman, *J. Chem. Soc.*, 85, 1305 (1904).

[3] The share of transport of tri-iodide ion, $C_{I_3^-} \times \Lambda_{I_3}/(C_{I_3^-} \times \Lambda_{I_3} + C_{I^-} \times \Lambda_I + C_{K^+} \times \Lambda_K)$ equals $\frac{1}{2}(B/A - 1)$ and may be obtained directly from the values of B/A given by these authors in the table on page 1316. The concentration ratio $C_{I^-}/C_{I_3^-}$ is given as C_2/C_1 in the tables on page 1309, the degrees of ionization of KI and KI_3 being assumed equal.

The method which we have used in determining Λ_{I_3} depends upon the measurement of the change of conductance produced by dissolving iodine in a solution of potassium iodide. A few incidental measurements of this kind have been made by LeBlanc and Noyes[1] and by Burgess and Chapman,[2] from which the last named authors calculated that the average value of the ratio Λ_{I_3}/Λ_I is 0.553. This close agreement with the results of their transference experiments is purely accidental; for the individual values (eight in all) derived from the conductance measurements vary irregularly between 0.51 and 0.60, corresponding to a variation of Λ_{I_3} between 39 and 46. The inaccuracy of these measurements is doubtless due to the fact that the amount of KI_3 present was much smaller than that of KI. We have avoided this source of error as far as possible by saturating the KI solution with iodine, and thus obtaining a concentration of KI_3 nearly equal to that of the uncombined KI.

The fundamental assumption which is made in interpreting any of these experimental results is that the only polyiodide present is KI_3. This depends upon the measurements of the equilibrium $I_3^- = I^- + I_2$ made by Jakowkin[3] at 25° and Dawson[4] at 13.5°, in which the concentration of I_2 as such in the aqueous solution was varied and determined by partition experiments, and the additional dissolved iodine was assumed to be present as KI_3. The values of the equilibrium constant[5]

$$K = \frac{(I_2)(I^-)}{(I_3^-)} = \frac{C_{I_2}\gamma C_{\Sigma I}}{\gamma' C_{\Sigma I_3}}$$

could not be directly determined but the values of the expression

$$K_1 = \frac{C_{I_2}C_{\Sigma I}}{C_{\Sigma I_3}}, \text{ where } K = \frac{\gamma K_1}{\gamma'}$$

We have also assumed that Λ_K at 25° = 74.8, and that $C_{\Sigma I}C_{I_2}/C_{\Sigma I_3}$ = 0.00138. The values of Λ_{I_3} calculated from the separate experiments, and given in the same order as on page 1309, are 42.3, 42.9, 42.6, 42.5, 41.9, 42.4, and 43.3.

[1] LeBlanc and Noyes, *Z. physik. Chem.*, 6, 402 (1890).

[2] Burgess and Chapman, *Loc. cit.*, 1310.

[3] Jakowkin, *Z. physik. Chem.*, 20, 19 (1896).

[4] Dawson, *J. Chem. Soc.*, 79, 238 (1901).

[5] Concentrations are represented by means of parentheses, or by the letter *C*. $C_{\Sigma I}$ means the total concentration of iodide. γ and γ' are the degrees of ionization of KI and KI_3 respectively.

were found to be remarkably constant when the concentrations of I_2, KI and KI_3 were greatly varied. We have collected in the following table some additional values of K_1 at 25° which we have calculated from the experimental data of Maitland.[1] A few of Jakowkin's results are also presented for comparison. The first column shows the concentration in mols per liter of the total potassium salt present, $C_{\Sigma K} = C_{\Sigma I} + C_{\Sigma I_3}$. The values of K_1 and the corresponding values of C_{I_2} are arranged in horizontal rows:

TABLE I.—VALUES OF $K_1 = C_{I_2}C_{\Sigma I}/C_{\Sigma I_3}$ AT 25°.

$C_{\Sigma K}$.					
0.0625	$C_{I_2} \times 10^4$	0.754	1.59	5.71	Jakowkin
	$K_1 \times 10^3$	1.38	1.40	1.41	
0.100	$C_{I_2} \times 10^4$	0.453	1.855	4.190	Maitland
	$K_1 \times 10^3$	1.39	1.38	1.36	
0.200	$C_{I_2} \times 10^4$	0.474	1.179	4.02	Maitland
	$K_1 \times 10^3$	1.41	1.39	1.35	
0.400	$C_{I_2} \times 10^4$	...	1.33	...	Maitland
	$K_1 \times 10^3$	...	1.32	...	
0.500	$C_{I_2} \times 10^4$	0.541	1.114	3.60	Maitland
	$K_1 \times 10^3$	1.37	1.33	1.27	
1.00	$C_{I_2} \times 10^4$	0.484	1.013	2.904	Maitland.
	$K_1 \times 10^3$	1.30	1.26	1.08	

It is evident that Maitland's results are in good agreement with those of Jakowkin, and that in the dilute solutions the amount of polyiodides higher than KI_3 must be extremely small. In the concentrated KI solutions, however, the values of K_1 are smaller and show a steady decrease with increasing concentration of I_2.[2]

The expression K_1 is related to the equilibrium constant K by the equation $K = (\gamma/\gamma')K_1$, where γ and γ' are the degrees of ionization of KI and KI_3, respectively. Dawson concluded from the constancy of K_1 that $\gamma = \gamma'$, but this is not necessarily true. It has been found, from conductance measurements, that in a mixture of two salts with a common ion the degree of ionization of each salt depends only on the total ion concentration and for highly ionized salts changes only very slowly with the ion concentration. Since, moreover, the degrees of ionization of KI and KI_3 do not differ greatly, it follows that the degree of ionization of potassium iodide, γ, will not be changed appreciably when a portion of it is converted into tri-iodide by dissolving iodine in its solution, and that also, in the different solutions which may be prepared from a given potassium iodide solution, the degree of ionization of KI_3 will have a definite, constant value, γ'.[3]

---

[1] Maitland, *Z. Elektrochem.*, 12, 264 (1906).

[2] This will be considered later; the corresponding values of K_1 for solutions saturated with I_2 are given in Table V, γ' being then assumed equal to γ.

[3] This conclusion, that for such a series of solutions γ/γ' is a constant, was reached

Upon the basis of the conclusion that the ionization γ of KI is unchanged by the addition of iodine, the results of our conductance measurements may be represented by the following equations, where L and L' represent respectively the specific conductances of the potassium iodide solution and of the same saturated with I_2:

$$1000\,L = \gamma C_{\Sigma I}\,(\Lambda_K + \Lambda_I)$$

$$1000\,L' = \gamma C'_{\Sigma I}\,(\Lambda_K + \Lambda_I) + \gamma' C'_{\Sigma I_3}\,(\Lambda_K + \Lambda_{I_3}).$$

Furthermore, since the change of volume on dissolving the iodine is negligible in dilute solutions we have:

$$C_{\Sigma I} = C'_{\Sigma I} + C'_{\Sigma I_3}.$$

For the simple case that $\gamma = \gamma'$ the difference between the two conductances then becomes:

$$1000\,(L - L') = \gamma C'_{\Sigma I_3}\,(\Lambda_I - \Lambda_{I_3});$$

for the general case, however, the difference assumes the form

$$1000\,(L - L') = (\gamma - \gamma')\,C'_{\Sigma I_3}\,(\Lambda_K + \Lambda_I) + \gamma' C'_{\Sigma I_3}\,(\Lambda_I - \Lambda_{I_3}).$$

Since $\gamma - \gamma'$ approaches zero with decreasing concentration, the two expressoins will become identical at the limit. In other words, if we calculate the difference between the conductances, $\Lambda_I - \Lambda_{I_3} = \frac{1000(L - L')}{\gamma C'_{\Sigma I_3}}$ assuming as a first approximation that $\gamma = \gamma'$, then the limiting value approached in dilute solutions will be a true measure of $\Lambda_I - \Lambda_{I_3}$. We have therefore made a series of determinations in which the initial potassium iodide concentration was varied from 0.1 to 0.001 normal in order to obtain the limiting value of the ratio 1000 $(L - L')/(I_3^-)$.

Preparation of the Substances and Solutions.

The *potassium iodide* solutions, 0 1 and 0.01 normal at 25°, were made by dissolving the requisite amount[1] of the pure salt (Kahlbaum's guaranteed reagent), powdered and dried to constant weight, and diluting (at 25°) to 2 liters. The remaining solutions were prepared from these by dilution by means of a calibrated 200 cc. pipette and a series of calibrated measuring flasks. The strength of the two stock solutions was checked to within 0.1 per cent. by liberating the iodine and titrating

by Osaka (*Z. physik. Chem.*, 38, 743 (1901)), but he made the assumption that the law of mass action could be applied to the ionization of these two salts. Osaka found in his preliminary measurements of the freezing points of 0.5–1.0 normal solutions of potassium iodide before and after adding iodine that after the addition of iodine the freezing point is distinctly higher than before, and concluded that KI_3 is somewhat less ionized than KI. But since the behavior of these concentrated solutions is in general so different from that of more dilute solutions it is not justifiable to conclude that in dilute solutions the degree of ionization of KI_3 is less than that of KI.

[1] The International Atomic Weights of 19.08 were used. No correction, however, was applied for buoyancy.

it by a method to be described in a subsequent paper, thus proving the absence of chloride or other impurity.

The *water* used was prepared by redistilling ordinary distilled water from an alkaline solution of potassium permanganate; it had a specific conductance of from 0.4 to 0.8 × 10^{-6} reciprocal ohms at 25°. The conductance of the water was in each case subtracted from the conductance of the weaker solutions.

The *sodium thiosulphate* solution used in titrating "free iodine" in the three more concentrated solutions was 0.07348 normal. It was standardized by comparison with an iodine solution which had been titrated against a weighed quantity of As_2O_3 according to the directions of Washburn.[1] For the titration of the more dilute iodine solutions this standard thiosulphate solution was diluted just before use to five times its volume.

The *iodine* used was obtained by purifying commercial resublimed iodine. This was ground with about one-quarter of its weight of potassium iodide and carefully sublimed; the iodine thus obtained was again sublimed without the addition of any potassium iodide.

The Experimental Method.

The *conductance measurements* were made in glass cells of the pipette form, such as have been described in another article from this laboratory.[2] Two were used, one of low resistance for the very dilute solutions, and the other of high resistance for the more concentrated solutions. The cell constants were determined by measuring in the cells at 25° freshly prepared solutions of potassium chloride 0.01 normal at 18°, the specific conductance of which was assumed to be 1413 × 10^{-6} at 25°.[3] The measurements were made in the usual way by means of an accurately calibrated bridge of the Kohlrausch roller pattern.

The *saturated solutions* were prepared as follows: Ten to thirty grams of freshly powdered iodine were placed in a 250 or 500 cc. glass-stoppered bottle of "Resistenz" glass, which had been well steamed out. After washing this iodine with a small quantity of a potassium iodide solution the bottle was filled with a potassium iodide solution of the same concentration, the stopper and neck of the bottle were carefully covered with a rubber tube, the bottles were rotated in a thermostat at 25° for different lengths of time, and finally were hung in the thermostat for a few minutes to allow the iodine to settle.

Portions of the saturated solution were forced by air pressure through a glass tube into the conductivity vessel, which was also immersed in the thermostat; and the conductance was quickly measured. Fresh portions of solutions were then forced into the cell in order that the measurement might be checked.

---

[1] Washburn, This Journal, 30, 31 (1908).

[2] Abbott and Bray, This Journal, 31, 732 (1909).

[3] This value is based upon recent measurements made in this laboratory by A. C. Melcher and by F. L. Hunt.

Other portions of the same solution were withdrawn by pipettes of known volume, run into solutions of potassium iodide, and the free iodine titrated with thiosulphate. In filling a pipette the solution was forced by means of air pressure through a filter of glass wool and asbestos connected with the pipette by a ground glass joint. This use of air pressure in transferring the saturated solutions prevented the error from evaporation of iodine which would have arisen if suction had been used. To avoid this error the measurements were also made as quickly as possible and only one-half, or at most two-thirds, of the solution in the bottle was used.

The Conductance and Solubility Data.

All the experimental data are presented in the following table:

TABLE II.

KI solution			KI solution saturated with iodine			Best values	
Milli-mols per liter	Equiv cond.	Spec cond. $\times 10^6$	Hours rotation.	Spec cond 10^6.	Milli-mols I_2 dissolved.	Spec cond. $\times 10^6$.	Total iodine dissolved.
100	130.8	13080	25	11500	51.1	11490	51.35
	130.8	13080	120	11485	51.6		
50	134.75	6737.5	25	5930	25.77	5930	25.77
20	139.4	2788	25	2468	11.13	2468	11.13
10	142.2	1422	20	1259	6.185	1260	6.185
	142.4	1424	54	1261	6.080[1]		
5	144.5	722.5	20	641.0	3.725	641	3.728
	144.8[1]	724.0[1]	54	642.0[1]	3.731		
2	147.0[1]	294.0[1]	4	260.2	2.292[1]	260.8	2.266
	146.7	293.4	20	260.8	2.266		
	146.6	293.2	54	261.2	.....		
1	149.95	147.95	4	131.6	1.772	131.7	1.788
	147.9	147.9	20	131.9	1.788		
	148.0	148.0	48	131.8	1.793		
	147.8	147.8	54	133.2[1]	1.787		

It will be seen that the duplicate measurements of conductance gave concordant results throughout, but the values of "iodine dissolved" in the saturated solutions are somewhat less satisfactory. The maximum variation from the mean is 1 per cent. in the most dilute solution, 0.5 per cent. in the most concentrated, and 0.1 per cent. in an intermediate solution (0.005 mol. KI).

The Equivalent Conductance of Potassium Iodide.

A comparison of the conductance data presented above with those obtained by earlier investigators is afforded by Table III. This contains values interpolated from the results at 25° of Ostwald,[1] of Jones and Douglas[2] and Schmidt and Jones,[3] all reduced from Siemann's units to reciprocal ohms by multiplying by 1.066. Values at 25° derived by combining the data of Kohlrausch and Steinwehr at 18° with Déguisne's temperature coefficients[4] and making a slight correction for the expansion of the solution are also included. The table also contains in the last two columns the percentage ionization of potassium iodide at 25° and at 18° derived from our data and those of Kohlrausch, respectively. These columns serve to show the consistency of the data at the two temperatures and the very small effect of temperature on the ionization.

---

[1] These data were rejected in deriving the best values because they were not consistent with the data at other concentrations.

TABLE III.—EQUIVALENT CONDUCTANCE AND PERCENTAGE IONIZATION OF POTASSIUM IODIDE.

	Λ for KI at 25°.					100γ for KI.	
Concentration.	Bray & MacKay.	Ostwald.	Jones & Douglas.	Schmidt & Jones.	Kohlrausch & Déguisne	(25°).	(18°).

0.02	139.4	139.3	139.3	140.3	...	92.1	92.30
0.01	142.3	143.1	142.7	142.4	...	94.1	94.20
0.005	144.5	146.2	146.0	144.8	...	95.5	95.60
0.002	146.7	148.7	149.1	146.8	...	97.0	97.05
0.001	147.9	150.0	150.3	148.3	147.9	97.8	97.85
0.0	151.3	...	...	...	...	100.0	100.00

In the last row of the table is given the equivalent conductance at zero concentration. To derive this we have employed a method which has already been described in several publications from this laboratory,[5] which consists in plotting values of $1/\Lambda$ against the corresponding values of $(C\Lambda)^{n-1}$ for different values of *n*. For the sake of comparison the results of Kohlrausch and Steinwehr on potassium iodide at 18° were plotted on the same diagram. It was found that in both cases a straight line was obtained between the concentrations 0.001 and 0.02 normal for the value $n = 1.45$; that the line expressing the results at 18° met the $1/\Lambda$ axis at a point corresponding to $\Lambda = 131.1$, identical with the value of Λ_0 chosen by Kohlrausch and Steinwehr; and that in the case of the results at 25° the corresponding value of Λ_0 is 151.3 ± 0.1. These results show that between the concentrations 0.001 and 0.02 the dilution law takes the form $(\gamma C)^{1.45}/C(1-\gamma) = \text{const.}$ At higher concentrations a lower value of *n* than 1.45 must be chosen.[6] This graphical method has also shown that our individual measurements are consistent with one another, and that the lower value (144.5) found for the equivalent conductance of the 0 005 normal solution is more nearly correct than the higher value (144.8).

[5] See for example THIS JOURNAL, 31, 745 and 1010 (1909).

[6] The conductance measurements at 18° for solutions more dilute than 0.001 normal indicate that *n* has a higher value than 1.45 in these very dilute solutions, and

It will be seen that the two conductance values of Kohlrausch and Déguisne agree almost completely with ours, and that the ionization values at 18° and 25° run closely parallel, those at 18° being uniformly slightly higher and by an amount that increases gradually as the concentration increases. The results of Ostwald and of Jones and Douglas agree with ours only at 0.02, being considerably higher at the lower concentrations, owing probably to errors introduced by the method of dilution employed. Those of Schmidt and Jones at the lower concentrations (0.01 to 0.001 normal) are much lower than those of Jones and Douglas and fairly concordant with our values; but at the higher concentrations (0 1 to 0.02) the results of Schmidt and Jones are widely divergent from all the others.

The most probable values of the conductances Λ_I and Λ_K of the separate ions were considered to be 76.5 and 74.8, respectively, the sum of which is of course equal to $\Lambda_0 = 151.3$. These values are based upon some unpublished conductance measurements at 25° which will be discussed in a later publication.

The Equivalent Conductance of Potassium Tri-iodide.

Before the data for the solutions saturated with iodine could be interpreted it was necessary to determine whether any correction should be made for the conductance of iodine in pure water. The results of experiments on the hydrolysis of iodine described in the following article show that the initial conductance of an iodine solution in water is due mainly to the acid formed by the hydrolytic reaction, $I_2 + H_2O = HIO + H^+ + I^-$, and that this hydrolysis is driven back almost completely in the presence of a dilute acid. Since an iodide may be expected to have the same effect, no correction has been made for the conductance of iodine in pure water.

It will also be shown in that article that the solubility of iodine as I_2 is 0.00132 mols per liter—a value that will be used in the following calculations.

To the measured conductances of the more concentrated solutions a small correction must, however, be applied on account of the increase of volume when the iodine is dissolved; for in determining the change of conductance resulting from the transformation of KI into KI_3, it is necessary to compare solutions of the same concentration with respect to potassium. Mr. R. C. Tolman, of this laboratory, has kindly furnished

that therefore the values of Λ_0 chosen at 18° and 25° are somewhat too high. For the sake of uniformity however, we have retained the Kohlrausch value.

us with the results of his preliminary measurements on the specific gravities of solutions obtained by dissolving varying amounts of iodine in a 0.25 normal KI solution. The volume-increase of 1 liter of the potassium iodide solution was found to be 0.2376 cc. per gram of iodine dissolved in it. It was calculated that the total concentration of potassium salts in the three most concentrated solutions saturated with iodine differed from the original round concentrations by 0.31, 0.16 and 0.05 per cent., respectively, thus giving 0.9969, 0.04992 and 0.01999 mols per liter. The specific conductances of pure potassium iodide solutions at the same concentrations were therefore calculated to be 0.013040, 0.006727 and 0 002786, respectively, and these values have been used in determining the decrease of specific conductance (Table IV, column 6).

In Table IV the final results and some quantities calculated from them are presented. Concentrations are expressed in the table in millimols per liter at 25°, but all calculations are based upon molal concentrations. The *first* column gives the total concentration of the potassium salts in the solutions, the values in the three most concentrated solutions having been obtained by correcting the values given in Table II as just described. The *third* column gives the concentration of the tri-iodide ($\Sigma I_3 = I_3^- + KI_3$), obtained by subtracting the solubility of I_2 (1.32) from the "total iodine dissolved," as given in the last column of Table II. The *second* column gives the concentration of iodide (ΣI) determined by taking the difference between the two concentrations just referred to ($\Sigma K - \Sigma I_3$). The *fourth* column gives the concentration of tri-iodide ion, (I_3^-), calculated under the assumption that the degree of ionization of KI_3 is the same as that of KI in the initial KI solution. The *fifth* column contains the ratio $\Sigma I_3/(\Sigma I + \Sigma I_3) = r$. The *sixth* and *seventh* columns show the decrease in specific and equivalent conductance, $L - L'$ and $\Delta\Lambda$, respectively, produced by replacing the iodide by exactly the same amount of tri-iodide. The *eighth* column contains the values of the ratio, $1000\ (L - L')/(I_3^-)$, which should be constant, and equal to $\Lambda_I - \Lambda_{I_3}$, if the ionization of KI_3 is the same as that of KI. The *ninth* column shows the values of the ratio, $\Delta\Lambda/\gamma$, which would equal the decrease of equivalent conductance if all the KI were replaced by KI_3, no assumption in regard to degree of ionization of the KI_3 being involved. The *tenth* column contains the values of Λ_{KI_3} calculated by subtracting $\Delta\Lambda/\gamma$ from the values of Λ_{KI} given in Table III, and the *last* column gives the corresponding values of the percentage ionization of KI_3, $100\gamma_{KI_3}$, calculated on the assumption that Λ_0 for KI_3 is equal to 115.8.

An inspection of the table shows that all the results are concordant except the value $r = (\Sigma I_3)/(\Sigma I + \Sigma I_3) = 4.90$ for the second solution, which is evidently too low. Since this value is based upon only a single titration of "total iodine dissolved," a more probable value, 4.97, has been obtained by interpolation, and the corresponding values of γ_{KI_3}, etc., calculated. These values are enclosed in brackets in the table.

TABLE IV.

Concentrations × 10³.					Decrease in cond.

5.00	2.592	2.408	2.30	0.482	81.5	16.3	35.4	33.8	110.7	95.6
2.00	1.054	0.946	0.918	0.473	32.6	16.3	35.5	34.5	112.2	96.9
1.00	0.532	0.468	0.458	0.468	16.2	16.2	35.4	34.6	113.3	97.8
0.00				0.462	0.0	16.4	35.5	35.5	115.8	100.0

A comparison of the values of γ_{KI_3} with those of γ_{KI} (Table III) shows that the degree of ionization of potassium tri-iodide is practically identical with that of KI up to a concentration of 0.1 normal. Each of the ratios $1000 (L - L')/(I_3^-)$ is therefore a separate determination of $(\Lambda_I - \Lambda_{I_3})$, the difference between the equivalent conductances of the tri-iodide ions. The average value of $\Lambda_I - \Lambda_{I_3}$ is 35.5, from which it follows that

$$\Lambda_{I_3} = 41.0 \text{ and } \Lambda_0 \text{ for } KI_3 = 115.8.$$

The limiting value (at zero concentration) of the ratio $\Delta\Lambda/r$ is equal to $\Lambda_I - \Lambda_{I_3}$, and the limiting values of $\Delta\Lambda$ and of r are therefore not independent. In the table $\Delta\Lambda$ is shown to increase slightly with increasing dilution, and the limiting value is probably as high as 16.4. It follows that, in solutions saturated with iodine, the ratio $r = (\Sigma I_3)/(\Sigma I + \Sigma I_3)$ tends toward the value $16.4/35.5 = 0.462$ as the concentration approaches zero.

From the values of this ratio in the different solutions it is seen that the proportion of tri-iodide in a solution saturated with iodine increases steadily with increasing concentration,[2] the whole change between 0.0

---

[1] An interpolated value.

[2] A comparison with the values of this ratio $(\Sigma I_3)/(\Sigma I + \Sigma I_3)$ determined by Noyes and Seidensticker (THIS JOURNAL, 21, 217 (1899); *Z. physik. Chem.*, 27, 359) shows that the agreement is fairly good at 0.1 normal, but that their values at smaller concentrations are always larger than ours and that the difference increases rapidly with increasing dilution. Since, as they point out, their values at the lowest concentrations are apparently affected by large errors, it seems not improbable that their values at higher concentrations are similarly affected, though of course to a smaller

and 0.1 normal being about 8 per cent. This effect is identical in direction with the very marked effect which has been observed in more concentrated solutions, where the ratio of total iodine dissolved in total potassium salt decreases rapidly with increasing salt concentration.

A Deviation from the Law of Mass Action.

This result may be expressed in another way: In potassium iodide solutions saturated with iodine, the ratio $(I^-)/(I_3^-)$, which according to the law of mass action should be constant, decreases from 1.16 to 0.99 when the potassium salt increases from 0.0 to 0.1 normal.

We have used the results of Laurie[1] to calculate at higher concentrations the apparent values of this ratio which are obtained when the same assumptions are made as at lower concentrations, *viz.*, that the solubility of I_2 as such is 0.00132 millimolal, that all the dissolved iodine in excess of this amount is present as tri-iodide, and that KI_3 is ionized to the same extent as KI. In order, however, to allow for the expansion of the solutions when iodine was dissolved in them, approximate corrections have been introduced by the method described above. The concentrations in the saturated iodine solution are thus referred to the volume of solution containing the same number of mols of potassium salt as were present in 1 liter of the original potassium iodide solution. The results, together with our own results at lower concentrations, are included in the following table. The table also contains the corresponding values of the equilibrium "constant" $K = (I^-)(I_2)/(I_3^-)$, obtained by multiplying the ratios $C_{I^-}/C_{I_3^-}$ by the solubility of I_2, 0.00132.

TABLE V.—VALUES OF $(I^-)/(I_3^-)$ AND $(I^-)(I_2)/(I_3^-)$ IN KI SOLUTIONS SATURATED WITH IODINE.

ΣK	1.000	0.850	0.700	0.500	0.344	...	..
ΣI_2 combined, mols per liter.	0.711	0.578	0.440	0.295	0.189	...	..
I_2 combined (mols)	0.742	0.598	0.452	0.300	0.191	..	..
In the volume (cc.)	1043	1035	1027	1018	1011	...	..
$C_{I^-}/C_{I_3^-}$	0.35	0.42	0.55(?)	0.67	0.80	...	..
$K \times 10^3 = 1.32\, C_{I^-}/C_{I_3^-}$	0.46	0.55	0.72	0.88	1.06	...	..

ΣK	0.100	0.020	0.010	0 005	0.002	0.001	0.0
$C_{I^-}/C_{I_3^-}$	0.99	1.04	1.06	1.08	1.11	1.14	1.16
$K \times 10^3 = 1.32\, C_{I^-}/C_{I_3^-}$	1.31	1.37	1.40	1.42	1.47	1.50	1.53

On plotting the values of $(I^-)/(I_3^-)$ against log (ΣK) it was found that a straight line was obtained from 0.001 to 0.1 normal ΣK, and that this line produced to normal concentration gave the value $(I^-)/$

---

percentage extent. As a possible source of error in these experiments, the presence of an organic impurity in the water may be mentioned; the reaction of this with iodine would produce an iodide, and the proportion of tri-iodide found would therefore be too great, especially in the dilute solutions.

[1] Laurie, *Z. physik. Chem.*, 67, 627 (1909).

$(I_3^-) = 0.92$ instead of the much lower value found (0.35). Thus the decrease of this ratio in concentrated solutions is much more rapid than was to have been expected from the results in dilute solutions.

Additional information with regard to this deviation from the law of mass action was obtained by comparing these values of the equilibrium function $K = (I^-)/(I_2)/(I_3^-)$ in saturated I_2 solutions with those obtained at other I_2 concentrations (Table I). On plotting K against the concentration of I_2 as determined from partition experiments, it was evident that in a dilute potassium iodide solution ($\Sigma K = N/16$) the values of K are practically constant and equal to 1.40; that in 0.1 and 0.2 normal solutions K decreases slightly with increasing I_2 concentration; and that this decrease is very pronounced in concentrated potassium iodide solutions. From the results for the most concentrated solutions (normal ΣK) the value of K at zero I_2 concentration was found by extrapolation to be 1.34×10^{-3}, which is almost as large as the values found in dilute potassium iodide solutions. Thus the deviations from the mass action law are very slight when the concentration of I_2 is small.

An obvious explanation of this decrease of K in the concentrated potassium iodide solution, which has frequently been offered, is that a polyiodide higher than KI_3 is formed, and that its concentration increases as I_2 is increased. But a difficulty is at once encountered when we consider the equilibrium in the saturated I_2 solution, *e. g.*, $I_5^- = I^- + 2I_2$. Here the ratio of (I_5^-) to (I^-) should be constant, and yet solid iodine separates when a concentrated solution is diluted. We are led to the result that if a polyiodide is present its concentration cannot be a measure of its "activity"[1] in the reaction. But if this second assumption is necessary even when a higher polyiodide is assumed to be present, then it seems worth while to determine if the assumption of a variation of the ratio of activity to concentration for tri-iodide or iodide is alone sufficient to explain the phenomenon—without the assumption of a higher polyiodide.

This concept of "activity" as introduced by Lewis is of great value in dealing with a problem involving a deviation from the law of mass action. For our purposes it is sufficient to recall that the following law is a thermodynamic consequence of the definition of activity. If the value of the activity (A) of each substance at equilibrium is substituted for its concentration in the mass-action expression, then the resulting activity function is a constant. Thus for the equilibrium, $I_3^- = I^- + I_2$, at constant temperature, $A_{I^-} \times A_{I_2}/A_{I_3^-} =$ constant. For our purposes we may, for the sake of convenience, place the activity (A) of each substance equal to the concentration (C) at infinite dilution.[2] As the concentration increases the activity will, in general, differ from the concentration, and the ratio of activity to concentration will also be altered when other substances are introduced into the solution. The problem of deviations from the law of mass action is thus resolved into the problem of determining how the ratio of activity to concentration varies for each substance under varying conditions. In the following we shall designate this ratio by the letter

---

[1] Lewis, *Proc. Am. Acad.*, 43, 259 (1907); *Z. physik. Chem.*, 61, 129 (1907).

[2] This is only justifiable when, as in the present instance, we are dealing with a

$$\rho = A/C.$$

We shall assume throughout that the concentration of any ion has the value derived from conductance measurements.

In the present example we may therefore conclude that at 25°, in solutions saturated with iodine,

$$A_{I^-}/A_{I_3^-} = C_{I^-}/C_{I_3^-} \text{ (for } K_{KI} = 0) = 1.16.$$

It is evident that the activity of I_2 as such is constant in all solutions in equilibrium with solid I_2, and may be considered equal to its solubility in pure water, since the concentration is very small, that ,is: $A_{I_2} = C_{I_2} = 0.00132$. The activity function,

$$K_A = A_{I^-} \times A_{I_2}/A_{I_3^-},$$

has therefore the value $1.16 \times 0.00132 = 0.00153$. This quantity, K_A, in virtue of the definition of activity, is, at any given temperature, constant under all circumstances. In the investigations of the equilibrium in solutions unsaturated with iodine (Table I) it is evident that the activity of I_2 in the aqueous phase, and not its concentration, was determined by the partition experiments.[1] The quantity K_1 (Table I), which is equal to K since γ' is now assumed equal to γ, therefore has the form

$$K = C_{I^-} \times A_{I_2}/C_{I_3^-}.$$

From the values of K, given in Tables I and V, we may calculate the values under different conditions of the expression

$$K_A/K = \rho_{I^-}/\rho_{I_3^-} = 0.00153/K.$$

Thus in 0.1 and 1.0 normal potassium iodide solutions the limiting values approached by the ratio $\rho_{I^-}/\rho_{I_3^-}$ as C_{I_2} approaches zero are $1.53/1.40 = 1.09$ and $1.53/1.34 = 1.14$, respectively; while in 0.0, 0.1 and 1.0 normal potassium iodide solutions saturated with iodine the values are 1.0, 1.17 and 3.34, respectively.

Thus if we can determine how one of the activity-concentration ratios,

---

single solvent at a constant temperature. In other cases it is best to adhere to the original definition of Lewis, according to which $A = C$ at infinite dilution only in the gaseous phase.

[1] This is exact only when the activity of iodine is proportional to its concentration in the organic solvent used in the partition experiments, which, however, is doubtless true, or nearly so, for CCl_4, $CHCl_3$, and CS_2, the solvents used.

as $A_{I^-}/C_{I^-} = \rho_{I^-}$, varies under different conditions we can at once calculate the corresponding values of the second ratio. As we shall see later, ρ_I^- is nearly constant, whence we conclude that $A_{I_3^-}/C_{I_3^-}$ decreases rapidly:

(1) in saturated I_2 solutions with increasing KI, and

(2) in a normal KI solution with increasing I_2.

Let us illustrate the significance of a variation in this ratio for a given substance. When the substance is at the same concentration in two different solvents, *M* and *N*, and has a smaller activity in *M*, then it will tend to escape from *N* to *M* (*e. g.*, through the gaseous phase if it is volatile). In such a case it is frequently stated that *M* is a "better solvent for the substance." Whenever the addition of any substance to a solution causes a decrease in the ratio of *A*/*C* for the original solute, the same idea may be applied by saying that the solution has become a better solvent for that solute.

In the present example we may thus state that a concentrated KI — I_2 solution is a better solvent for tri-iodide than is a pure potassium iodide solution or pure water. This phenomenon is doubtless connected with the mutual solubility of KI and I_2,[1] an idea which has been expressed by Parsons[2] in the phrase "solution in a dissolved solid."

The Composition of Concentrated Potassium Iodide Solutions Saturated with Iodine.

Important evidence relating to the presence of polyiodides higher than KI_3 in concentrated potassium iodide solutions saturated with iodine is furnished by the electromotive force determinations of Laurie.[3] The problem, however, cannot be completely solved without the knowledge, for some substance as I^-, of the variation of the activity concentration ratio in the saturated iodine solutions with increasing potassium iodide concentration. Accordingly, in the following detailed calculations the simple assumption referred to above has been made that $C_{I^-} = A_{I^-}$. Other assumptions are considered later and the complete results are summarized in Table VI.

In Laurie's measurements a half-cell containing 0.0005 mol I_2 dissolved in a potassium iodide solution was combined with another containing the same potassium iodide solution saturated with iodine. The diffusion potentials were eliminated by inserting between the half-cells a 10 times normal solution of ammonium nitrate.[4]

---

[1] The great solubility of KI in liquid iodine has been noted by Lewis and Wheeler, *Z. physik. Chem.*, 56, 179 (1906).

[2] Parsons, *J. Physic. Chem.*, 11, 669 (1907).

[3] Laurie, *Z. physik. Chem.*, 67, 627 (1909).

[4] Cumming's tests of this method, *Trans. Faraday Soc.*, 2, 213 (1906) depend upon the agreement between the measured e. m. f. (using 10 *N* NH_4NO_3), and the value calculated from the Nernst equation; but he used concentrated solutions, such as *N*

When the electrode reaction is considered to be

$$I^- + \oplus = {}^1/_2 I_2,$$

then the electromotive force (aside from the diffusion potential) is:

$$E = 0.0591 \ [\log (A_{I^-})_d/(A_{I^-})_s - {}^1/_2 \log (A_{I_2})_d/(A_{I_2})_s]$$

where the subscripts d and s refer to the dilute and saturated solutions, respectively.

By means of this equation the quantity which we wish to determine $(A_{I^-})_s$ may be calculated, since E was measured by Laurie and the other three activities may be derived as follows:

In the experiment with normal potassium iodide solutions,

$$E = 0.1252 \text{ volts.}^1$$

By our assumption,

$$(A_{I^-})_d = (C_{I^-})_d = 0.79 \times 0.9995 = 0.790,$$

where 0.79 is the degree of ionization of the potassium iodide and 0.9995 its concentration (the remaining K salt, 0.005, being present as triiodide).

The activity of iodine in any phase in equilibrium with solid I_2 has a constant value; as explained above

$$(A_{I_2})_s = 0.00132.$$

Finally $(A_{I_3^-})_d$ may be calculated from the equations

$$(A_{I_3^-})_d = (C_{I_3^-})_d/1.14 = 0.79 \times 0.0005/1.14 = 3.46 \times 10^{-4},$$

and

$$(A_{I_2})_d = K_A(A_{I_3^-})_d/(A_{I^-})_d = 0.00153 \times 3.46 \times 10^{-4}/0.790 = 6.70 \times 10^{-7}.$$

It is to be noted that the assumption is here made that the proportion of higher polyiodide such as KI_5 is negligible in this dilute I_2 solution, but this is evidently justifiable since we shall find that its concentration is small even in the saturated I_2 solution.

On substituting these values in the above electromotive force equation, it is found that $(A_{I^-})_s = 0.267$, which, according to our assumption, is equal to $(C_{I^-})_s$.[2] According to the view adopted early in the

---

HCl — 0.1 N HCl, in which it is very doubtful if the Nernst equation will give accurate results. Therefore the accuracy of the NH_4NO_3 method of eliminating potential differences is still unknown; but it is probably sufficiently accurate in the present instance for our purpose.

[1] In Laurie's article, page 632, the "NH_4NO_3 correction" of 0.0008 volt is a misprint for 0.0080.

[2] Laurie considered the electrode reaction $I^- + \oplus = \frac{1}{2}I_2$, and applied the Nernst formula, thus tacitly assuming that $A_{I^-} = C_{I^-}$. It is interesting to note that if he had adopted the equally possible electrode reaction $I_3^- + \oplus = {}^3/_2 I_2$ he would have obtained absolutely different results, since this corresponds to the assumption that $A_{I_3^-} = C_{I_3^-}$. Since Laurie adopted the first view his value for the concentration of I^- (0.264), is almost identical with ours (0.267). But he assumed that the degree of ionization depends upon the actual concentration of potassium iodide present, and his values for C_{KI} are therefore smaller than ours.

paper the degree of ionization of potassium iodide in this mixture depends on the total ion concentration and therefore is the same as in the pure potassium iodide solution. It follows that the total concentration of iodide, $C_{\Sigma I} = 0.267/0.79 = 0.338$, a value which is obviously independent of the degree of ionization originally assigned to the normal potassium iodide solution.

The total concentration of the potassium salt present in other forms than potassium iodide is therefore $1.000 - 0.338$ or 0.662, while the concentration of combined iodine is 0.742 mol I_2. This result evidently indicates that a small amount of a polyiodide higher than KI_3 is present. If we consider it to be only KI_5, then we have

$$C_{\Sigma I_5} = 0.080 \text{ and } C_{\Sigma I_3} = 0.582.$$

We thus reach a conclusion similar to that of Laurie, that a large part of the dissolved iodine in the normal potassium iodide solution saturated with iodine is present as tri-iodide. A similar treatment of the remaining measurements shows that the amount of higher polyiodide decreases as the potassium iodide concentration is decreased, and becomes negligible in the neighborhood of the 0.1 normal solution.

The activity of the tri-iodide ion in the normal potassium iodide solution saturated with I_2 is given by the equation,

$$(A_{I_3^-})_s = (A_{I^-})_s/1.16 = 0.230.$$

If the KI_3 is ionized to the same extent as KI, then the ratio of $A/C =$ for tri-iodide ion is: $0.230/0.79 \times 0.582 = 0.50$, which, of course, is considerably larger than the value (1/3.34), which we have previously calculated on the assumption that no higher polyiodide was present. Our previous calculations, however, will hold for concentrations of ΣK below 0.1 normal.

For the sake of comparison with these results a second series has been calculated from the electromotive force measurements in a similar way on the much less probable assumption that $C_{I_3^-} = A_{I_3^-}$. The two sets of results are presented in columns III and I in the following table. This table also contains, in the second column, the corresponding results when, according to the extrapolation from dilute solutions made early in the paper the ratio $C_{I^-}/C_{I_3^-}$ is assumed to be 0.92, and in the last column those obtained from the sole assumption that no polyiodide higher than KI_3 is present.

An inspection of this table shows that this complicated problem has been reduced to the determination of the variation, with increasing potassium iodide concentration, of the ratio of activity to concentration for a single substance, as iodide ion, in a saturated iodine solution. It is evident that, no matter what assumption is made, one or more of the substances involved will show marked deviations from the law of the ideal solution that activity and concentration are equal.

TABLE VI.—ACTIVITIES AND CONCENTRATIONS OF THE CONSTITUENTS OF THE NORMAL KI SOLUTION SATURATED WITH I_2.

	(I) Assuming $C_{I_3^-} = A_{I_3^-}$.	(II) Assuming $C_{I^-}/C_{I_3^-} = 0.92$	(III) Assuming $C_{I^-} = A_{I^-}$.	(IV) Assuming $C_{\Sigma I_5} = 0$.
A_{I^-}	0.305	...	0.267	...
$A_{I_3^-}$	0.262	...	0.230	...
$C_{\Sigma I}$	0.463	0.408	0.338	0.258
$C_{\Sigma I_3}$	0.332	0.443	0.582	0.742
$C_{\Sigma I_5}$	0.205	0.149	0.080	0.000
$\Sigma_I/\Sigma_{I_3} = C_{I^-}/C_{I_3^-}$	1.39	0.92	0.58	0.35
A_{I^-}/C_{I^-}	0.83	0.89	1.00	1.20
$A_{I_3^-}/C_{I_3^-}$	1.00	0.71	0.50	0.36

In the case of an aqueous solution of a single salt several examples are known in which the activity of a univalent ion increases somewhat less rapidly than its concentration (derived from conductance measurements), and there are at present no exceptions to this rule. This has recently been emphasized by Lewis and von Ende[1] in connection with their work upon the electromotive force of thallous-ion concentration cells. Another illustration is evidently furnished by Jahn's investigations of chloride-ion concentration cells[2] from which he concluded that the degrees of ionization ordinarily calculated from conductance measurements are too high. Some additional examples will be considered in later articles.

From the analogy with Jahn's experiments it is extremely probable that investigations of iodide-ion concentration cells free from iodine, using for example thallium-thallous-iodide electrodes, will yield similar results, and that therefore the activity of iodide-ion in pure potassium iodide solutions increases somewhat less rapidly than its concentration. If this applies in the present case in which the solutions are saturated with iodine, then the composition of the normal solution considered above will probably lie between the values given in the second and third columns of the table, and the solution will contain a greater proportion of higher polyiodide than calculated by Laurie. It is also interesting to note that the activity of tri-iodide ion increases much less rapidly than its concentration, and that this is even more striking when A_{I^-} is equal to or increases more rapidly than C_{I^-}.

But it is by no means certain that the relationship between A_{I^-} and C_{I^-} in potassium iodide solutions free from iodine will be the same as that in solutions saturated with iodine, and the two cases must be considered as two separate experimental problems.

The relation between A_{I^-} and C_{I^-} in dilute potassium iodide solutions saturated with iodine may be determined by combining the results of electromotive force measurements of concentration cells, using iodine electrodes, with the values of C_{I^-} determined in the present investigation. Unfortunately, the existing measurements of Crotogino,[1] in which each iodine electrode was measured against a calomel electrode, are probably not very accurate, and the corrections for the diffusion potential cannot be readily calculated. The results[1] show that A_{I^-} increases more rapidly than C_{I^-}, which is an indication that the composition of the normal potassium iodide solution saturated with iodine is intermediate between the values given in the last two columns of Table VI, and that the amount of higher polyiodide present is very small. This conclusion, however, can scarcely be accepted as correct without further experimental investigation.

---

[1] THIS JOURNAL, 32, 732 (1910).

[2] Jahn, *Z. physik. Chem.*, 33, 545 (1900).

While this evidence is somewhat conflicting, it would seem that the results given in column III of Table VI cannot be very far wrong. Thus, roughly speaking, the ratio of activity to concentration for iodide ion is independent of the concentration. The same ratio for tri-iodide ion diminishes rapidly with increasing concentration, and in all probability the higher polyiodide ions will be found to show even greater abnormalities in the same direction.

Summary.

In this investigation, conductance measurements at 25° have been made with potassium iodide solutions between 0.1 and 0.001 normal, and of the same solutions when saturated with solid iodine. The solubility of iodine in each solution has also been determined.

These results have led to the conclusions that the degree of ionization of KI_3 in dilute solutions is practically identical with that of KI up to a

---

[1] Cf. Sammet, *Z. physik. Chem.*, 53, 674–5 (1905). Crotogino's results, recalculated, are presented in the following table, the potential of the $N/16$ KI electrode being taken as zero. The last column contains the values of E calculated by means of the formula

$$E = 0.0591 \log C'_{I^-}/C''_{I^-},$$

i. e., on the assumption that $A_{I^-} = C_{I^-}$. The values of C_{I^-} are calculated from the data given in Table IV.

ELECTROMOTIVE FORCE MEASUREMENTS OF CROTOGINO.

ΣK.	C_{I^-}.	E measured.	E calc
$N/1024$	0.000509	—0.122	—0.102
$N/256$	0.001956	—0.081	—0.068
$N/64$	0.00744	—0.040	—0.034
$N/16$	0.0277	0.000	0.000
$N/4$	0.0980	0.0038	0.032

The large differences between E measured and E calculated are partly due to diffusion potentials, since the mobility of K^+ is greater than that of I_3^-. We have calculated approximately that 4 millivolts is the value of the diffusion potential between two solutions where there is a fourfold change in the concentration of ΣK; but, since the measurements were made against a calomel electrode, this value must be too high. It is therefore evident that E measured is always greater than E calculated, and that A_{I^-} increases somewhat more rapidly than C_{I^-}.

concentration of 0.1 normal; and that the conductances at 25° of iodide ion and tri-iodide ion are 76.5 and 41.0, respectively, that of potassium-ion being assumed equal to 74.8.

Burgess and Chapman, by means of transference experiments, have made an independent determination of Λ_{I_3} and found a value only slightly greater than ours, namely 42.5. We have therefore adopted an intermediate value, 41.5, as the most probable value of Λ_{I_3}.

It has also been found that in potassium iodide solutions saturated with iodine the ratio $C_{I^-}/C_{I_3^-}$, which according to the law of mass action should be a constant, decreases from 1.16 to 0.99 between 0.0 and 0.1 normal; thus showing that an effect due to the presence of potassium iodide, which has been known to exist in more concentrated solutions, is not negligible even in these very dilute solutions.

Finally we have attempted to determine the composition of concentrated solutions of potassium iodide saturated with iodine, and have illustrated the usefulness of the concept of "activity," as defined by Lewis, in dealing with deviations from the law of mass action. An examination of the existing solubility and electromotive force data has shown that the problem may be solved if the relation between the activity and concentration of iodide ion in solutions saturated with iodine is known. By concentration of an ion is understood the value ordinarily calculated from conductance measurements. Although the somewhat conflicting nature of the evidence prevents an exact solution of the problem, the conclusion is reached that the ratio of activity to concentration for iodide ion is nearly independent of the concentration, that the same ratio for tri-iodide ion decreases rapidly in the concentrated solutions, and that probably higher polyiodide ion show this abnormality in an even higher degree. In a normal potassium iodide solution saturated with iodine, the concentration of KI_5 is calculated to be about 0.08 molal, if this is the only higher polyiodide present.

THE HYDROLYSIS OF IODINE AND OF BROMINE.

BY W. C. BRAY.

Received June 13, 1910.

I. The Hydrolysis of Iodine.

During the investigation described in the preceding paper, we were confronted with the problem of how to account for the conductance of aqueous iodine solutions. From calculations based on Sammet's[1] determinations of the equilibrium constants, we were led to conclude that both of the following reactions must be considered:

---

[1] *Z. physik. Chem.*, 53, 687 (1905).

$$(1)\quad I_2 + H_2O = H^+ + I^- + HIO, \text{ and}$$

$$(2)\quad 3I_2 + 3H_2O = 6H^+ + 5I^- + IO_3^-;$$

and we could predict that the conductance would rise very rapidly at first (reaction (1)), and continue to rise slowly (reaction (2)) to a much higher value than we had found in our preliminary experiments. This prediction has been completely verified by the results of the conductance and solubility measurements described below.

The experimental methods employed were the same as in the experiments described in the preceding article. All measurements were made at 25°. In the final conductance experiments three different portions of powdered iodine were used; these were rotated with frequently renewed portions of water over a period of about three weeks to ensure the removal of all soluble impurities. The conductance then showed a constant value when measured after two hours' rotation. The measurements were made in a low resistance cell with smooth electrodes. The conductance of the water used varied between 0.4 and 0.9×10^{-6}; it was determined in each case and subtracted from the measured conductance. Some experiments with water alone showed that under the regular experimental conditions its conductance changed very little; in 16 hours from 0.89 to 0.94×10^{-6}; in 41 hours 0.58×10^{-6}, unchanged; in 54 days from 0.44 to 1.5×10^{-6}.

The conductance measurements for aqueous solutions are given in Table I:

TABLE I.—SPECIFIC CONDUCTANCE × 10^6 OF IODINE IN AQUEOUS SOLUTIONS.

Hours rotation.	1/4.	2.	4.	8.	15.	16.	18.	21.	40.	(54×24.)
Portion I	3.8	...	..	...	...	...	4.9	4.7	...	19.1
Portion II	...	4.0	4.3	4.7	4.9	4.8	...	...	...	63.9(?)
Portion III	3.8	3.9	4.0	4.0	4.5	4.6	...	...	5.4	..

These results show that the specific conductance of aqueous iodine solutions rises rapidly to 4.0×10^{-6}, and continues to rise very slowly for a long period of time. The results obtained with Portion II are uniformly high, which is due to the fact that the stopper of the bottle did not fit properly; the introduction of an organic impurity and the resulting formation of an iodide would explain the very high result (63.9).

In order to determine the effect of the presence of hydrogen ion the preceding experiments were repeated with approximately 0.001 *N* HCl and HNO_3. In each case the iodine was first washed with the acid and then rotated over night with it before making measurements, in order to eliminate changes due to adsorption. The first two experiments in Table II were performed with the iodine of Portion I in a cell with platinized electrodes which had been heated;[1] the remaining two were preliminary experiments made at an earlier date by Mr. Mackay in a cell with platinized platinum electrodes. The conductance of the acid was measured at the time the acid was added to the iodine.[2]

TABLE II.—SPECIFIC CONDUCTANCE × 10^6 OF IODINE IN 0.001 *N* ACID SOLUTIONS.

Acid used. Hours rotation	HCl. 3.	HCl. 15.	HCl. 42.	HNO_3. 42.
Acid + iodine	420.0	420.2	419.4	417.4
Acid alone	418.8	419.3	418.1	416.3
Difference	1.2	0.9	1.3	1.1

These values for the conductance of iodine are the differences between two large numbers and are therefore much less accurate than the determinations in aqueous solutions. But these results, obtained under widely different circumstances, make it almost certain that the specific conductance of iodine in acid solution is about 1 × 10^{-6}, which is much smaller than the value obtained in pure water.

These experiments were also repeated with 0.001 *N* NaCl solution, using the iodine of Portion III, Table I, in order to determine if the decreased conductance of iodine in the acid solution was due merely to the presence of an ionized substance:

TABLE III.—SPECIFIC CONDUCTANCE × 10^6 OF IODINE IN 0.001 *N* NaCl SOLUTION.

Hours rotation.	1/2.	3.	7.	14.	(55×24.)
NaCl + iodine	130.2	130.4	130.4	131.0	137.3
NaCl alone	127.1	127.1	127.1	127.0	127.0
Difference	3.1	3.3	3.3	4.0	10.3

The conductance of iodine in dilute sodium chloride is thus seen to increase in a manner very similar to that observed in water solutions, though the values obtained are somewhat smaller. The specific conductance (× 10^6) rises rapidly to 3.3 (in water 4.0) and remains nearly constant for several hours; in 14 hours it reaches the value 4.0 (in water 4.6); and in 54 days increases to 10.3 (in water 19.1).

The probable explanation of these results is that the initial value of the conductance of aqueous iodine solutions is mainly due to the rapidly occurring hydrolysis:

$$I_2 + H_2O = H^+ + I^- + HIO,$$

and that this hydrolysis is driven back almost completely in acid solutions.[3]

---

[1] Whetham and Griffiths, *Phil. Trans.*, 194A, 330 (1900).

[2] In two blank experiments in which the hydrochloric acid alone was rotated in the thermostat for two days the conductance remained unchanged.

[3] It is possible that the conductance of iodine in acid solution, 1 × 10^{-6}, is due to the presence of the ions $I^- + I^+$ (cf. W. A. Noyes, THIS JOURNAL, 23, 463 (1901); Stieglitz, *Ibid.*, 23, 797 (1901); Walden, *Z. physik. Chem.*, 43, 415 (1903)). If this is true, then in KI solutions the concentration of I^+ would be reduced to a very small value.

As a check on this result, the relative solubilities of iodine in water and dilute hydrochloric acid have been determined, and also the change of them with the time. The saturated solution was forced into a 100 cc. pipette through an asbestos filter connected with it by a ground-glass joint; the 100 cc. were run into a potassium iodide solution containing sulphuric acid, and the titration was made with freshly prepared (approximately) $N/200$ thiosulphate. The thiosulphate solutions were not accurately standardized, since the measurements desired were only comparative. The value adopted for the total solubility of iodine at 25° was that of Hartley and Campbell,[1] 0.001337 mol I_2 per 1000 grams water, or 0.001333 mol per liter; the solubility, after two hours' rotation, being assumed to have this value. After each experiment extending over a long period of time, the iodine was washed with water and its solubility again determined by rotating it two hours with fresh water. The iodine used in the experiments with 0.001 N HCl was Portion III; in the aqueous solutions Portions I and II. In these experiments only the first 100 cc. portion from each 250 cc. bottle was used, since the second portion, when taken, gave somewhat lower results.

TABLE IV.—RELATIVE SOLUBILITY OF IODINE IN WATER AND IN HYDROCHLORIC ACID SOLUTIONS.

Solvent.	Water.		0.001 N HCl.		0.001 N NaCl.
Time.	Iodine.	Iodate.	Iodine.	Iodate.	Iodate.
1.5 hours...........	2.664	..	...	..	...
2 hours...........	2.666[2]	0.002 or less	2.639	..	...
2 hours...........	..	..	2.639	..	...
3 hours...........	2.666	..	..	..	...
16 hours...........	2.668	..	2.653	..	...
41 hours...........	2.666	0.010 or less	2.665	0.010 or less	...
48 hours...........	2.665	..	...	..	...
27 days............	2.80	..	2.72	0.017 or less	...
27 days............	2.83	0.017	...	..	...
54 days............	..	0.027	...	..	0.025

The iodate concentration was also determined approximately by adding 100 cc. of the saturated solution to a potassium iodide solution containing sodium hydrogen carbonate and an excess of carbonic acid, decolorizing with thiosulphate, adding excess of sulphuric acid, and titrating after 3–5 minutes the iodine now liberated by the action of HIO_3

---

[1] *J. Chem. Soc. Trans.*, 93, 741 (1908). These authors made an extended series of measurements at different temperatures and used carefully purified iodine and conductivity water. Other determinations (in mols per liter) are, Jakowkin, 0.001337; Noyes and Seidensticker, 0.001342; Sammet, 0.001341.

[2] Value derived from several concordant experiments.

on HI.[1] By determining roughly the rate at which iodine is subsequently liberated by the action of oxygen on hydriodic acid, the very small error due to this reaction was eliminated. The iodate was also determined in a single experiment in which the solvent was 0.001 *N* NaCl (in which iodine, Portion III, was used). The results are given in Table IV, in milliequivalents (of $^1/_2I_2$ and $^1/_6HIO_3$) per liter.

The solubility of iodine in the acid solution is (after two hours) just one per cent. less than in water, which is at any rate qualitatively in agreement with the conductance results. The solubility increased slightly in two days in the acid, but remained practically constant in the aqueous solution; and later increased steadily in both cases.[2]

If we assume that the initial solubility in the acid solution is a measure of the true solubility of iodine as I_2, then this value is 1.320 millimols per liter. From the 41-hour experiment, after correcting for the iodate and the tri-iodide due to the iodide formed in the reaction, the value 1.320 is again obtained. The most probable source of error is the presence of iodide (and consequently tri-iodide), and the results are therefore more likely to be too high than too low.

Another method of calculating the true solubility is to correct the value found in pure water by means of the conductance data, Table I. Assuming that the conductances, 4.0, 4.6, and 5.4, after 2 16, and 41 hours, respectively, are due solely to the acid (mainly HI) formed by the reactions (1) and (2), then the ion concentrations obtained by dividing them by $\Lambda_H + \Lambda_I = 425$ are approximately 0.0094, 0.0108 and 0.0127 millimol per liter. The corresponding iodine concentrations (in equivalents), which are to be subtracted from the solubilities are approximately three times these values; since for each equivalent of H^+ there are two oxidation equivalents of HIO (or IO_3^-) and roughly one oxidation equivalent (= 0.5 mol) of I_3^- (since about one-half of the iodide ion originally formed is converted into tri-iodide ion). The true solubilities after 2, 16 and 41 hours are therefore 1.320, 1.318 and 1.314 millimols I_2 respectively. These results may be too low if the conductance is not wholly due to the acid formed in the reactions (1) and (2).

The agreement between these two independent methods confirms the correctness of both, and the value 1.32 millimols I_2 per liter was therefore chosen as the true solubility at 25° of iodine as such.

[1] Bray, *Z. physik. Chem.*, 54, 470 (1905). The amount of dilute thiosulphate required in the first stage of the titration was always considerably less than the theoretical amount, but increased when the concentration of potassium iodide present increased. This phenomenon is probably due to direct oxidation of the thiosulphate to sulphate (cf. *Ibid.*, 472).

[2] The unexpectedly high values for the 27-day experiments may be due to an experimental error, since all depend on a single (comparative) determination of the solubility of iodine after two hours; but are more probably due to the entrance of some organic matter through the stoppers.

It is now possible to calculate the equilibrium constant of the hydrolysis: $I_2 + H_2O = H^+ + I^- + HIO$, from the above given value of the H^+ concentration. Since it seems probable that the initial conductance 4.0×10^{-6} of an aqueous solution is a measure of the hydriodic acid formed in this reaction, $(H^+) = (I^-) = (HIO) = 0.94 \times 10^{-6}$ mols per liter, and the equilibrium constant

$$(H^+)(I^-)(HIO)/(I_2) = 0.6 \times 10^{-12}.$$

This value is much smaller than the limiting values, 10^{-8} to 10^{-10} estimated by Sammet; but he considered his results to be of very little value and gave no details of his measurements.

It is interesting to calculate the maximum conductance which should be finally attained by the saturated aqueous solution as a result of reaction (2) from Sammet's (accurate) value of its equilibrium constant: $(H^+)^6(I^-)^5(IO_3^-)/(I_2)^3 = 2.8 \times 10^{-47}$. The concentrations of the other substances are calculated from the known concentration of the iodine to be: $(H^+) = 3.16 \times 10^{-5}$, $(I^-) = 2.63 \times 10^{-5}$, and $(IO_3^-) = 0.53 \times 10^{-5}$, and the corresponding specific conductance is calculated to be 13×10^{-6}. This value is somewhat larger than that obtained in the sodium chloride solution, 10.3×10^{-6}, and somewhat smaller than the value in aqueous solution, 19.1×10^{-6}.

II. The Hydrolysis of Bromine.

It is well known from the comprehensive investigation of Jakowkin[1] that dilute solutions of chlorine are hydrolyzed to a very considerable extent. The hydrolysis constant at 25° is

$$(H^+)(Cl^-)(HClO)/(Cl_2) = 4.48 \times 10^{-4}.$$

Since bromine occupies an intermediate position between chlorine and iodine in so many instances, it is almost certain that bromine solutions will also exhibit hydrolysis. This hydrolysis is mentioned in a recent article by Jakowkin,[2] but no experimental data are given. In the following some preliminary measurements are described:

A large portion of liquid bromine was placed in a 250 cc. bottle and shaken successively with eight portions of fresh water. Conductance measurements were made, and the correction for the specific conductance of water applied, as in the preceding experiments. Portions of each solution were also removed in a small pipette designed to prevent an error due to evaporation; and were added to a concentrated solution of potassium iodide containing sulphuric acid; the liberated iodine was titrated with thiosulphate. The results are presented in the following table. In experiments 3(*b*) and 7(*b*) the water was not renewed. In the final experiment, the solution was probably not saturated, since the amount of bromine left was very small.

[2] Jakowkin, *Ibid.*, 70, 188 (1910).

TABLE V.—CONCENTRATION AND CONDUCTANCE OF SATURATED BROMINE SOLUTIONS

No.	Time (hours)	Equiv. conc.	Spec. cond. × 10^6.
2	70	0.506	7440
3*a*	1	0.465	4160
b	20	0.466	4160
4	2	0.440	2210
5	1	0.424	907
6	1	0.424	734
7*a*	1	0.411	726
b	6	0.425	805
8	2	0.411	728

The concentration decreases slightly, and the conductance greatly in the first five experiments, probably owing to the gradual removal of some impurity, such as hydrobromic acid or potassium bromide. The bromine appears, from the approximate constancy of the two series of results, to have been nearly pure in the last four experiments; and the following values are probably not greatly in error: solubility, 0.21 mol Br_2 per liter;[1] specific conductance, 727×10^{-6} reciprocal ohms.

If we assume that the conductance is solely due to the hydrobromic acid formed by the hydrolysis, $Br_2 + H_2O = H^+ + Br^- + HBrO$, then the concentration calculated for $(H^+) = (Br^-) = (HBrO)$ is 0.0017. This corresponds to 0.8 per cent. hydrolysis, and the calculated equilibrium constant is:

$$(H^+)(Br^-)(HBrO)/(Br_2) = 2.4 \times 10^{-8}.$$

This value differs very little from the geometric mean, 1.7×10^{-8}, of the hydrolysis constants of chlorine and iodine.

Summary.

From conductance and solubility measurements of iodine and of bromine in water, the hydrolysis constants $(H^+)(I^-)(HIO)/(I_2)$ and $(H^+)(Br^-)(HBrO)/(Br_2)$ are found to be 0.6×10^{-12} and 2.4×10^{-8}, respectively.

BOSTON, March, 1910.

THE THERMAL DISSOCIATION OF CALCIUM CARBONATE.

BY JOHN JOHNSTON.

Received June 16, 1910.

Measurements of the dissociation pressures of calcium carbonate have been made through a range of temperatures by Debray,[2] LeChatelier,[3]

---

[1] This value agrees well with that determined by Winkler (Seidell, solubilities, page 67) 3.36 g. per 100 g. soln., or approximately 0.206 mol per liter.

[2] *Compt. rend.*, 64, 603 (1867).

[3] *Id.*, 102, 1243 (1886).

Brill,[1] Pott[2] and Zavriev.[3] Quite recently, E. H. Riesenfeld[4] has discussed the data of each of these authors. He concludes that, owing to errors in the measurement of pressure or of temperature, or of both, the data of the first three authors are altogether untrustworthy, and sets up an involved empirical formula to express the mean results of Zavriev and Pott. Pott made four series of measurements over the temperature range 600–900°; these, however, are by no means so concordant as might be wished, *e. g.*, for 892° he found pressures which varied from 593 mm. to 776 mm. Still, a curve drawn through the midst of his points coincides approximately with that which represents the results of Zavriev, which are relatively few in number but more concordant among themselves.

From the results of either author it follows that the dissociation point (*i. e.*, the temperature at which the pressure of carbon dioxide is one atmosphere) is close to 910°. This value was confirmed by special experiments made by Riesenfeld, who determined anew the temperature at which a loss of weight occurred when the carbonate was heated in an atmosphere of pure carbon dioxide. He showed, moreover, that the possibility of formation of solid solutions of calcium oxide in the carbonate and *vice versa* is practically excluded, while it was shown by Zavriev that no basic carbonate exists.

It has therefore now been definitely proved that the dissociation of calcium carbonate proceeds according to the scheme $CaCO_3 \rightleftarrows CaO + CO_2$, and to that scheme solely. The discrepancies in the results are thus to be attributed entirely either to errors in the measurement of the temperature of the substance, or to errors in the pressure, due either to the fact that equilibrium conditions had not been attained or to the presence of water vapor or of some other impurity capable of developing a pressure.[5]

The apparatus used by both Pott and Zavriev consisted essentially of a long porcelain tube closed at one end, connected to a manometer at the other. In this tube were placed quantities of substance weighing from 2–5 grams, and the thermoelement was embedded in the charge in such a way that the junction was in the hottest part of the furnace. Now Zavriev observed directly differences of more than 50° in the temperature at various points of somewhat larger charges contained in a boat 5 cm. in length; so it is not unreasonable to suppose that the temperature variations throughout the charge were still considerable in the actual measurements. This difficulty has been encountered in all accurate high temperature work, but its importance, and the magnitude of the error introduced thereby, have not yet been generally appreciated.[1] For accurate work it is of the highest importance that the temperature of the charge be as uniform as possible; for otherwise, since the carbon dioxide is in equilibrium with that calcium oxide which is at the *lowest* temperature, one cannot determihe with any certainty the appropriate temperature corresponding to the pressure observed. In the author's experiments,[2] this difficulty was obviated by using charges of only about 0.1 gram, the total vapor space being not more than 5 cc.; this possesses the additional advantage that a transfer of a very small amount of carbon dioxide from the solid to the vapor phase suffices to bring the system into equilibrium, and consequently equilibrium conditions are established comparatively rapidly.

The apparatus used was a slight modification of an apparatus previously described by the author.[3] The substance was contained in a platinum tube 6 cm. in length, 6 mm. in external and 5 mm. in internal diameter, which was sealed directly on to a glass tube and thereby, through an adjustable mercury trap, connected to a mercury manometer, on which the pressures were read directly with the aid of a fine mirror scale divided in millimeters. After complete evacuation of the apparatus, the platinum tube was heated gently for some time in order to expel any water or other volatile impurity; by manipulation of the stopcocks the mercury was raised in the trap, thereby delimiting the vapor space. The platinum tube was enclosed almost entirely in a small vertical resistance furnace, and was well packed with asbestos at the mouth of the furnace. The temperature was in general increased step by step; in a few cases it was dropped some degrees with a corresponding drop in the pressure. In all cases the reading was taken only when at constant temperature the pressure had attained a constant value; at low pressures, this required an interval of some hours, but at the higher pressures half an hour usually sufficed.

The temperature of the charge was measured by means of a thermoelement the junction of which was welded on to the outside closed end of the platinum tube; elsewhere the thermoelement wires were insulated by small Marquardt tubes. The element used had previously been carefully calibrated at the melting points of zinc, silver and copper (418°,

---

[1] Cf. Day and Sosman, *Am. J. Sci.*, 29, 99, 102 (1910); W. P. White, *Idem.*, 28, 335 (1909).

[2] To avoid possible misunderstanding, it may be stated that the measurements were completed in April, 1909; that at that time I had seen only the preliminary paper of Zavriev (*Compt. rend.*, 145, 428 (1907)), and was entirely unacquainted with the work of Pott; further, that Table 1 is a complete record of the measurements which I have made.

[3] *Z. physik. Chem.*, 62, 333, 335 (1908).

960°, and 1083° respectively), the electromotive forces being measured by the usual arrangement of potentiometer and galvanometer. After being welded on the element was compared several times with a previously calibrated standard element the junction of which was immersed in calcium carbonate inside the platinum tube, the other conditions being precisely those of the actual pressure measurement. By this means it was shown that the maximum variation in the temperature of the charge did not exceed 2° and that the difference between the temperature registered by the element welded outside and that of the standard element inside the tube was 2.5° at 400° and 5° at 900°,[1] the variation being practically linear. All the temperatures given have been corrected for this difference, and it is considered that they are certainly correct to within ±2°. Four series of observations were made; in two series, pure precipitated calcium carbonate alone was used, some carbon dioxide being driven off by the initial heating after evacuation; in the other two series, the substance taken was a mixture of the pure carbonate with pure freshly ignited oxide. All the observations are brought together and arranged in Table 1; *p* is the pressure in millimeters of mercury, *t* and T the centigrade and the absolute temperatures respectively. These points are all plotted on Fig. 1, from which it is evident that they all lie close to the graph of equation VI*a*. The derivation of this equation will now be given.

TABLE 1.—ACTUAL EXPERIMENTAL RESULTS.

---

[1] It was found that the absolute magnitude of these temperature differences varied within 1° or 2° with the depth of immersion of the platinum tube in the furnace and with the efficiency of the packing at the mouth of the furnace; this variation of the differences could, however, be rendered inappreciable by reproducing always the same conditions.

In a previous paper[1] it was shown that for a number of heterogeneous equilibria similar to that under consideration, the dissociation pressure is connected with the heat of reaction[2] ΔH by the equation

$$\log P = \frac{\Delta H}{4.576T} - \frac{I'}{4.576} \qquad (I)$$

I' being the so-called thermodynamically indeterminate constant; and that this relation holds within the limits of accuracy of our present knowledge of ΔH and of the other thermochemical quantities involved. The above simple relation is derived by neglecting all the higher terms; this is equivalent to the assumption that ΔH is independent of the temperature.

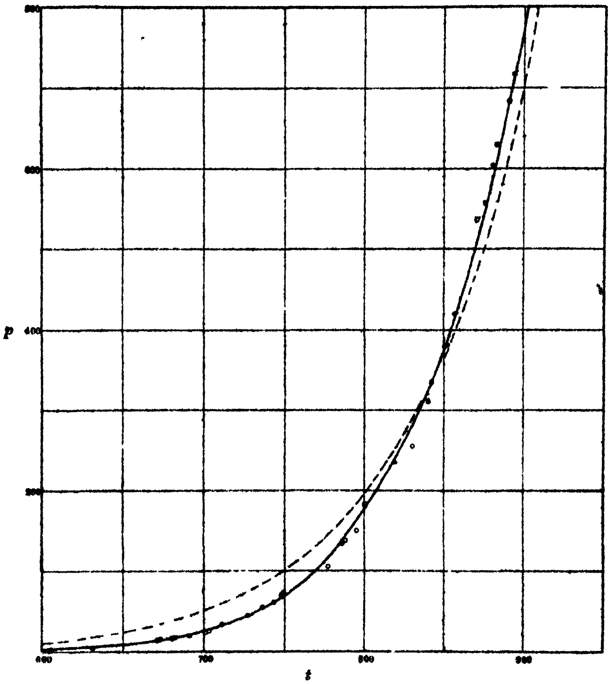

Fig. 1.—Experimental results on the dissociation pressure of $CaCO_3$. The full line is the graph of equation VI*a*; the broken line that of Riesenfeld's equation.

In the present case, our knowledge of the thermal quantities, though by no means satisfactory, is such that it is advisable to insert terms which shall represent the change of ΔH with the temperature. Consequently, we write $\frac{d(\Delta H)}{dT} = \Delta C_p$ and assume $\frac{d(\Delta C_p)}{dT} = \alpha$ where α is a constant; ΔC_p is the change in heat capacity of the system when the reaction $CaCO_3 = CaO + CO_2$ takes place. Hence, by integrating, we obtain

---

[1] THIS JOURNAL, 30, 1357 (1908); *Z. physik. Chem.*, 65, 737 (1909).

[2] ΔH is the amount of heat *absorbed*, as ordinarily measured calorimetrically, when the reaction $RCO_3 = RO + CO_2$ takes place. In the former paper, the pressure was expressed throughout in atmospheres; in the present paper, p is expressed always in millimeters mercury; this is more convenient, and causes only a numerical difference in the value of I. It may be noted that $4.576 \log P = R \ln P$ where ln is the natural log, and R the gas constant.

$$\Delta H = \Delta H_0 + \Delta C_{p0}\, T + \tfrac{1}{2}\, \alpha T^2 \qquad \text{(II)}$$

and therefore equation (I) becomes[1]

$$-RT \ln p = \Delta H_0 - \Delta C_{p0} T \ln T - \tfrac{1}{2}\, \alpha T^2 + I\, T \qquad \text{(III)}$$

In order to derive numerical values of the coefficients in equation (III) from the thermal data available, it is necessary to proceed in the following somewhat roundabout manner: The mean of the concordant values for the heat of reaction obtained by Thomsen and by de Forcrand is 42900 cal.; *i. e.*, $\Delta H = 42900$ when $T = 300°$. Now, by making a least square solution for all the experimental data comprised between $T = 1000°$ and $T = 1167°$ on the assumption that the equation $\log p = a/T + b$ holds (*i. e.*, on the assumption that within the above temperature range ΔH is fairly constant), we obtain the equation

$$\log p = -8419/T + 10.071 \qquad \text{(Ia)}$$

Hence at the mean temperature, say $T = 1100$, we have, by comparison with equation (I),

$$\Delta H = 8419 \times 4.576 = 38500 \text{ cal.}$$

By substitution of these pairs of values in equation (II) and elimination of ΔH_0, the equation

$$5.5 = -\Delta C_{p0} - 700\, \alpha \qquad \text{(IV)}$$

results; this can be solved by combining it with some recent results on the specific heats of calcium carbonate and oxide. Lindemann,[2] namely, found that the specific heat, at the ordinary temperature, of $CaCO_3$ was 0.2027; and that of CaO was 0.1821. Hence, the values of C_p (the molecular heat capacity) are 20.3 and 10.2 respectively. When $T = 300°$, C_p for CO_2, as deduced from the work of Holborn and Henning, is 9.0; hence

$$\Delta C_p = 9.0 + 10.2 - 20.3 = -1.1 \text{ when } T = 300.$$

This statement is equivalent to the equation

$$-1.1 = \Delta C_{p0} + 300\, \alpha \qquad \text{(V)}$$

from which, by combination with (IV), we obtain

$$\alpha = -0.011$$

$$\Delta C_{p0} = 2.2$$

and hence from II, $\Delta H_0 = 42700$.

---

[1] Cf. Haber, "Thermodynamics of Technical Gas Reactions," pp. 26, etc.; Johnston, *Loc. cit.*, p. 1358.

[2] Nernst, Koref, and Lindemann, *Sitzungsber. Akad. Wiss., Berlin*, 1910, 247.

Inserting these values, equation III becomes

$$-RT \ln p = 42700 - 2.2\ T \ln T + 0.0055\ T^2 + I\ T$$

which may be written in a form more convenient for calculation,

$$\log p = -9340/T + 1.1 \log T - 0.0012\ T - I''. \qquad \text{(VI)}$$

When the corresponding values of p and T are substituted in equation (VI), concordant values of I'' are obtained, the mean of which is —8.882. Finally, therefore, as the equation which represents p (expressed in mm. mercury) as a function of T (the absolute temperature) we have

$$\log p = -9340/T + 1.1 \log T - 0.0012\ T + 8.882. \qquad \text{(VI}a\text{)}$$

This equation reproduces the observations over the whole range within the probable error of experiment;[1] and since its form is theoretically the most satisfactory, consistent with present knowledge, it may be used with some confidence for extrapolation. By means of equation VI*a* the equilibrium pressures have been calculated for a number of temperatures (centigrade); the results are presented in Table II. The dissociation point is 898°.

These results are considered to be better than any of the existing data on the subject because of the superior accuracy with which the temperature of the dissociating substance was determined. For the sake of comparison, however, results interpolated graphically from the experimental data of Zavriev and of Pott are included in Table II.

TABLE II.—EQUILIBRIUM PRESSURES (IN MM.) FOR $CaCO_3$ AT ROUND TEMPERATURES.

t.	Calc. by equation VI*a*.	Interpolated from the data of Zavriev.	Pott.
500	0.11	...	...
550	0.57	...	...
600	2.35	..	...
650	8.2	...	...
700	25.3	43	53
750	68	95	101
800	168	197	195
850	373	381	350
900	773	697	667
950	1490	...	...
1000	2710	...	...

From the data of these authors, Riesenfeld deduced the mean values at five temperatures—700°, 750°, 800°, 850° and 900°;[2] and on the basis of these results, with the aid of the Nernst formula for heterogeneous equilibria, arrived at the equation[3]

---

[1] Equation I*a* fits the data from T = 1000 to T = 1167 almost as well as equation VI*a*; but, on account of the fact that ΔH actually does vary with the temperature, it is not satisfactory as an extrapolation formula.

[2] The values are close to the arithmetic means of columns 2 and 3, Table II.

[3] P is in atmospheres. It may be noted that the coefficient of the first term on

$$\log P = -9300/T + 1.75 \log T + 0.011{,}916\ T - 0.000{,}020{,}323\ T^2 + 0.000{,}000{,}008{,}2446\ T^3 + 3.2.$$

The graph of this equation over the experimental range is drawn as a broken line in Fig. 1, which shows that from about 800–900° the results from both equations are not very different. It is otherwise at other temperatures, and the discrepancy becomes especially noticeable at higher temperatures; at 1500°, Riesenfeld's equation leads to a value of 6,790,000 atmospheres, whereas equation VI*a* gives 151 atmospheres. In order to bring out the difference between the two formulas and the consequent uncertainty of extrapolation, Fig. 2 has been constructed by drawing the graphs of both equations for a range of temperature extending from 400–1500° C. This was accomplished by plotting the values of log *p* (in mm.) against those of $10^6/T$;[1] that part of either curve

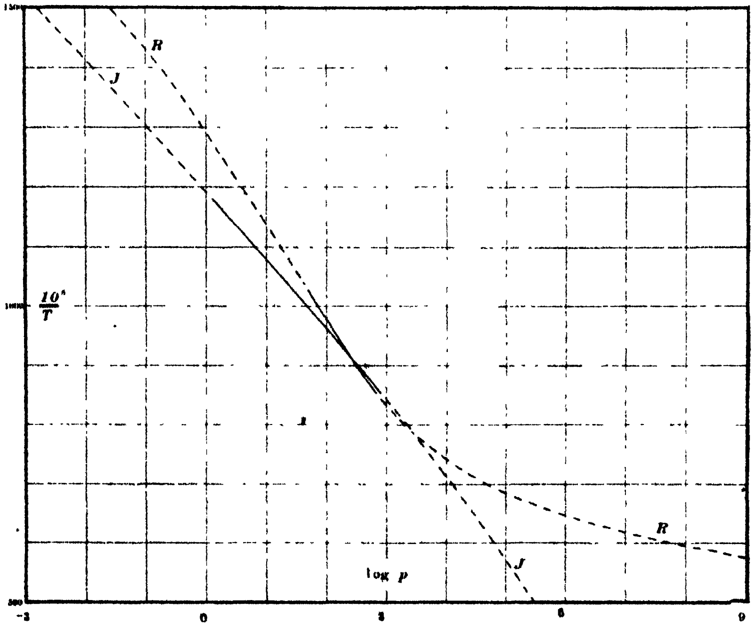

Fig. 2.—Graphs of Riesenfeld's equation (RR) and of equation VI*a* (JJ): the portions extrapolated are represented by broken lines.

---

the right-hand side is derived from the heat of reaction at room temperature, and is the only coefficient to which a direct physical interpretation can be given; that of the second term and the constant are taken from Nernst; the other three coefficients were chosen so as to fit the pressure data.

[1] Plotting with these coördinates possesses the advantages: that the graph of equations such as VI is nearly a straight line, and is absolutely a straight line so long as ΔH is independent of T; that the value of ΔH at any point can be readily derived from the slope of the curve at that point.

based on direct experiment is drawn full, while the extrapolated portions are represented by broken lines. Comment is unnecessary.

Summary.

In preceding measurements of the equilibrium pressure of the reaction $CaCO_3 \rightleftarrows CaO + CO_2$, the errors have been due mainly to a lack of definiteness in the temperature of the reacting system; in the author's experiments this difficulty has been obviated by the use of a very small quantity (0.1 gram) of material, by which means the extreme temperature variation throughout the charge did not exceed 2°. This necessitated the use of a form of apparatus in which the vapor space was always small; this, and the mode of measuring the temperature accurately, are described in the paper. It is considered that the uncertainty in the temperature is not greater than ±2°.

The results of four separate series of measurements can be well reproduced by the equation

$$\log p = \frac{-9340}{T} + 1.1 \log T - 0.0012\,T + 8.882$$

where p is the equilibrium pressure (expressed in millimeters of mercury) at the absolute temperature T. The pressure reaches one atmosphere at 898° C. Two of the numerical coefficients of the above equation are derived from the heat of reaction and the heat capacities of the components; the form of the equation is consistent with our present theoretical knowledge; consequently, in spite of the somewhat unsatisfactory character of the thermal data, the equation may be used with some confidence for extrapolation. The above equation represents the experimental results much better than the formula proposed by Riesenfeld, and derived from the approximation formula of Nernst; values extrapolated by means of the latter diverge from, and are inherently less probable than, those derived from the former, especially at temperatures above 1000°.

GEOPHYSICAL LABORATORY, CARNEGIE INSTITUTE OF WASHINGTON,
WASHINGTON, D. C.

ON THE CONDUCTIVITY OF SOME CONCENTRATED AQUEOUS SOLUTIONS AT ZERO.

BY W. H. SLOAN.

Received May 9, 1910.

As a preliminary step to an investigation of the conductivities of certain salts in mixed solutions of water and ammonia, some measurements were made of the conductivity of potassium iodide in concentrated aqueous solutions, which gave unexpected values. Further investigation confirmed these results, and the measurements were extended to potassium bromide, sodium nitrate, ammonium nitrate, silver nitrate, and copper

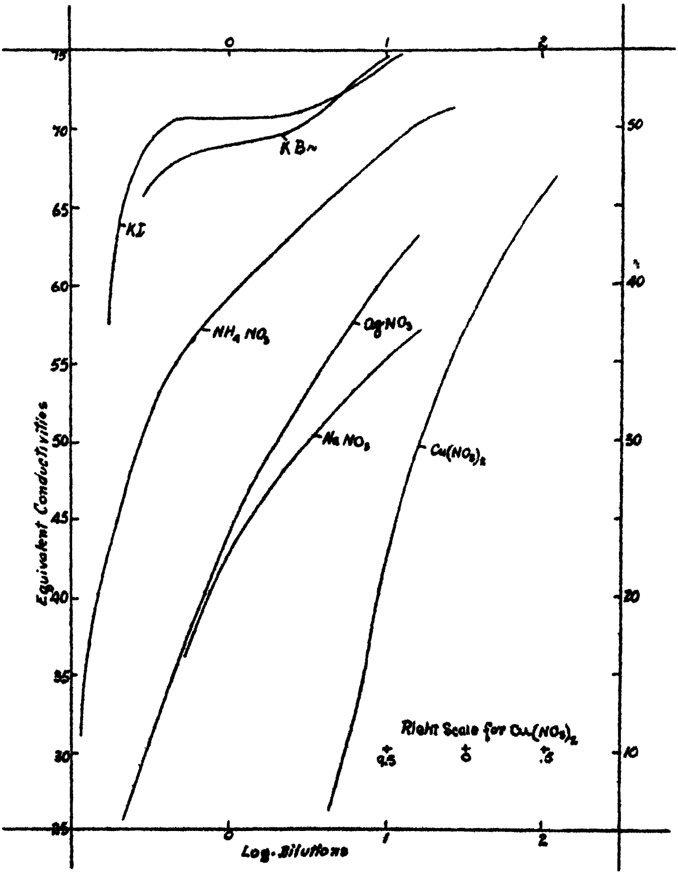
nitrate. Of these, the potassium bromide resembles the potassium iodide to some extent, but its limited solubility prevented measurements of any concentrated solutions. The other salts gave no exceptional values, save in the case of copper nitrate, where in the concentrated solutions, the specific conductivity of the solution increased from a dilution of 0.13 up to 0.26 and then fell off again. (See table Copper nitrate).

The measurements were made by means of a wire bridge and a Kohlrausch conductivity cell. A large Dewar tube was used for a thermostat, which was filled with crushed ice and water. With the use of a stirrer, a very constant temperature of 0.05° to 0.1° + was easily maintained.



(This type of thermostat was first used on account of the special type of cell necessary in the conductivity measurements of the ammonia solutions. The use of the Dewar tube made the reading of the volumes possible from the outside).

The water used was twice distilled, first from dilute sulphuric acid and potassium dichromate, and then from a barium hydroxide solution. The salts used were of Baker's Special Analyzed Chemicals, and in the case of the potassium iodide, the measurements were checked against a recrystallized sample. In every case several readings were taken on the bridge, and in the case of the potassium iodide, four different samples of salt, and three different cells were used, all giving check results.

The above results were obtained where Λ = equivalent conductivity and $\phi/_{1000}$ = dilution.

In plotting the curves, the logarithms of the dilutions were used.

The results obtained for the concentrated solutions of potassium iodide are decidedly different from those given by Jones and Douglas,[1] but the type of curve agrees very closely with that of Kahlenberg,[2] the molecular conductivity being a little higher than Kahlenburg's.

In plotting the conductivities of potassium iodide and potassium bromide at 18°, on the same basis, the values as given by Kohlrausch and associates, show the same tendency, but not so marked, but the concentrations are not so great.

The values at 0° for potassium iodide resemble in some respects, the conductivities of certain salts in methylamine and liquid ammonia, as given by Franklin and Gibbs[3] and Franklin.[4]

A satisfactory explanation of the results obtained does not seem possible at present. It is hoped that further measurements may produce some clue.

This work was carried out at the suggestion and under the direction of Prof. E. C. Franklin.

ELECTRIC COMBUSTION FURNACE FOR METHANE DETERMINATION.

BY J. A. FRIES.

Received June 13, 1910.

In connection with the respiration calorimeter experiments upon cattle which are being carried on here, it is necessary to determine the amounts of combustible gases (consisting chiefly or wholly of methane) excreted. For this purpose an electric combustion furnace has been in use in this laboratory during several periods of 50 consecutive hours each, and is giving perfect satisfaction.

The work to be done and the size and construction of the furnace are so different from those of ordinary combustion furnaces that a description of the furnace may not be without interest and value.

Work Required of the Furnace.—From the continuous current of air passing through the respiration calorimeter chamber when an experiment is in progress, samples for analysis are taken at frequent and regular intervals, the quantity of these samples being equal to a continuous air current of 3.5 liters per minute. This amount of air passes through the combustion tube, where the combustible gases are oxidized, platinized kaolin serving as a catalyzer.

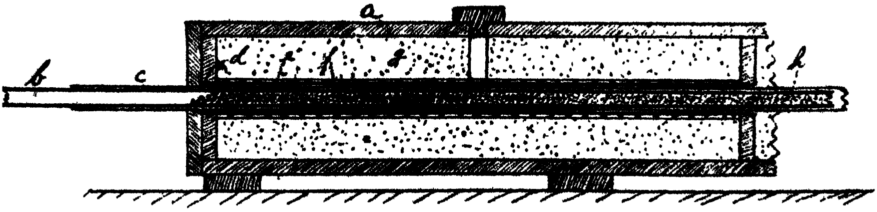
Combustion Tube.—The combustion tube, which is similar to that used previously with a gas furnace for the same purpose during a number of years, is a seamless copper tube 3.35 meters long, $^3/_4$ inch iron pipe size, inside diameter about 20 mm., and with walls about 3 mm. thick. The heated section of this copper tube is protected by a nickel-plated brass tube 8 feet long which fits loosely over it.

Electric Current.—The electric current at our disposal is a three-phase alternating current of about 110 volts pressure during the day, but in the evening and night when the most lighting is required, the voltage is increased to between 120 and 125.

Material for Furnace.—The outside box and supports for the tubes were $^3/_4$ inch thick asbestos lumber. Three quartz tubes, 37 mm. inside diameter, each about 70 cm. long, were used for cores upon which were wound the resistance coils, consisting of 6 mm. Nichrome ribbon. A 3 mm. asbestos cord and an 18 mm. asbestos tape were used to keep the resistance coil in position and prevent short circuiting.

Construction of the Furnace.—The accompanying sketch of a section of the furnace shows the construction of the same.

The outside dimensions of the asbestos box are: 215 cm. long, 17.5 cm. wide, and 19 cm. high. The asbestos was worked and screwed together like ordinary wood. Cross partitions supporting the ends of the quartz tubes were securely fastened to the sides of the box. Each quartz tube was wound separately with about 4 meters of Nichrome ribbon 6



Cross-section showing one-third of the furnace: *a*, asbestos lumber; *b*, copper tube; *c*, brass tube; *d*, quartz tube; *e*, Nichrome ribbon; *f*, asbestos tape; *g*, quartz sand; *h*, platinized kaolin.

mm. wide and 0.3 mm. thick, having a resistance of 173 ohms per 1000 feet. This length made a coil of 29 turns equally spaced over the exposed length of the tube. The ribbon was wound directly on the quartz tube, wired fast with resistance wire at each end, and between each turn was wound a 3 mm. asbestos cord. Between the turns of the cord an 18 mm. asbestos tape was wound directly over the Nichrome ribbon. This method of winding made it all very firm and practically impossible for the ribbon coils ever to work loose and the loops to come in contact with each other. The wound quartz tubes were put in position so that they formed a straight opening. The ends of the coils leading out to the binding posts on the outside of the asbestos box were doubled back upon themselves twice and wired together, in order to reduce the resistance and the heating of them by the current. Very thin asbestos was laid over joints and any crack in the asbestos tape winding so as to keep the sand away from the tubes, and then the box was filled with fine quartz sand. About the middle of each tube and coil there was left a round hole, 1 inch in diameter, extending from the outside of the lid to the asbestos covering on the ribbon, and by means of this opening the condition of the tubes as to heat can be observed at any time. The binding posts were screwed on the side of the box and the doubled up ends of the ribbon project between the lid and upper edge of the side of the box. Three of these binding posts connect the three main wires and the three ends of the resistance coils. The coils themselves were connected in star fashion, that is, the three free ends were united.

This method of wiring reduces the voltage in the coils and hence less ribbon is required per coil for a given amount of heat than by the mesh method of wiring. The maximum heat possible under this system of wiring would be

$$\text{main voltage}/\sqrt{3} \times \text{amperes}.$$

By actual test the voltage across these resistance coils varied from 60.5 to 62.5, and the ammeter measured about 23.5 amperes, while at the same time the voltage between the three mains was 107.5 to 108.5. The load on the main was not perfectly balanced nor was the current very steady, but from the average of the readings, the heat generated in each coil would be 1434 watts, or computed to the surface of the tube, equal to 1.7 watts per square centimeter.

This amount of heat proved to be entirely too much and the temperature of the furnace rose to nearly 1200°. The greater efficiency noticed in this furnace, when compared with the results of laboratory tests made with quartz tubes wound with wire and insulated with magnesia covering, must be ascribed to the better insulating quality of the sand, and to the fact that a broad ribbon was used for resistance coils instead of a small wire.

In order to reduce the heat in the furnace, a coil consisting of 5 feet of the same ribbon was put in as outside resistance in each of the three main wires and in order to meet the fluctuations and increase in voltage on the main, two sets of coils, 1 foot ribbon per coil, were so arranged on the top of the box that one or both sets could be thrown in by means of two switches. Each of these sets of coils equals about 1 ampere difference in the current.

By this arrangement of the resistance, the current can be held at 15 to 15.5 amperes, which maintains a temperature of 700° or a little less in the furnace. This is equivalent to about 0.79 watt per square centimeter tube surface. With the copper combustion tube in position, the temperature of the furnace is reduced somewhat near the ends of the furnace, but under these conditions the heat has been found to be sufficient for the work required.

The ends of the copper combustion tube were threaded and reduced to $^1/_4$ inch iron pipe size by means of brass fittings, the joints of which were also soldered. The return pipe from the furnace to the train of absorption tubes is iron connected with good rubber tubing.

Test of the Furnace and Combustion Tube.—When all connections had been made ready for use the whole system was put under 5 inches mercury pressure and suction and showed no leak. Next, the oxidation capacity of the furnace was tested by allowing alcohol vapor to be carried through with the air current, the carbon dioxide formed being absorbed and the air again allowed to pass through a similar combustion tube heated by gas. It was found that the combustion was perfect in the electric furnace, not a trace of carbon dioxide being found after the second furnace.

After this test a weighed quantity of alcohol was oxidized with the following results:

		CO_2.	H_2O.
5.4127 grams alcohol, sp. gr. 0.82478:	Theoretical,	9.2271 g.	6.2542 g.
	Found.	9.2210 g.	6.1920 g.

The carbon dioxide found agrees as well as can be expected with the theoretical, but the water is a little low. This was caused by stopping the experiment a little too soon, some of the water still remaining condensed in the connections. The time used for the determination was $3^1/_2$ hours. This test was considered entirely satisfactory and the furnace has proven so ever since.

Expansion of Copper Tube.—The copper combustion tube expands about 1 inch in length when heated, besides a very small amount in diameter, hence it should not fit too tightly in the furnace, nor have very sharp edges nor rough surfaces over which to move. Because of this expansion it is advisable to use rubber connections at the cool ends or some flexible tin or lead pipe where such material can be used. The small unevenness commonly found in the quartz tubes does not seem to interfere with the expansion.

Durability of Copper Combustion Tube.—Copper tubes such as have been described have been in use with the gas furnace for as many as 1100 hours before being renewed. With the electric furnace, where the heat is much more uniform, the tube, which in this case is nickel-plated on the outside, may last even longer.

Advantage of Electric Furnace over the Gas Furnace.—By the electric furnace a source of probable error—that of combustible gases under certain atmospheric conditions contaminating the air supply of the respiration calorimeter—has been removed. It supplies more uniform heat. It is more economical than gasoline gas since even with much outside resistance the amount of heat lost is only a very small fraction of that wasted by a large gas furnace. There is no trouble in regulating the heat as there is with a varying gas supply.

THE PRECIPITATION OF THE IRON GROUP AND THE COMPOSITION OF CERTAIN FERRIC FORMATES.

By O. F. Tower.

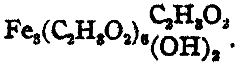
Received June 7, 1910

The difficulties of precipitating the metals of the iron group, *viz.*, iron, aluminium and chromium are well known. Many prefer to attempt no independent separation, but to precipitate them along with the zinc group by using both ammonium hydroxide and ammonium sulphide. This, however, entails a complex and rather tedious method of analysis, unless chromium is known to be absent. In case manganese is absent the metals of the iron group may be separated rather sharply by repeating the process of precipitation. After the first precipitation with ammonium hydroxide, the precipitate is dissolved in hydrochloric acid and the metals reprecipitated with ammonium hydroxide as before. In this way any zinc or nickel dragged down in the precipitation are fairly completely removed. The most complete method of separation, however, no matter what other common metals may be present, is to precipitate them as basic acetates. Furthermore, the presence of PO_4''' causes no complications when the basic acetate process is employed, provided sufficient $\overset{\cdots}{Fe}$ is present. In addition to causing the removal of the PO_4''', $\overset{\cdots}{Fe}$ is required to insure the precipitation of chromium. The great objection to the use of the method, however, is the great difficulty experienced in filtering and washing the precipitate of basic acetates.

On this account, in 1861, F. Schulze[1] recommended the use of ammonium formate for precipitating iron and aluminium, claiming that the basic formates are much easier to filter and wash than the corresponding acetates. This paper contains an account of an investigation of this point together with a few matters closely related to it.

Schulze's conclusions, in the main, have been confirmed. Both iron and aluminium can be practically completely precipitated by boiling with ammonium formate provided the solution is sufficiently dilute. The boiling need be continued only for a moment. The precipitate has a flocculent appearance and looks as if it could be filtered with great ease. Filtration is, however, not so rapid as Schulze describes, but can be accomplished in less time than in the case of the basic acetates. Chromium by itself is not precipitated by boiling with ammonium formate, but is carried down by basic ferric formate, hence the presence of $\overset{\cdots}{Fe}$ is required for the complete precipitation of the group. The presence of ammonium chloride is desirable, as it causes the precipitate to be thrown down in larger flakes, which facilitates filtration.

The procedure found to give the best results follows: After hydrogen sulphide has been expelled from the filtrate of the copper-tin group and iron, if present, has been oxidized (if Fe is not present, 5–10 cc. molar $FeCl_3$ must be added), add ammonium chloride, and then dilute the solution until the concentration of any one of the metals of the iron group does not exceed 1/100 molar, and heat the whole to boiling. Add about 10 cc. 4 *N* ammonium formate and continue to boil for about one minute. Filter hot, preferably with the suction pump. The group is then analyzed as usual, except that, of course, iron must be tested for in the original solution, or at least before the precipitation of the group.



The question arose as to the nature of the precipitate and the composition of the ferric formates in general. This is especially interesting in view of the recent work of Werner and his associates on the acetates of the metals of this group[2] and on the formates of chromium.[3] For example, Weinland and Gussmann[4] have been unable to isolate ferric triacetate by any of the methods given for its preparation. There crystallizes usually from strongly acid solutions containing ferric hydroxide and acetic acid a basic salt of a triferric base, *viz.*, $Fe_3(C_2H_3O_2)_6{}^{C_2H_3O_2}_{(OH)_2}\cdot H_2O$, the formula indicating that only one acetate radical is replaceable. Another acetate containing one less hydroxyl group than this was also prepared. The formula of basic ferric acetate is commonly given as $Fe(OH)_2C_2H_3O_2$. But the basic acetate precipitated in the usual manner was found to correspond to the formula $\begin{bmatrix} C_2H_2O_2 \\ Fe_3(OH)_2 \\ O_3 \end{bmatrix}$, or, if the three iron atoms do not remain together, it may be written $Fe_2O_3.Fe(OH)_2C_2H_3O_2$ or

Ludwig[1] and also Scheuer-Kestner[2] claim to have prepared ferric triformate by allowing formic acid to act upon moist ferric hydroxide, the acid being present in large excess, crystals of the salt appearing after gradual evaporation. It was, however, found to be impossible to obtain the triformate by this or any of the other processes tried.

Ferric hydroxide was prepared by neutralizing ferric chloride with ammonium hydroxide, the precipitation being carried out at great dilution and both hot and cold. When precipitated in the cold ferric hydroxide dissolves readily in excess of cold formic acid; precipitated hot, it dissolves very slowly, but may be made to dissolve completely by continued agitation. When ferric hydroxide is boiled with excess of formic acid, complete solution does not take place. For the following experiments a paste of well washed ferric hydroxide and water was prepared, which contained about 1 mol. per liter. The formic acid used was a Kahlbaum preparation and had a specific gravity of 1.22.

A certain volume of the ferric hydroxide paste was treated with an equal volume of the formic acid, and the mixture shaken until complete solution took place. Whether evaporated in the air or under a desiccator, crystals were deposited upon the sides of the containing vessel. These were collected and kept in a desiccator over soda-lime for several days to remove the last traces of acid and then were transferred to one containing sulphuric acid, where they remained until analyzed. The mother liquor from these also deposited a good crop of fine crystals on the bottom of the containing vessels, which were dried in the manner just described. Formic acid was determined by treating a weighed quantity of the crystals with excess of 0.5 *N* sodium hydroxide, heating carefully for 15 minutes, letting cool, and transferring to a graduated cylinder. After the ferric hydroxide had completely subsided, an aliquot portion of the supernatant liquid was drawn off and titrated with 0.2 *N* hydrochloric acid. The method was rapid, although not very accurate, but sufficiently so for the present purpose. Iron was determined by filtering off the ferric hydroxide remaining in the cylinder, washing with hot water free from alkali, and weighing the residue in a platinum crucible. The accompanying table gives the results of the analysis of crystals obtained in all the ways mentioned above. It will be observed that they were of uniform composition, and that this composition does not correspond to the formula of the triformate but to that of a basic

salt of a triferric base of the same composition as the acetate precipitated under similar conditions except for the molecule of water of crystallization. Various modifications of the process outlined above were tried but no normal ferric formate could be obtained.

The formate obtained dissolves very slowly in cold water, more rapidly in warm. The salt cannot be obtained again from the solution, as a more basic salt described below was the only one deposited. It also dissolves slowly in formic acid. Neither the acid nor the aqueous solution gives a precipitate with chloroplatinic acid, and no evidence has yet been obtained to show that one, and only one, of the CHO_2 radicals is ionized as was found by Weinland and Gussmann to be the case with the corresponding acetate.

When ammonium formate in excess is added to ferric chloride solution the liquid becomes dark red and on warming deposits a brown flocculent precipitate. This precipitate was filtered out, washed, dried and analyzed in the manner just described. The results of the analysis are shown in the accompanying table. The composition of the precipitate is evidently that of the second formula and is therefore analogous

Fe. Per cent.	CHO_2. Per cent.	
57.0	15.1	Required for $Fe(OH)_2CHO_2$, Fe 41.4 per cent., CHO_2 33.4 per cent.

in composition to the basic acetate thrown down under similar conditions.

Whether ammonium chloride is present or not during the precipitation makes no difference in the composition of the precipitate. When a mixture of ferric chloride and ammonium formate in excess stands at ordinary temperature for several days an amorphous precipitate is deposited whose composition in the samples investigated does not correspond to that of the basic salt just described, as can be seen from the following table. The substance is richer in formate than the one precipitated hot. It corresponds somewhat closely in composition to the formula of a basic diformate, but I incline to the belief that it is a mixture of the basic monoformate with a small quantity of some formate richer in formic acid.

Fe. Per cent	CHO_2 Per cent

50 7	19 3

Required for $\left[Fe_3\begin{matrix}(CHO_2)_2\\OH\\O_3\end{matrix}\right]$, Fe 51.9 per cent, CHO_2 27 9 per cent

Summary.

1. The iron group may be precipitated as basic formates, which filter somewhat more readily than the basic acetates.

2. The presence of iron is necessary for the precipitation of chromium.

3. It was found impossible by any of the methods heretofore described to prepare normal ferric formate. In its place was always obtained a good crystalline precipitate corresponding to the formula $Fe_3\begin{matrix}(CHO_2)_7\\(OH)_2\end{matrix}$.

4. The basic formate precipitated under the usual conditions possesses a composition expressed by the formula $\left[Fe_3\begin{matrix}CHO_2\\(OH)_2\\O_3\end{matrix}\right]$.

WESTERN RESERVE UNIVERSITY, CLEVELAND

A RAPID AND ACCURATE METHOD FOR THE DETERMINATION OF TITANIUM.

BY O L BARNEBY AND R M ISHAM

Received May 2, 1910

Having a number of determinations of titanium in rutile and iron ores to make and failing to obtain consistent results by use of the common methods the authors proceeded to investigate for a shorter yet accurate process for this determination. Low's method[1] adapted from Blair gives good results, but requires too much time for the ordinary analysis. This method was used in checking three series of analyses. Gooch's method was not tried as it seemed to have the same disadvantage as the other methods—requiring too much time to obtain a pure product of weighable titanium oxide.

Methods depending on the precipitation of titanic acid in boiling solutions containing sulphurous and sulphuric acids gave low results. Those requiring SO_2 or H_2S reduction of the iron and precipitation of the titanium with ammonia or by boiling with sodium or ammonium acetate and acetic acid were found to give high results when a large excess of iron was present, and required repeated treatments to completely remove the latter element.

---

[1] Low's "Technical Analysis of Ores," p. 189.

This accords with the results of Blair,[1] Fresenius,[2] and others. Pisani's[3] volumetric method, modified by Wells and Mitchell,[4] reducing the titanium from $TiCl_4$ or $Ti(SO_4)_2$ by zinc in the presence of free acid and titrating with potassium permanganate in an atmosphere of carbon dioxide failed to give accurate results. In no case where considerable titanium was present was the reduction absolutely complete and frequently the results were from 5–10 per cent. low after prolonged reduction by the zinc. This is in accordance with the published work of Wells and Mitchell[5] on the application of this method.

Rothe's method[6] for the removal of the iron from titanium in the determination of the former, used likewise by Noyes, Bray and Spear[7] to separate titanium and zirconium from iron and thallium in their System of Qualitative Analysis finds application in removing most of the iron quickly. The method attributed to Ledebur by Classen[8] for pig iron analysis will not give good results due to the presence of titanium in the silica and graphite which is discarded, the solubility of titanic acid in hydrochloric acid, and the contamination of the final product by foreign elements such as aluminium.

The method as outlined below is based on the volatilization of the silica by hydrofluoric acid in the presence of sulphuric acid, evaporation to dryness and fusion with sodium carbonate and a little sodium nitrate to convert the iron and titanium to insoluble ferric oxide and sodium titanate, extraction with hot water to remove the soluble phosphates, sulphates and aluminates; solution of the ferric oxide and sodium titanate in hydrochloric acid, extraction of ferric chloride with ether; reduction of slight traces of iron with sulphur dioxide; precipitation of the titanic acid by boiling in acetic acid solution, filtration and ignition to titanium oxide (or colorimetric). (If the directions as given are strictly followed usually the sulphur dioxide reduction may be omitted as the iron will have been completely removed.)

The weighed sample in a platinum crucible is moistened with water, 5–10 drops concentrated sulphuric acid, and 1 cc. of hydrofluoric acid are added, and the mixture heated on an asbestos hot plate until cessation of sulphur trioxide fumes. Five or ten grams of sodium carbonate and a little sodium nitrate are added and the mixture fused at least 30 minutes. The crucible and cover are cooled, placed in a beaker, covered with hot water and heated until the melt is disintegrated. Ferric oxide and sodium titanate are left in the residue insoluble in hot water. The crucible is removed, washed and any adhering particles of ferric oxide and sodium titanate are dissolved out with hot hydrochloric acid (sp. gr. 1.11). These solutions are saved. The residue in the beaker is filtered and washed with hot water. The filter is perforated and the residue carefully washed down into a clean beaker with hydrochloric acid (sp. gr. 1.11). The hydrochloric acid washings from the platinum crucible are transferred to the beaker and the whole heated on the hot plate until solution is complete and volume is reduced to 15-20 cc. The solution is cooled, 2 cc. of concentrated hydrochloric acid added, and transferred to a separatory funnel, the beaker being rinsed with hydrochloric acid (sp. gr. 1.11). An equal volume of ether, which has been previously shaken with concentrated hydrochloric acid, is added to the solution, a rubber stopper is inserted in the top, the funnel is inverted, the stopcock opened and the whole thoroughly shaken. The stopcock is then closed and the funnel placed in an upright position and allowed to stand 10 minutes. The aqueous layer is drawn off into another separatory funnel. The ether is rinsed twice by shaking well with 5-10 cc. portions of hydrochloric acid (sp. gr. 1.11) and the washings added to the aqueous solution. (The ether is run off into an ether residue bottle and saved for purification.) The treatment with ether is repeated two or three times until the ether layer no longer shows any greenish tinge due to the presence of dissolved iron. The aqueous solution is then transferred to a beaker and 3-5 cc. of hydrogen peroxide added. If the solution does not develop a fairly intense color the titanium may be determined colorimetrically by the method given below.

---

[1] Blair's, "Chem. Anal. of Iron," p. 180.

[2] Fresenius-Cohn, *Quant. Chem. Anal.*

[3] *Ibid.*, Vol. 1, 285.

[4] This Journal, 17, 878.

[5] *Loc. cit.*

[6] *Mitth. Köngl. tech. Vers.*, 10, 132; *Stahl und Eisen*, 12, 1052; 13, 333.

[7] This Journal, 30, 515.

[8] Classen's, "Ausgewählte Methoden der Anal. Chemie," p. 501.

If an intense color develops the solution is heated to expel dissolved ether, 10 cc. of concentrated sulphuric acid are added and the solution evaporated to sulphur trioxide fumes. The cooled solution is diluted to about 100 cc. (any platinum present should be precipitated by hydrogen sulphide at this point) and the solution nearly neutralized with ammonia. One or 2 grams of ammonium bisulphite are added and the solution warmed on the hot plate for half an hour. Ten to 15 grams of ammonium acetate are added and 5-10 cc. of glacial acetic acid and the solution boiled for 15 minutes. Filter. The precipitated titanic acid is filtered off washed with dilute acetic acid (not over 11 per cent.), ignited and weighed as titanium oxide.

In case the hydrogen peroxide test as performed above indicates the presence of only a small amount of titanium the quantity may be determined colorimetrically. Heat the solution to expel dissolved ether, cool, transfer to a Nessler's tube, treat with 4-5 cc. of hydrogen peroxide, dilute to 100 cc. and determine by comparison with measured quantities of a standard solution of titanic acid in hydrochloric acid, which have been subjected to the same peroxide treatment. This comparison can be most conveniently carried out by adding the standard solution, drop by drop from a burette, to a Nessler's tube containing hydrogen peroxide and hydrochloric acid and made up to near the 100 cc. mark. The solution should be agitated from time to time and the process continued until an equivalent color is developed.

In following out this method as outlined three ores were used. Sample A was a sample of rutile from Kahlbaum, sample B was a specimen of concentrates from a Virginia ore, and sample C was a titanium iron ore from Lower Canada. These ores were analyzed by the method given above and the results checked by use of the method proposed by Low. The results obtained are tabulated in the following table.

In a preliminary effort to show the quantitative nature of the ether separation the following experiments were performed: I. A solution of titanic acid in hydrochloric acid was standardized by precipitation with ammonium hydroxide and ignition to titanium oxide. II. Blanks were run, carrying 10 cc. portions of the titanium solution through three ether separations with final precipitation with ammonium hydroxide. III. Separations were run by mixing 10 cc. portions with 5 cc. of a saturated ferric chloride solution and subjecting the mixture to the regular ether treatment with sulphur dioxide reduction and ammonium acetate precipitation.

---

[1] Using Low's method whenever iron was present it was found necessary to refuse and reprecipitate to free the titanium oxide from ferric oxide.

I (*a*) 0.1140	II (*a*) 0.1142	III (*a*) 0.1141
(*b*) 0.1139	(*b*) 0.1144	(*b*) 0.1140
		(*c*) 0.1141

It is suggested that for the analysis of pig iron, steel, etc., a 5–10-gram sample be dissolved in 30–40 cc. of concentrated hydrochloric acid to which 4–5 cc. concentrated nitric acid has been added, and the solution evaporated to the consistency of sirup. Add 1–2 cc. of concentrated hydrochloric acid, take up with 20 cc. of hydrochloric acid (sp. gr. 1.11), and filter. Transfer the filtrate to a separatory funnel and the residue to a platinum crucible.

After one treatment with ether as given above, the aqueous solution should be treated with ammonia, the precipitate filtered out and added to the residue in the platinum crucible. Ignite filter paper, treat with hydrofluoric acid, fuse, and complete the determination as previously given.

We note that in the original colorimetric work of Weller,[1] as well as in all subsequent modifications, the titanium was oxidized in the presence of sulphuric acid. For the sake of comparison equivalent solutions of titantium in sulphuric and in hydrochloric acid were prepared. We found that the color developed by oxidation was fully as intense and stable, in hydrochloric as in sulphuric acid. Inasmuch as solutions containing 1 mg. or more of titanium developed a somewhat higher color with hydrochloric acid it is advisable to use a standard solution of titanium in hydrochloric acid for the comparison.

Observing the aqueous titanium solution in the ether extraction to be colorless if peroxide-free ether is used led us to doubt the formation of a "yellow-white compound" with ether described by Rosenheim and Schütte.[2] These authors write: "The yellow-white, very indistinctly micro-crystalline mass, which remains after the action of hydrochloric acid and ether on titanium hydroxide, was almost completely soluble in cold water and precipitated gelatinous titanic acid on boiling." Treating titanium hydroxide in all degrees of hydration with several proportions of hydrochloric acid in ether gave no color mentioned above provided the last trace of peroxide was removed from the ether. If even a small amount of peroxide was present, Rosenheim and Schütte's observations were confirmed.

Conclusions.

1. The volumetric method based on the reduction of titanium to the tri-valent state and oxidation with permanganate gives low results.

2. With the sulphur dioxide reduction when considerable iron is present the titanium product is usually contaminated with some iron.

---

[1] *Ber.*, 15, 2593.

[2] *Z. anorg. Chem.*, 26, 241.

3. The ether separation removes practically all the iron from the titanium very quickly.

4. Refusion of the ignited product with sodium carbonate for purification, which requires considerable time, is never necessary by use of this method. The final product is pure, unless zirconium is present, in which case this element is removed by the usual phosphate precipitation.

5. This method combines the colorimetric and gravimetric determinations and the color comparison is made in solutions always totally free from iron. For convenience hydrochloric rather than sulphuric acid solutions of titanic acid are used.

6. The method is accurate and not long.

7. Rosenheim and Schütte's yellow compound probably owes its color to the presence of peroxides in the ether used.

APPARATUS FOR THE DETERMINATION OF ARSENIC.

BY OTIS D. SWETT.

Received May 28, 1910.

The many existing forms of apparatus for the determination of arsenic which give trustworthy results appear to have left little to be sought for with regard to this most essential feature. The more or less complex construction of these forms, however, together with the sources of error which usually accompany such construction, seem to justify an attempt to devise an apparatus for arsenic determination which, besides yielding accurate results, shall comprise fewer parts than are found in the other forms, and shall be compact and portable.

With these points in mind, an apparatus has been devised which is illustrated in the accompanying drawing.[1]

A is a round wooden base with a central depression and three vertical lugs which form an extension of the sides of the depression.

B is a glass vessel, 4 cm. outside diameter and 14 cm. long, with flat closed bottom, supported by the base *A* in the depression between the vertical lugs. The vessel *B* is provided with a lower side tube *b*, projecting beyond the base *A* between the vertical lugs, and with the upper side tube *b'*.

C is an inner tube, 18 mm. outside diameter, closed at its lower end, enlarged conically at its upper open end, rolled out and sealed to the top of the vessel *B*, which is closed in to meet it, and then ground on its inner surface to receive a stopper.

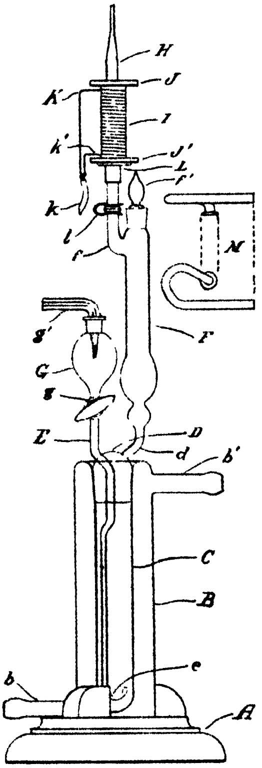
D is a hollow stopper with dome-shaped closed top, tapering to the other end, which is open, and ground to fit the neck of the inner tube *C*.

---

[1] Glass work by Mr. Edw. O. Sperling, Bureau of Standards.

F is a vertical drying tube, with the usual enlargement and moisture bulb, communicating with the interior of the stopper *D* through the offset tube *d*.

f is a side tube, extending laterally from near the top of the drying tube to the vertical axis of the apparatus, then vertically to the top level of the drying tube, flattened and ground to fit the correspondingly flattened and ground ignition tube *H*.



f' is a light ground glass stopper fitting the ground open end of the drying tube.

E is a tube passing through, and sealed to, the top of the hollow stopper *D*, and extending within the inner tube *C* to near the bottom, where it terminates in a gas trap, *e*, and extending upwards from the hollow stopper *C*, with an offset bend, to the stopcock *g* and communicating through this with the 5 cc. funnel *G*, which is closed in at the top to a small neck ground to take the enlarged and suitably ground capillary tube *g'*, this latter being drawn out somewhat smaller at the lower end, bent at right angles above the funnel neck, and so shaped at the outer end as to accommodate a rubber tubing.

H is a hard glass tube 6–4 mm., drawn out at one end in a suitable manner for the production of the mirror, and flattened and ground at the other end to fit the similarly finished end of the side tube *f* as described.

I is a heating coil, consisting of a threaded spool of "lavite"[1] 12 mm. outside diameter and 8 mm. inside diameter, wound with number 26 "Advance" resistance wire,[2] and mounted with a shield disc *J*, of the same material which prevents the tube above from becoming overheated.

J' is a "lavite" disc similar to *J*, upon which the heating tube *I* rests.

K, *K'* are the conducting wires and *k* is the two-wire insulated conductor from which they project.

L is a metallic sleeve, fitting snugly over the ignition tube *H*, cut to form spring fingers bearing firmly upon the ignition tube, and carrying, as an integral part, a disc which forms a flange around the upper end of the sleeve, thereby providing a means for supporting and vertically adjusting the heating coil *I*.

[1] Manufactured by the D. M. Steward Mfg. Co., Chattanooga, Tenn.

[2] Manufactured by the Driver-Harris Wire Co., Harrison, Newark, New Jersey.

l is a clip, adapted to hold firmly together the flattened and ground ends of the side tube *f* and ignition tube *H*.

M is a glass tube 5 to 7 mm. inside diameter made to fit the flattened and ground end of the tube and bent horizontally to keep within the radius of the apparatus.

The ignition tube first employed was of transparent silica, mounted by a short mirror tip. The metal clip being above the heating tube, and not thoroughly shielded from the heating coil, gave rise to irregular mirrors. When a tube, however, is used for both ignition and deposition, a number of such tubes must be on hand when making up a set of standards and for consecutive analyses, so that silica, on account of its cost, is barred. Instead, Jena boro-silicate glass, or indeed a high quality combustion glass, may be used.

A modified form of the vessel *B* has been designed, which is essentially an Erlenmeyer flask, provided with side tubes and carrying the sealed-in tube *C*, thereby eliminating the wooden base, and providing space for a larger reaction vessel.

With slight modifications this apparatus is adapted for use with many methods heretofore proposed.

For the Marsh,[1] Berzelius-Marsh,[2] and Sanger-Berzelius-Marsh[3] methods, the drying tube is charged with calcium chloride retained in place by means of absorbent cotton plugs. Lump or granulated arsenic-free zinc is introduced into the tube *C*, sulphuric or hydrochloric acid is admitted from the funnel *C* through the cock *g* and tube *E*, followed by the solution to be tested for arsenic after all air has been expelled from the apparatus.

In the application of the Gutzeit, Ritsert, Flückiger, Lohmann[4] methods, applied quantitatively by means of a set of standards for comparison, the drying tube is charged with absorbent cotton and a few strips of lead acetate paper or its equivalent, and the ignition tube is replaced with the curved tube *N*, into which the impregnated test paper is introduced.

The stopper tube *g′* is provided for connection with a supply of arsenic-free hydrogen, as suggested by Munroe and in use by his students,[5] thereby materially reducing the time required for a determination by affording a means of rapidly removing all air from the apparatus, and also effecting a saving of arsenic-free zinc and acid.

Provision is made by the outer vessel or jacket *B*, with the side tubes *b* and *b′*, for either cooling the reaction chamber *C*, as recommended by the earlier authorities, or for heating it as recommended by Harkins,[1] by passing through it either cold or hot water.

[5] THIS JOURNAL, 17, 885, 890 (1895).

In the preparation of standard mirrors for comparison, as recommended by Sanger,[2] as small a quantity as 0.005 mg. As_2O_3 may be standardized by means of this apparatus. The mirrors prepared vary distinctly with a variation of 0.005 mg. of As_2O_3 in the known solutions used and duplicate mirrors from equal quantities of As_2O_3 agree quite as well as those illustrated in Sanger's paper.

GEORGE WASHINGTON UNIVERSITY, WASHINGTON, D. C.

A COLORIMETRIC DETERMINATION OF MANGANESE IN THE PRESENCE OF IRON.

BY M. R. SCHMIDT.

Received June 17, 1910.

The following method has been used by the writer for some time, and has been found to give uniform satisfaction in the determination of small quantities of manganese in the presence of iron, in certain pharmaceutical preparations, such as peptonates, sirup of hypophosphites, etc. No originality can be claimed for the method, as it was proposed several years ago by Walter,[3] but it is believed that the details of manipulation here given will lead to the greatest rapidity in attaining accurate results. The usual basic acetate method of separating manganese from iron requires, in order to effect complete separation, at least two precipitations of the iron, and subsequent evaporation of the filtrates in order to insure complete precipitation of the manganese by bromine or other reagents. This involves considerable loss of time, and when dealing with small quantities of manganese, the total experimental errors often amount to a considerable percentage of the weight of the manganese involved. The present method requires no previous removal of iron, and the results are accurate when the total manganese amounts only to a few milligrams. Moreover, duplicate determinations can be made in one-half hour. The determination depends on the power of the persulphates to convert bivalent manganese into permanganic acid in the presence of silver nitrate.

A standard solution of manganese containing 2 mg. of manganese in each 10 cc. is found to be most convenient, and is prepared as follows: Run 182.1 cc. of exactly tenth-normal potassium permanganate solution into a liter flask, add about 100 cc. of 10 per cent. sulphuric acid and 12 cc. of 3 per cent. hydrogen peroxide. Warm the flask slightly until the oxygen is driven off, cool again and dilute to the mark. Prepare also a solution of silver nitrate, containing 20 grams of the salt in a liter. 1 cc. of this solution must be used with each mg. of manganese present.

---

[1] THIS JOURNAL, 32, 520 (1910).

[2] *Loc. cit.*

[3] *Chem. News*, 84, 239 (1901).

To make a determination, remove 5 cc. of the unknown solution to a small beaker by a pipette. Dilute to about 100 cc., add 2 or 3 cc. of ether, and precipitate with ammonium sulphide. Warm the solution on the steam bath, stirring vigorously, and after the precipitate is settled filter through a small folded filter and wash thoroughly with water containing a little ammonium sulphide. Dissolve the precipitate on the filter with the smallest possible quantity of dilute sulphuric acid, collecting the filtrate and washings in a small Erlenmeyer flask. Boil to expel hydrogen sulphide, add a little nitric acid to oxidize the iron and then add one drop of silver nitrate solution. If a turbidity occurs, which indicates imperfect washing of the sulphides, add silver nitrate in very slight excess, boil again, and filter through a small dense filter into a 100 cc. flask. To this solution, which should be perfectly clear, add 1 cc. of silver nitrate solution for each mg. of manganese which is present, followed by about 1 gram of ammonium persulphate, and place the flask on a steam bath. The contents soon turn yellow, then red, and in about one minute the purple color of permanganic acid is fully developed. Cool the flask, fill to the mark, stopper and shake well. Into another 100 cc. flask, introduce 10 cc. of the standard manganese solution, and about 20 cc. of dilute sulphuric acid. Add 2 cc. of the silver nitrate solution and 1 gram of ammonium persulphate, and proceed exactly as with the unknown solution. Fill a burette with the latter, and fill one of two comparison tubes, which must be of the same diameter, with a portion of the standard permanganic acid solution. Fill another burette with distilled water, run about 10 cc. of the unknown solution into the second comparison tube, and dilute with water until the color is equal in intensity to that of the standard solution, viewing the tubes from the side. Suppose, for instance, that 12 cc. of the unknown permanganic acid solution were taken and 18 cc. of water added. This solution, of the same intensity as the standard solution, is of the same strength, and contains 0.02 mg. in 1 cc. or, $(12 + 18) \times 0.02 = 0.60$ mg. in all. This is equivalent to 12 cc. of the original solution, which therefore contains 5 mg. manganese, derived from 5 cc. of the original preparation, giving a percentage of 0.10.

It is found at times that the oxidation of the manganese is only partial, and the solution, instead of becoming purple, is clouded by a brown precipitate of manganese dioxide. In such cases, add a few mg. of sodium sulphite or bisulphite, or a few drops of sulphurous acid solution, until the solution becomes clear again. Then add more silver solution, and another portion of ammonium persulphate and warm again.

The ether used when precipitating the sulphides has the effect of causing the precipitate to settle quite rapidly.

Following are results obtained in duplicate determinations of several preparations. In all of these preparations iron was present in amounts from 3–5 times the amount of manganese.

	1 cc contains milligram Mn.
1	0.205 0.243
2	0.1468 0.1520
3	0.734 0.723
4	0.588 0.606

In order to test the accuracy of the method, 0.6316 gram of crystallized manganous sulphate, free from effloresced portions, was dissolved in 250 cc. of water, 10 cc. of this were taken, and after oxidation diluted to 200 cc.

On comparing with the usual standard, the 200 cc. were found to contain 6.392 mg. of manganese, corresponding to 0.6505 gram of manganous sulphate originally, or 102.9 per cent. To another 10 cc. of the original solution, 1 gram of iron alum was added and the manganese determined as before. In this case 6 178 mg. of manganese were indicated in the 10 cc., corresponding to 99.2 per cent. of theory. Here the concentration of the iron was roughly 20 times that of the manganese.

The method has already been applied to the determination of manganese in rocks,[1] and should prove excellent for determining manganese in waters.

LABORATORY OF SHARP & DOHME.

NOTES.

The Chemical Laboratory of the University of Washington.—The University of Washington on April 16, 1910, formally opened for use a new chemical laboratory which cost when completed a total of $230,000. This building is of concrete and steel construction and is three stories in height. The design of the building was made by the architects of the Alaska-Yukon-Pacific Exposition according to drafts prepared by the writer after his visit to all the modern laboratories of Europe and America. It contains certain features of construction which may be of interest to those chemists who are contemplating erection of buildings or equipment of laboratories. A drawing of the general floor plan of the building accompanies this note.

---

[1] Hillebrand, *Bull.* 305, U. S. G. S., p. 99 (1907).

It will be observed that the offices and classrooms occupy the central portions of the building and the laboratories the outlying wings. The main laboratories, 12 in number, are separated by a line of flues extending from the basement to a tunnel immediately beneath the roof. These two lines of flues are exhausted by large fans run with a common motor. It will be seen also that this plan involves the use of light from only one end and side of each laboratory, the hoods occupying the one long side of each laboratory. This plan would have been attempted with some hesitancy had it not been for the unqualified satisfaction expressed by Professor Witt in Charlottenberg with the side lighted laboratories. It is with considerable satisfaction that we find the result of this construction is an eminently satisfactory lighting and ventilating system—both work admirably.

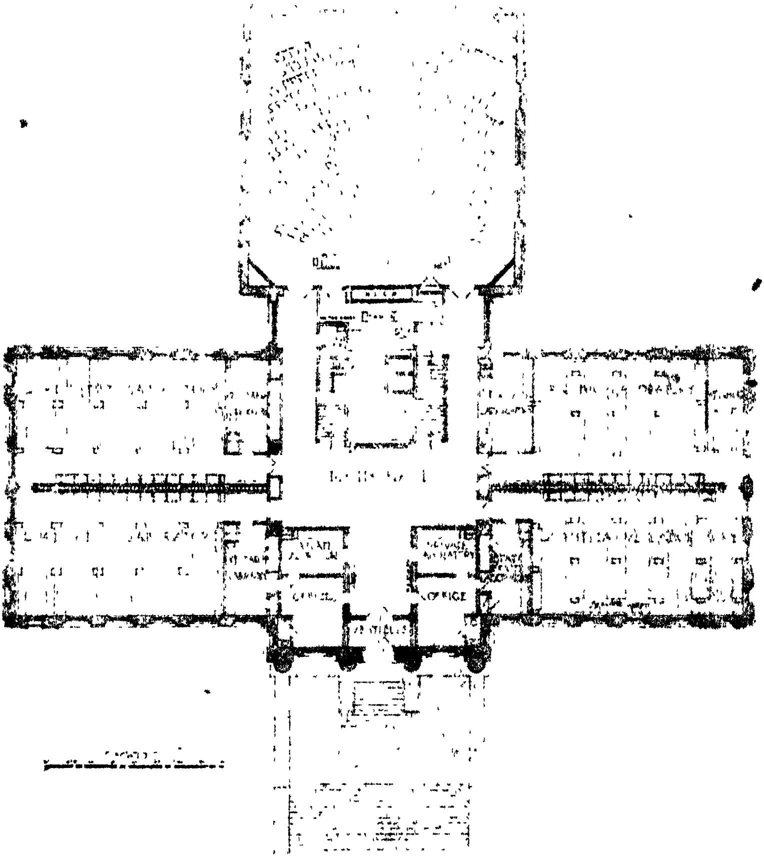

Fig. 1.

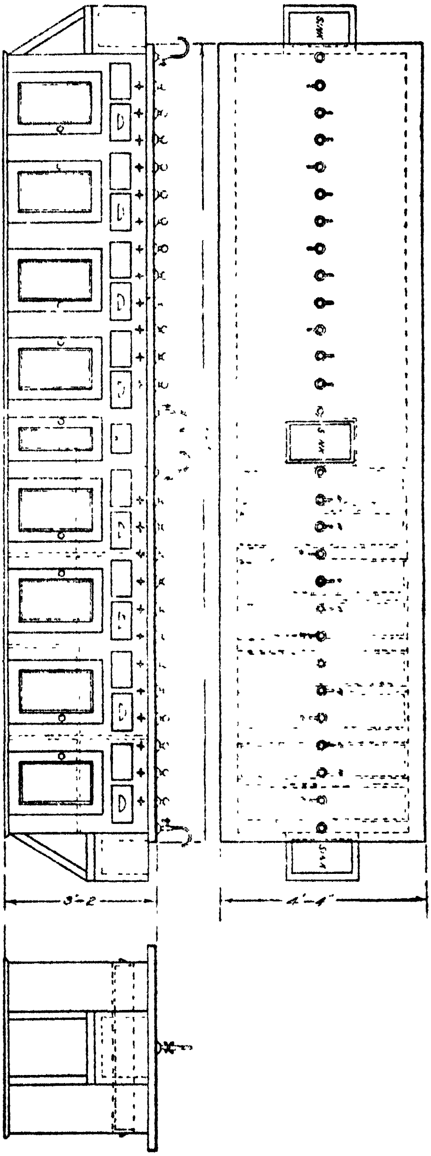
A second feature of the laboratory is the use of alberene stone, exclusively, for sinks and for the floors of the hoods. Only two types of desks were provided for the laboratory. These desks are primarily, for general chemistry, type 1; and quantitative work, type 2. It is type 2 which varies most from the common laboratory construction and which has proven the most satisfactory. This is illustrated in Fig. 2. All stopcocks are operated by a long arm control situated immediately beneath



QUANTITATIVE ANALYSIS DESK
UNIVERSITY OF WASHINGTON

Fig. 2.

the ledge of the desks. No obstruction is therefore placed upon the tables except the gas and water outlets. The table tops are finished with the aniline black finish recommended by the United States Bureau of Chemistry. The table tops are of Washington fir and similar tables have been in use in this university for six years without needing either refinishing or repairing.

The pressure system and the hydrogen-sulphide system reach the hoods only, which also are furnished with gas and water. The hydrogen-sulphide generating apparatus is situated without the building on the roof. It is of the general type used by Professor Fischer, of the University of Berlin, and is not wholly satisfactory. The air-pressure system is automatic and varies between 45 and 15 pounds in the compressor, being delivered into the laboratory at a uniform pressure of 15 pounds. We find this most satisfactory for blast lamps.

One item of construction has proven highly satisfactory. The main lecture room, as shown in Fig. 1, opens directly into the stockroom, the rear half of which is equipped as a preparation room for the lecture. Back of the lecture table is a hood slightly raised above the level of the table, opening both into the stockroom and lecture room, and ventilated by a separate one-horse power motor. This makes the disposition of ill-smelling or poisonous materials extremely easy and effective. The lecture table is practically an exact duplicate of that of Professor Beckmann of the University of Leipsic.

The stock rooms occupy a tier of three rooms, one on each floor, in the exact center of the building and are connected both by an elevator and an internal stairway. An excellent feature is a large room 40 by 60 feet with concrete floor covered with asphalt and brick walls and concrete pillars, which is for the machinery used in the laboratory, such as grinding machines, filter presses, cement testing material, stills, etc.; in general those operations which are carried out on a large scale and are likely to be either dirty or dangerous.

The main hall in two floors of the building is equipped with a very complete "first aid to the injured" set of materials. These cases are always open and have on them simple directions for emergency surgery. These have already shown their great value as time and trouble savers as well as guaranteeing a certain immunity from serious injury.

The department is also equipped with a departmental library, which promises to be eminently satisfactory.

We have made certain mistakes in the construction of the laboratory, of course, and were limited financially and so prevented from putting in certain desirable features, for example, an exhaust system for filtration. Taken all in all, however, the laboratory is a source of great satisfaction and considerable pride on the part of the writer and he will be glad to do whatever he can in assisting others to profit both by our successes and failures.

H. G. BYERS.

A Modified Burette for Standard Alkali Solutions. Glass stoppered burettes offer serious obstacles to their constant employment for standard solutions of caustic alkalis. The tendency of the stopcock to stick, rapid wear, resulting in leakage, or breaking of the cock or of the shell, and other difficulties constitute serious objections to this form of burette for caustic alkali solutions. The type of burette in which a glass tip is connected to the burette by means of a rubber tube, the flow being controlled by a pinchcock or a glass ball, is an alternative which is still in considerable use, but the objection to this type on the ground of inaccuracy is well understood, and the United States Bureau of Standards will not calibrate such burettes.

It occurred to the writer that the substitution of metal for glass for the movable part of the stopcock might overcome the difficulty and that of the metals adapted to this purpose, silver might perhaps be preferable both because of its fairly good resisting powers towards caustic alkali, as well as on the ground of reasonable cost. Accordingly, a burette fitted with a silver stopcock was tried by filling with half-normal potassium hydroxide solution and allowing to stand for a week. The stopcock did not show the slightest sign of sticking or leakage. The burette was then emptied and filled with 30 per cent. sodium hydroxide solution and in the course of several weeks the stopcock was operated several times nearly every day. The stopcock is still apparently in as good condition as when first received, although it has not been lubricated again since it was first put into use. This stopcock was made for the writer by the Bausch & Lomb Optical Company, of Rochester, New York.

PAUL RUDNICK.

CHEMICAL LABORATORY OF ARMOUR AND COMPANY,
CHICAGO, ILL.

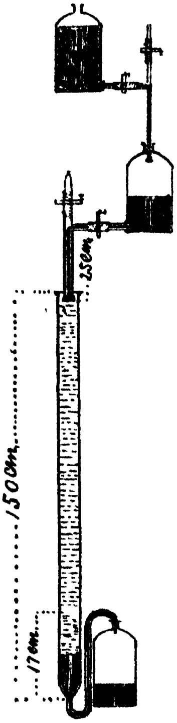
The Purification of Mercury.—The accompanying cut is of an apparatus which has been used by the writer in the Harvard laboratory for more than a year, and he believes it possesses several advantages over the original apparatus of L. Meyer,[1] and, perhaps, over a somewhat similar modification of the original by Hildebrand[2] in that large quantities of mercury can be rapidly and thoroughly freed from those substances which are likely to occur in it and which dissolve in dilute nitric acid or in mercurous nitrate.

The method of Meyer is so familiar to every one that details are unnecessary. The writer uses a 5 cm. tube, 1.5 m. long. He finds that 8 per

---

[1] *Z. anal. Chem.*, 2, 241.

[2] THIS JOURNAL, 31, 933.



cent. acid is better than the more dilute solution recommended by Meyer.

The mercury is atomized by forcing it through chamois skin tightly stretched over the end of a 25 mm. tube and bound fast by means of a cord. This large tube is drawn down sharply as shown in the figure and sealed to a 5 mm. tube which is attached to the T-tube of the aspirator bottle. It is so adjusted that the atomizing skin is about 15 mm. above the surface of the acid, and the pressure of the mercury is so regulated by means of the screw pinchcock as to make the fine streams just continuous, otherwise the skin may be so distended as to become hemispherical, in which event some of the mercury may be sprayed on the sides of the tube and collect in small drops.

The object of the upper aspirator bottle and filter, precisely like the lower one, is to increase the capacity of the reservoir and to remove solid particles which tend to clog the pores of the atomizing skin.

In offering the above suggestion the writer lays little claim to originality. It is but a slight modification of a time-honored method, but he does claim that in his hands it works far more rapidly, requires no attention, and the product obtained by one passage through the acid is much purer than by the original method, and he trusts that others may have a like experience with it.

C. J. MOORE.

CAMBRIDGE, MASS

On the Preparation of a Cuprous Nitrate, $CuNO_3.2NH_3$.—Cuprous nitrate, of the formula $CuNO_3.2NH_3$, was prepared as follows:

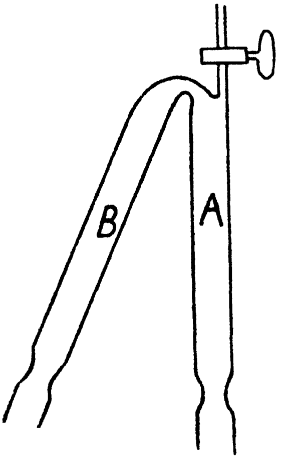
A glass tube of two arms, the one carrying a stopcock, was drawn out as shown in Fig. 1. An approximately weighed amount of dried cupric nitrate of the formula $Cu(NO_3)_2.4NH_3$[1] was introduced into the arm A and the stopcock attached to a cylinder of dried ammonia. Ammonia was then passed through both arms and A sealed off. A piece of bright copper foil was then introduced into B and the arm sealed off at the lower end.

Ammonia was now distilled into A under pressure (A was placed in ice water for this purpose) until nearly full. The solution of cupric nitrate was then poured over into B. A was washed free of cupric nitrate by distilling some ammonia over from B, and then pouring it back again. This was repeated until no color was obtained in A. The solution was then allowed to stand in contact with the copper foil until the color of deep blue gave way to a practically colorless solution.

---

[1] $Cu(NO_3)_2.NH_3$ is easily prepared by supersaturating an aqueous cupric nitrate solution with ammonia, when it crystallizes out, and may then be washed and dried over sulphuric acid. It is a stable salt in contact with the air, and is very soluble in ammonia

The solution was then transferred to A, and B washed by repeated distillations of the ammonia from A to B, and then pouring back into A. The ammonia was then allowed to gradually distil off through the stopcock. As the solution concentrated, the cuprous nitrate crystallized out. A was then sealed off, evacuated, and weighed. The salt was then dissolved in dilute nitric acid, washed out, and the copper determined electrolytically. The tube was dried, evacuated and weighed.



The weight of the crystallized salt was 0.5786 gram; weight of copper 0.2292 gram, giving 39.61 per cent. copper, in fair agreement with the formula $CuNO_3.2NH_3$ which requires + 39.86 per cent. The increased weight of salt obtained corresponds (weighings of cupric nitrate and copper foil approximate) to the loss of weight in the copper foil.

The salts obtained were not entirely pure. A few blue crystals separated out with the colorless cuprous nitrate, showing the presence of a little cupric nitrate. This could not be separated owing to their similar solubility. Possibly this could be avoided by using more elaborate apparatus, but it seemed as if there was a point of equilibrium reached when the cupric nitrate was nearly reduced. The salt is not stable in the air, oxidizing very rapidly.

A recent analysis of another sample by Mr. G. H. Bohart, of this laboratory, in which the nitrogen was also determined, gave practically the same result for the copper content, and also agreed very closely with the theoretical nitrogen content for the above formula.

The preparation of the above salt was suggested by Prof. E. C. Franklin.

W. H. Sloan.

[Contribution from the Chemical Laboratory of the Massachusetts Institute of Tech.]

THE CONDENSATION OF SOME PRIMARY AROMATIC AMINES WITH CHLORAL-ANILINE.

By Stroud Jordan.

Received June 10, 1910

It has been known for a long time that when one molecule of an amine, as aniline, is brought in contact with one molecule of an aldehyde, as chloral, an addition product will be formed, but if the amine is increased to two molecules while the aldehyde is kept constant at one molecule a condensation product will be formed and a molecule of water will be eliminated.[1] Further than this, no definite relationship has been established between these two reactions, so that the purpose of this paper will be to point out some of the relations existing between these two reactions and their products.

It has been shown in the following work that it is possible to form a condensation product by the action of one molecule of a free amine with one molecule of an addition product, without the presence of free chloral. It has also been shown that it is possible to form a condensation product in which two unlike amines will be joined to the same chloral residue, by the action of one molecule of a free amine with the addition product of chloral and an unlike amine. By these two experiments it has been shown that the addition product *can* be an intermediate step in the formation of the condensation product and that it will change over into the condensation product upon the addition of an excess of a free amine.

The products which will be studied in the following work are:

First, the condensation of aniline with chloral-aniline, and

Second, the condensation of 1,3,4-nitrotoluidine with chloral-aniline. In this second product it will be noticed that it was very difficult to prepare a pure sample of the condensation product, on account of the ease with which it decomposed in nearly every solvent. This decomposition product was proved to be 5-chlorine-3-nitro-4-toluidine and this work will be taken up later, in this laboratory, as a probable method of chlorination for the aromatic amines. This work will also be followed up later to determine the rate of reaction and also as a study of intermediate reactions.

Experimental.

The Condensation of Aniline with Chloral-aniline.—For this preparation eight grams of the freshly prepared addition product were dissolved in one hundred cc. of 95 per cent. alcohol and to this were added three grams of pure aniline after which the whole mass was heated up to boiling and then allowed to stand for six hours. This gave a light yellow solution which crystallized out, on evaporation over a water bath. This crude compound consists of yellowish crystal masses which melted at 98–100°, but after two crystallizations from alcohol and petroleum ether it gave pure, white needles, melting at 107–8°. This compound was proved to be the condensation product, by making its hydrochloride and hydrobromide, by the melting point of the aceto derivative, by its crystalline form and melting point and by the detection of free aniline and chloral, when the condensation product was decomposed.

From the above reactions it may be concluded that the condensation of aniline and chloral may be made by the interaction of one molecule of aniline with one molecule of chloral-aniline, thus dividing the condensation reaction into two steps: $C_6H_5NH_2 + CCl_3CHO = C_6H_5NH—CCl_3CHOH$, and $C_6H_5NH—CCl_3CHOH + C_6H_5NH_2 = (C_6H_5NH)_2CCl_3CH + H_2O$.

The Condensation of 1,3,4-Nitrotoluidine with Chloral-aniline.—For this preparation one and one-half grams of aniline and two and one-half grams of chloral were brought together in an open vessel, without the presence of a solvent. The temperature was never allowed to exceed 40° so that no water would be driven out from the reaction, thus guarding against the formation of any condensation product. This reaction gave the addition product of aniline and chloral, described by A. Eibner.[1] To this addition product were added two and six-tenths grams of 1,3,4-nitrotoluidine, which had been previously dissolved in one hundred cc. of benzene, after which the whole mass was heated at a slow boiling temperature for two and one-half hours, under a reflux condenser. This solution was then filtered off from any byproduct that might be present and the clear benzene solution was allowed to crystallize out, which gave a yield of six and two-tenths grams of a crude product melting at 90–6°, being approximately a 95 per cent. yield of the theoretical amount of condensation product which should have been formed by this reaction. The crude product, obtained in this manner, was purified by crystallization from benzene at room temperature, raising the melting point to 98–9°. This compound crystallized from benzene in light, yellowish-brown, crystal masses which crawled up the sides of the beaker. It was easily soluble in alcohol, acetic acid, acetone, benzene, ether and toluene, but not so soluble in gasoline, petroleum ether and ligroin.

Three analyses of this compound, for chlorine, gave: 28.44, 27.45 and 28.07 per cent. Cl, calculated for $C_{15}H_{14}N_3O_2Cl_3$, 2840 per cent.

This condensation product was apparently unaffected when treated with water, either hot or cold, for only a slight amount of decomposition was ever noticed, but when it was treated with concentrated hydrochloric acid a mixture of aniline hydrochloride, nitrotoluidine hydrochloride and free chloral was obtained. These compounds were recognized by making the hydrochloric acid solution alkaline with sodium hydroxide and distilling with steam. The aniline came over in the first distillate, mixed with a little nitrotoluidine, while the nitrotoluidine remained behind in the distilling flask, mixed with a little aniline. These two compounds were proved to be present by their behavior with acids, melting points and other derivatives. The toluidine gave a melting point of 78° and formed a hydrochloride which decomposed at 230–4°, while the aniline gave the characteristic phenyl isocyanide odor and an acid derivative with hydrochloric acid, which was proved to be the hydrochloride of aniline.

---

[1] *Ann.*, 302, 340–80 (1898).

When bromine was added to a glacial acetic acid solution of the condensation product it reacted very vigorously, forming a white, crystalline precipitate and liberating chloral. This bromine derivative was proved to be a mixture of the aniline and nitrotoluidine hydrobromides and some of the higher bromine derivatives, by making it alkaline with sodium hydroxide and distilling with steam. Free aniline was the first to come over with the steam and was recognized by making its hydrochloride and acetyl derivative. The nitrotoluidine remained behind in the distillation flask and was recognized by its melting point and the decomposition point of its hydrochloride. The separation of these two amines was not complete, for there was always a trace of the nitrotoluidine in the aniline distillate and the residue, left in the distillation flask, was mixed with some of the higher bromine derivatives and some free aniline.

A molecular weight determination was next made, using glacial acetic acid as a solvent, but there was always an error, due to the fact that the condensation product was unstable and would break down into 5-chlorine-3-nitro-4-toluidine. While this decomposition was very slight, it was sufficient to keep the molecular weight low and the best result that was obtained, by the freezing point method, was 348.+. The theoretical molecular weight for this compound should be 374.+. This molecular weight will show, however, which of the three following possibilities this compound really is:

Substance	M P	M W	Per cent. Cl.	Color.	Form.
The condensation of aniline and chloral..	107–8°	315.35	33.72	White	Needles
The condensation of nitrotoluidine and chloral......	108–9°	433.35	24.52	Golden yellow	Needles
	Found.	Found.	Found.	Found.	
The condensation of aniline, chloral and nitrotoluidine..	98–9°	348	28.44	Yellowish	Masses
		Theoret.	Theoret.		
		374.35	28.40		

In considering the two possibilities with which the mixed-type condensation has been compared it has been assumed that when the nitrotoluidine is added to the addition product of aniline and chloral either a mixed-type condensation has been formed or a reaction has taken place causing the addition product to change over into a simple condensation product with the liberation of half of the chloral and one molecule of a free amine, either aniline or nitrotoluidine. No mention has been made of the possibility of a mixture which would contain the condensations of aniline and chloral and nitrotoluidine and chloral because the crude products, and also the purified products, which have been obtained by this work, have always shown very constant melting points and the behavior towards acids has always been the same.

From the foregoing work it has, therefore, been concluded that the mixed-type condensation product has been prepared in which one molecule of aniline and one molecule of nitrotoluidine are condensed with one molecule of chloral, according to the following reactions: $CCl_3CHO + C_6H_5NH_2 = CCl_3CHOH\ NHC_6H_5$, and $CCl_3CHOH\ NHC_6H_5 + C_7H_5N_2O_2 = C_{15}H_{14}N_3O_2Cl_3 + H_2O$.

The subsequent decomposition of this condensation product, giving 5-chlorine-3-nitro-4-toluidine, would probably take place in the following two steps, for the reason that nitrotoluidine and chloral will form an addition product which breaks down into the same chloral derivative, without the presence of either free or combined aniline: $C_{15}H_{14}N_3O_2Cl_3 \longrightarrow CCl_3CHOH.NHC_6H_3NO_2CH_3 + C_6H_5NH_2$, and $CCl_3CHOH.NHC_6H_3NO_2CH_3 + HCl \longrightarrow C_7H_8N_2O_2Cl$ + aldehyde derivative.

BOSTON, MASS

THE DETERMINATION OF TOTAL SULPHUR IN ORGANIC MATTER.

BY HERMAN SCHREIBER

Received June 7, 1910.

Introduction.

A great many methods have been proposed for the determination of total sulphur in organic matter, but probably only two of these are either easy to manipulate or accurate, namely, the Barlow-Tollen,[1] or absolute method, and the Osborne,[2] or peroxide method. When the latter is applied to solid material, however, it leaves much to be desired in the way of ease of manipulation and speed, and has absolutely no claim to exactness of detail. It is true that the water used for moistening the sample is measured and the sodium carbonate is weighed, but the amount of sodium peroxide added varies with the material analyzed and with the rate at which the reagent is added. The amount of acid which must be added after fusion is also an unknown factor; it varies in each case which necessitates making the solution alkaline again, and then acid. These, however, are not all of the difficulties encountered. The fusions have a tendency to burn and blow out of the crucible, and this happens most frequently when the determinations must be rapidly made, for the peroxide method has a dignity all its own and will brook no haste or impatience. All of these objections were keenly realized when it became necessary to make about 100 sulphur determinations in a recent research.

---

[1] THIS JOURNAL, **26**, 341 (1904).

[2] U. S. Dept. Agr., Bureau of Chemistry *Bull.* **107**, revised, p. 23.

An ideal method for this determination should embody several features: First, it must not call for excessive amounts of reagents, nor such as will interfere with the precipitation of the barium sulphate or contaminate the precipitate; second, the reagents employed must serve two purposes, they must destroy all of the organic matter and all of the sulphur must be fixed and oxidized to sulphate; third, the method must be fairly rapid and not require a large amount of practice, so that an analyst can make the determination from time to time without great delay and difficulty.

It is difficult to outline a method which will meet all of these conditions, but after making quite a number of experiments the following procedure was evolved, which seems to fulfil the requirements more nearly than the peroxide method.

The Proposed Method.

Weigh 1 gram of material in a nickel crucible of 100 cc. capacity, add 10 cc. of a solution made by dissolving 100 grams of sodium nitrate and 150 grams of sodium hydroxide in 500 cc. of water. Then add 5 grams of crystallized magnesium nitrate and stir with a platinum rod, making sure that the mass is thoroughly mixed and that the sample is broken up as much as possible. Wash down the material adhering to the stirring rod and sides of the crucible with the smallest possible amount of water. (This is essential since the addition of much water will prolong the subsequent heating unnecessarily.) Heat for one hour on a hot plate covered with a thin sheet of asbestos paper, keeping the temperature at about 130°. Then put the cover on the crucible, tilting it in such a fashion as to leave an opening for the steam to escape and heat further for one hour at from 150–160°, or until the material is entirely dry. If the fusions begin to bump, lower the heat so that the covers will not be jarred down tight on the crucibles, and the material lost by frothing. When the mass is entirely dry, put the covers on tight and heat gradually until the temperature reaches 180°, then heat for thirty-five minutes, maintaining the temperature at about 180–200°. These temperatures were determined by laying the thermometer down on the hot plate.

Now set the crucible (with the cover on tight) into a round hole in a piece of asbestos board, so that about 1.5 inches of the lower part of the crucible shall project below the asbestos board as Lunge[1] has directed, the asbestos board to be laid flat. Heat with the Bunsen burner for half an hour, allowing the flame to just touch the bottom of the crucible during the first fifteen minutes, and then with the full heat during the last fifteen minutes. (Never let the inner cone of the Bunsen burner strike the crucible.) During the first five minutes of heating with the full flame keep the crucible in an upright position, then remove the cover and tilt the crucible so as to fuse any material which may have crept up the sides. Then return the crucible to the upright position, replace the cover, and heat for five minutes more. When the fusion has solidified, and before it has entirely cooled, place the crucible in a 600 cc. beaker with 150 cc. of distilled water and cover with a watch glass. Put the crucible cover in the beaker, beside the crucible, and slightly rotate and tilt the beaker so that all parts of the crucible shall be touched by the water. Run in 13 cc. of hydrochloric acid (specific gravity 1.19) from a burette and again rotate the beaker slightly. Tip the crucible so that the other side comes in contact with the acid liquor, allow it to stand a few minutes, and remove the crucible and cover, washing the liquid adhering to them back into the beaker by means of distilled water. Any fused material adhering to the sides of the crucible can easily be removed with a stirring rod. Place the beaker on the steam bath and heat for about half an hour and then let it stand in the cold over night. Filter and wash the insoluble residue. Heat the filtrate on the steam bath or otherwise, and precipitate with a 10 per cent. barium chloride solution.

---

[1] *Chemisch-Technische Untersuchungs Methoden*, 1, 428 (1904).

In all of the determinations here reported the solutions were precipitated by heating on the steam bath, adding 10 cc. of barium chloride to the solution quickly, and stirring as soon as the precipitate began to form. After adding the barium chloride the solutions were allowed to remain on the steam bath about one hour, and were then removed to the table and stood in the cold over night, after replacing any water lost by evaporation. All filtrations, except the solution of the fusions of the barium sulphate with sodium carbonate, were filtered through S and S blue ribbon filter paper. The fusions of the barium sulphate were filtered through white ribbon filter paper and all precipitates were washed with cold water.

In this method a crucible loses from 0.3–1.3 grams of its weight in each determination, an average of 0.9 gram as calculated from 20 determinations. By the peroxide method the crucible loses from 1.2–2 grams of its weight in a fusion, an average of 1.4 grams based on 13 determinations. Using a griddle hot-plate, 14 by 18 inches, 18 fusions can easily be made in a day. The only way in which a determination can be lost is by heating too rapidly on the hot-plate, thus causing it to boil over or spatter.

Description of Samples and Analytical Results.

Total sulphur was determined by both the peroxide method and the proposed method on five samples of dried white of eggs, three of which were made from the same lot of eggs by boiling with various amounts of copper sulphate, washing free of copper, and drying and grinding; one was a sample of commercial dried albumin; and one was the white of eggs

[1] Results given have been corrected for blank.

[2] After fusing barium sulphate with sodium carbonate.

[3] Determination by E. W. Boughton, Contracts Laboratory.

boiled in the shell, dried, and ground. Sulphur was also determined on four samples of mustard seed, and one sample of ground mustard. *A* is pure white mustard, *B* is black mustard containing 64 per cent. of charlock, *C* is commercial ground mustard, *D* is pure brown mustard, and *E* is commercial ground seed. These samples were furnished by the Microchemical Laboratory. Sulphur was also determined on five samples of vulcanized rubber furnished by the Contracts Laboratory.

The 60 determinations were made without repeating any, except No. 8136, unless a loss occurred by the leaking of the crucible. This happened in three instances only, so that the work represents fairly well the results which the two methods will give under the same conditions without repetition and selection of results. Twelve determinations were made at a time with each kind of material, two determinations on each sample, and two blanks. The results obtained are given in Table 1. The peroxide fusions were not hurried, but were allowed to fuse for three or four hours. No. 8136 is a sample of rubber tubing which was not ground very finely, and which had been found to contain about 50 per cent. of free sulphur. These facts probably account for the discrepancies in the determination.

Discussion of Results.

Skinner[1] comparing the Barlow-Tollen's and peroxide methods found that the latter gave slightly higher results in five out of seven cases, the difference averaging about +0.11 per cent. of SO_4 or +0.036 per cent. of sulphur. The proposed method gives sulphur results about 0.1 per cent. lower than the peroxide method, the average of the 12 values which were lower by the proposed method would thus be about 0.064 per cent. less than by the absolute method. Both of these discrepancies are well within the experimental error. Also it should be noted that the difference between the figures obtained by fusing the barium sulphate in the peroxide method and reprecipitating, and those resulting from the first precipitation by the proposed method (as given in columns B and C, Table 1) varies from —0.04 to +0.11 per cent. In six out of twelve cases the figures obtained by the first precipitation in the proposed method are nearer the values obtained by fusing and reprecipitating the barium sulphate in the peroxide method than they are to the results of the first precipitation in the peroxide method. The peroxide method gives a very high blank as compared to the proposed method; with the former this blank amounted to from 0.009–0.0028 per cent. of sulphur and in the latter it amounts to from 0–0.0007 per cent. As the blanks by the peroxide method are very high an error would be introduced if they were not run in each set. This is very clearly demonstrated in the determinations of sulphur in sulphuric acid solutions as given in Table 2.

---

[1] U. S. Dept. Agr., Bureau of Chemistry, *Bull.* 116, p. 92.

Sulphuric Acid Solutions.

To determine the effect of the salts in solution on the precipitation of sulphuric acid, fusions were made by the peroxide method and by the proposed method, definite volumes of dilute sulphuric acid being added to the solutions and blanks run at the same time. The fusions were made exactly as in the case of the total sulphur determinations given in Table 1. Then they were dissolved, an excess of 2 cc. of hydrochloric acid was added, the solution was filtered, and the measured amount of dilute sulphuric acid added. The sulphuric acid was precipitated with barium chloride solution in the same manner as in the other determinations. The results are given in Table 2.

TABLE 2.—DETERMINATION OF SULPHUR IN DILUTE SULPHURIC ACID SOLUTIONS BY FOUR DIFFERENT METHODS.

Quantity of solution used cc	By precipitating from distilled water after adding 2 cc excess of concentrated hydrochloric acid Gram.	By weighing as ammonium sulphate by Lunge's method Gram	By precipitating from a solution containing a fusion.	
			By the proposed method. Gram	By the peroxide method. Gram.
10 of solution A . . .	0.0140	0.0142	0.0141	0.0127
	0.0141	0.0142	0.0141	0.0147
25 of solution A	0.0352	0.0350	0.0362	0.0340
	0.0351	0.0349	0.0361	0.0355
10 of solution B . .	0.0799	0.0795	0.0832	0.0811
	0.0800	0.0796	0.0832	0.0805
Blanks[1]	. .	.	0.0001	0.0024

The proposed method gives results 0.1 per cent. too high when 3.5 per cent. of sulphur is in solution and 0.3 per cent. too high when 8 per cent. of sulphur is present. This occlusion of salts evidently compensates for an error which would cause the result to be low, as can be seen from Table 1 and the experimental data.

Lunge and Stierling[2] found that in the precipitations of sulphuric acid in aqueous solution and in the presence of salts, the quick addition of the barium chloride solution gave erroneous data in aqueous solution and correct results in the presence of salts while the slow addition of the precipitant gave just the opposite.

The proposed method employs about 7.6 grams of salt (calculated as chlorides) and the peroxide method 15 grams or more.

[1] Corrected for in values given.

[2] See also Allen and Johnston, THIS JOURNAL, 32, 617, where they state, "A very good uncorrected determination may be obtained by precipitating rapidly but it is due to partial compensation of variable errors, and is not in any case so reliable as one which is made by slow precipitation and corrected as described." This agrees with Lunge and Stierling's conclusion on page 350 of their article, 6th Intern. Congress Applied Chem., 1906, p. 347.

Preliminary Experiments.

The preliminary experimental work leading up to this method consisted in testing the various reagents which have been proposed in methods for the determination of sulphur, varying the temperature, reagents, and time and manner of treatment. The 22 experiments made involved 160 single determinations exclusive of those that were lost on account of faulty manipulation, or seemed valueless from the nature of the reaction.

Determinations were made by using mixtures of reagents composed of from 1.25–3 grams of sodium hydroxide, 5–15 cc. of water, 0.5–1 gram of sodium carbonate, 1–2 grams of sodium nitrate, 1–3 grams of magnesium oxide, and from 3–10 grams of crystallized magnesium nitrite.

The treatment of the material with the reagents varied from drying on the steam bath and burning to heating at from 80–230° for from one and a half to five hours before burning. By these means values were obtained which ranged, for instance, from 1.13–1.45 per cent. of sulphur on a sample which contained 1.56 per cent. by the peroxide method, and from 3.91–4.50 per cent. on a rubber containing 4.17 per cent. by the peroxide method. Of 75 determinations, each the average of two duplicates, the peroxide value was the highest except in three instances. When the preliminary heating was continued for from two and a half to five hours, rising above 175° for at least thirty minutes of that time, it was noticed that the values usually approached the peroxide value by 0.1 per cent.

These preliminary determinations all indicate that adding reagents in solution, drying, and then ashing causes a loss of sulphur and that the substance must receive a definite preliminary heating before the sulphur can be absorbed by the alkaline reagent. This was noted after repeated experiments had been made with modifications of Eschka's method and it seemed probable that when the alkaline reagent was added in solution, the mixture dried down, and a coating consisting of an alkaline oxidizing medium was formed, all of the sulphur would be absorbed. This idea was substantiated by subsequent experiments.

Potassium salts were not tried in any of the experiments as Lunge and Stierling[1] have found that potassium chloride dissolves twice as much barium sulphate as sodium chloride does. The use of sodium carbonate was discontinued after the twelfth experiment as Barlow[1] has shown that as far as the absorption of sulphur is concerned soda can be omitted when magnesia is present.

---

[1] The determination of sulphuric acid by means of barium chloride in the presence of interfering substances. Report of the Sixth International Congress of Applied Chemistry, 1906, p. 347. Allen and Johnston, THIS JOURNAL, 32, 606, state that the increased loss is due, not entirely to the slightly greater solubility of the barium sulphate in potassium chloride, but to the loss of "free sulphuric acid" from the precipitate on ignition or more exactly, the loss due to the volatilization of the "free sulphuric acid" is greater than that due to the solubility of the barium sulphate in the potassium chloride present. However, in their article in *J. Ind. Eng. Chem.*, 2, 199 they state that in rapid precipitation "the quantity of free sulphuric acid is lowered and under certain conditions practically vanishes."

The values obtained by these different methods rarely approached those by the peroxide method nearer than 0.1 per cent., which suggested that the latter may be too high. It was therefore decided to examine a new lot of samples by the peroxide method, fuse the barium sulphate obtained with soda, reprecipitate, and determine the sulphur by the proposed method. The results obtained are given in Table 1.

It appears that the first precipitation of the sulphuric acid by this method gives values very nearly approaching those obtained by fusing the barium sulphate obtained by the peroxide method and reprecipitating. The differences between the two sets of results thus obtained range from —0.04 + 0.11 per cent. (an average of 0.04 per cent.) as given in the last column of Table 1; these differences are within the experimental error.

THE INVERSION OF CANE SUGAR BY INVERTASE. V. THE DESTRUCTION OF INVERTASE BY ACIDS, ALKALIS, AND HOT WATER.

BY C. S. HUDSON AND H. S. PAINE.

Received June 15, 1910

Measurements of the Rate of Destruction.—In a previous publication[2] it was shown that invertase is destroyed by both acids and alkalis. At the temperature of 30° the destructive action became noticeable first at the acid concentration of 0.01 normal and rapidly increased with the acid strength, becoming almost instantaneous at 0.05 normal; the alkaline destruction began a little below 0.01 normal and became almost instantaneous at 0.045 normal. It is to be supposed that at lower temperatures these rates will all be smaller and that at such temperatures a stronger acidity or alkalinity will be required for a noticeable destructive action. On the other hand, at higher temperatures the rates of destruction will doubtless be greater and the destructive action will be noticeable for weaker concentrations of acidity and alkalinity. At a sufficiently high temperature the acid and alkaline ions of water itself will doubtless cause a noticeable destructive action of pure water on invertase. It has long been known that hot water destroys invertase and other enzymes; as these views appear to correlate this destruction by hot water with the destruction by acids and alkalis at low temperatures, measurements were made for the purpose of tracing the destructive action of these three agents at different temperatures, in order to learn in what manner the actions are related. The measurements were made by the procedure that was described in the former publication; the results being recorded in Table 1 and shown graphically in Fig. 1. The recorded rates of destruction are the velocity coefficients of the unimolecular destruction reaction, multiplied by 1,000, the units of measurement being minutes and decimal logarithms.

TABLE 1.—RATES OF DESTRUCTION OF INVERTASE BY ACIDS, ALKALIS, AND WATER AT VARIOUS TEMPERATURES

Temperature.	Concentration of hydrochloric acid.	Rate of destruction.	Concentration of sodium hydrate.	Rate of destruction.
0°	0.03 normal	1	0.03 normal	2
	0.04	3	0.04	5
	0.06	9	0.05	17
	0.08	34	0.06	42
	0.10	99	0.08	125
15°	0.03	3	0.03	9
	0.04	10	0.04	38
	0.05	19	0.05	136
	0.06	55	..	...
30°	0.015	1	0.01	3
	0.02	5	0.02	11
	0.03	42	0.03	50
	0.04	96	0.04	245
	0.05	365	..	...
45°	0.01	1	0.01	12
	0.02	26	0.02	41
	0.03	772(?)	0.025	128
60°	0.005	7	0.001	14
	0.0075	18	0.0025	146
	0.01	152	Distilled water	1
65°	0.002	233	0.0001	91
	0.003	301	0.0002	210
			Distilled water	74

The results may best be interpreted from a consideration of the figure; it is seen that as the temperature is raised the rate of destruction by acids and alkalis increases until finally at or about the temperature of 60° distilled water itself slowly destroys invertase, and at 65° the destruction by water is quite rapid. It is evident that the destruction of invertase by hot water is due to the same cause as is its destruction by acids and alkalis. The latter reactions are doubtless hydrolyses of the complex enzyme molecule and it is therefore to be concluded that *the destruction of invertase by hot water is caused by a hydrolysis of the enzyme.* This conclusion doubtless applies to other enzymes also. As far as is known this is the first evidence offered to explain the cause of the well-known destruction of enzymes by hot water. This point of view explains why dry enzyme preparations can be heated without destruction to temperatures over 100° in case no water is present; the hydrolysis does not then take place.

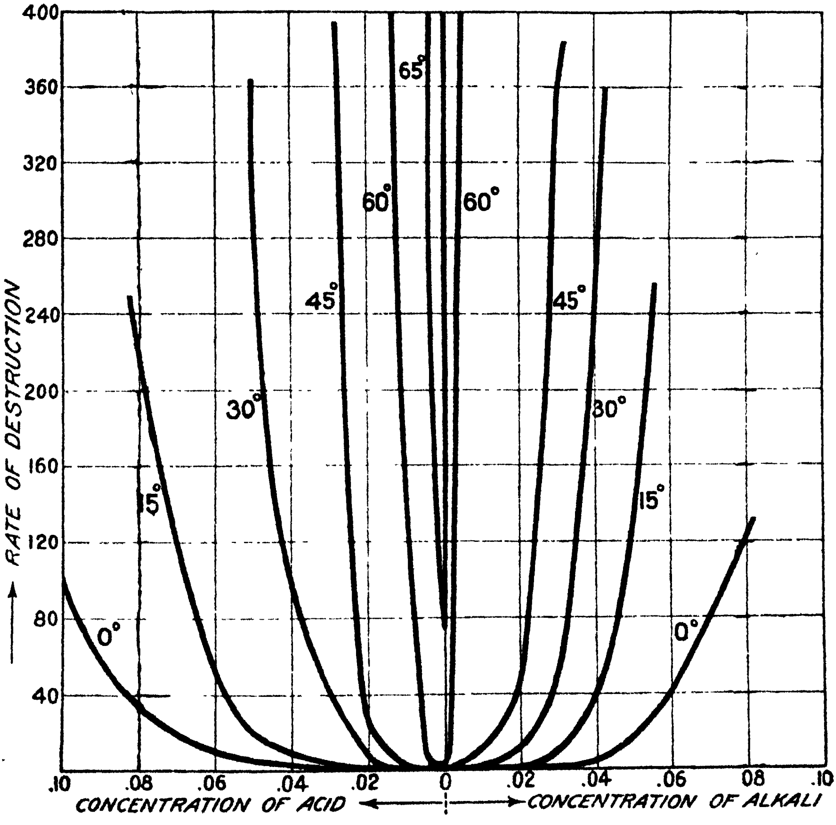

Fig. 1.—The rates of destruction of invertase by acids, alkalis, and water, at various temperatures.

The Influence of Temperature in Increasing the Rates of Destruction.—In Table 2 the rates of destruction in the same medium at different temperatures are compared, and in the last column the coefficient which shows how many fold the rate increases for 10° rise in temperature is recorded. Some of the very large and very small rates do not agree with the general average in showing a coefficient of the value of 2–4, but the limits of error in these cases are larger. The average value of the coefficient is 3.1, which agrees with the general observation that this factor for most chemical reactions varies between 2 and 4. The hydrolytic destruction of invertase by acids, alkalis, and hot water thus falls in with the common types of chemical reactions.

TABLE 2.—THE TEMPERATURE COEFFICIENT OF THE DESTRUCTION.

Temperature interval.	Concentration.	Rates.	Coefficient for 10° rise.
0–30	0.04 HCl	3– 96	3.2
0–15	0.06 HCl	9– 55	3.3
0–30	0.03 NaOH	2– 50	2.9
0–30	0.04 NaOH	5–245	3.7
0–15	0.05 NaOH	17–136	4.0
30–45	0.02 HCl	5– 26	3.0
30–45	0.01 NaOH	3– 12	2.5
30–45	0.02 NaOH	11– 41	2.4
Average			3.1

The Protective Action of Fructose against the Destruction of Invertase.—In a forthcoming article the authors will show the very marked effect of cane sugar in protecting invertase from destruction by alcohol; experiments are now described which show that fructose shares with cane sugar this remarkable property, and also protects invertase from destruction by acids and alkalis. The latter protective action has not yet been tested for cane sugar. The experiments were made by the usual procedure, the rate of destruction being measured first in the absence of fructose and then with it present in the concentrations of 2.7, 5.4, and 10.9 per cent. The data are recorded in Table 3 and the action of fructose in protecting invertase from acid destruction is shown in Fig. 2.

TABLE 3.—THE ACTION OF FRUCTOSE IN PROTECTING INVERTASE FROM DESTRUCTION BY ACIDS, ALKALIS, AND HOT WATER.

Temperature.	Concentration of destroyer.	Concentration of fructose.	Rate of destruction.
30	0.04 *N* HCl	0.0	100
		2.7	26
		5.4	12
		10.9	2
30	0.03 *N* NaOH	0.0	100
		2.7	3
		5.4	3
		10.9	4
30	50 per cent. alcohol	0.0	100
		2.7	1
		5.4	1
		10.9	1
61	Distilled water	0.0	100
		2.7	32
		5.4	16
		10.9	24

The rates of destruction given in the table are expressed as per cent. of the rate for the destroyer when no fructose is present. The rates actually found when no fructose is present, expressed as velocity coefficients of the unimolecular destruction reaction, using minutes and decimal logarithms, are 0.04 normal hydrochloric acid, 0.096; 0.03 normal sodium hydroxide, 0.050; 50 per cent. alcohol, 0.85; and water, 0.0052.

It will be seen from the figure that the protective action of fructose in the case of hydrochloric acid is not at all proportional to the concentration of the sugar but approaches a limiting value asymptotically. The limiting value for the protection seems to have been reached in the case of the alkaline solutions and the alcohol with only 2.7 per cent. fructose; this is probably also true for the protection from hot water because the measurements in this case are very difficult to perform accurately, and the values found--32, 16, and 24—do not differ far beyond the possible error.

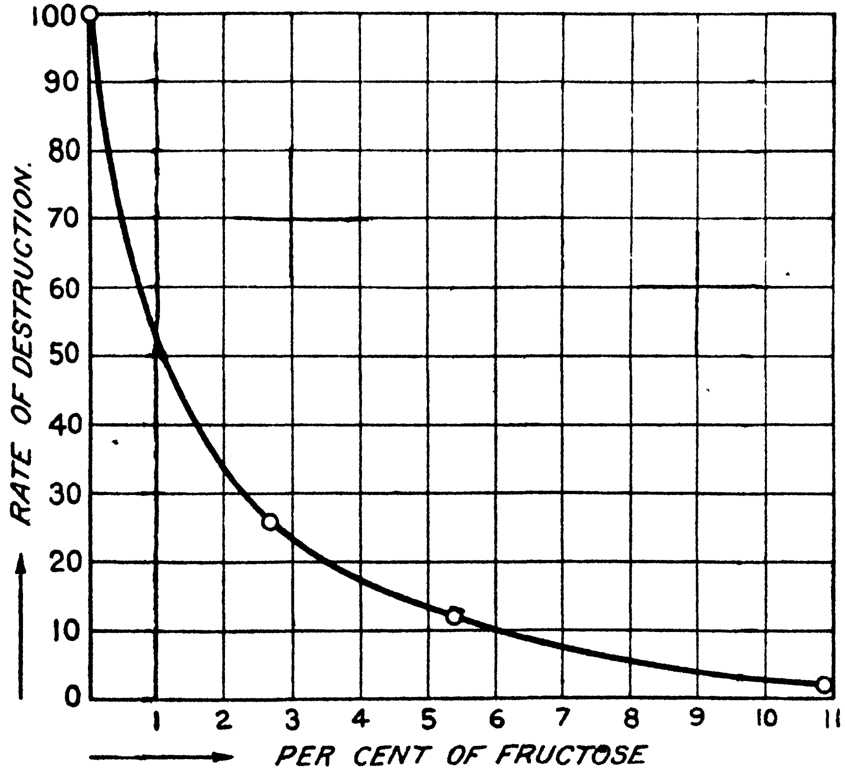

FIG. 2.—The action of fructose in protecting invertase from destruction by acid.

These results on the protection of invertase by fructose can doubtless be interpreted best by assuming that the enzyme forms a combination with the sugar which is more resistant to the destructive action of acids, alkalis, hot water, and alcohol than is invertase itself.

BUREAU OF CHEMISTRY, U. S. DEPT. OF AGRICULTURE,
WASHINGTON, D. C.

OUTLINE OF A THEORY OF ORGANIC CHEMISTRY FOUNDED ON THE LAW OF ENTROPY.[1]

By Arthur Michael

Received June 27, 1910

There appears to be no generalization in science more firmly established than the second law of thermodynamics, which demands that every spontaneous chemical change shall be accompanied by an increase of entropy, and that the system shall endeavor to realize this increase to its maximum extent.

Since the law of entropy represents the fundamental principle, underlying and regulating all chemical phenomena occurring in nature, it must necessarily be the correct scientific basis for the theory of organic chemistry. But it is a curious fact that there has been as yet little attempt to use this basic chemical principle in connection with organic theory; this theory has been developed along lines so mechanical in their character that it is perhaps no exaggeration to speak of them as essentially pictorial. This unilateral, mechanical development is due largely to the interpretation of the phenomenon called valency; and, if we are to incorporate the law of entropy into chemical theory, it is here that our theoretical conceptions will require a radical modification.

Before entering a discussion of the subject of valency, we shall mention a conception of the chemical genesis of matter, since it prepares the way for the theoretical views which follow. A simple hypothesis is to assume that cosmos was originally made up of two kinds of matter, which were the carriers of two kinds of chemical energy,[2] and that the temperature of the system was inconceivably low. Chemical energy, as it now appears to us, exists in two conditions. One of these is freely and perfectly convertible into less active chemical energy and into various forms of physical energy; and this less active chemical energy can be reconverted into the active form only partially and then with comparative difficulty. We shall designate the active form free, the relatively inactive form, bound *chemical* energy,[3] and, as the transformations of chemical energy must have obeyed the law of entropy since the beginning of cosmos, the original corpuscles were exclusively carriers of free *chemical* energy, and the accumulation of bound *chemical* energy and the various forms of physical energy now existing have been gradually evolved from it.

---

[1] Address delivered at the Second Decennial Celebration of Clark University, Worcester, Mass., September 15, 1909.

[2] To distinguish between them they will be called positive and negative, but this does not imply any connection with positive and negative electricity.

[3] The terms free and bound *chemical* energy, as here used, are not to be confused with the terms free and bound energy as used in physical chemistry, with which they are not identical.

The permanence of the law of entropy justifies the conclusion that the chemical relations which existed between the corpuscles at the beginning were similar to those which now exist between the atoms and the molecules. We may, therefore, assume that the free *chemical* energy of unlike and like corpuscles united to form aggregations in which the corpuscles were held together by bound *chemical* energy. At first the chemical evolution of matter must have been accompanied by an enormous rise of temperature, but later, owing to the decreasing amount of free *chemical* energy in the cosmical system, a period must have come when the loss of heat through radiation was greater than its formation, and then the temperature of the system must have begun to decrease. We may assume, too, that the atoms of those elements, the molecules of which now show the greatest stability toward heat were formed first and during the hottest period of cosmical evolution. Hence, the atoms of hydrogen, and those of the non-metals, with small atomic weight, represent the earliest forms of atomic matter.

If we suppose that in the formation of the atoms of certain elements the free *chemical* energy of the corpuscles was very largely converted into bound *chemical* energy and heat, their atoms would be extremely inert toward other atoms and incapable of uniting with each other. Such elementary matter is represented by the so-called noble gases, in the atoms of which the relation of free corpuscular to free atomic *chemical* energy is analogous to that of free atomic to free molecular *chemical* energy in the atom and molecule of nitrogen. Further, if we suppose that thermic, or other conditions, toward the end of the corpuscular period of chemical evolution no longer permitted a sufficient conversion of free into bound *chemical* energy, we get a glimpse into the genesis of radioactive matter, the atoms of which contain so much free corpuscular *chemical* energy that they represent a reversible system and are, therefore, gradually breaking down into smaller parts, which then rearrange according to the changed conditions of cosmos.

Kekulé,[1] in his memorable paper, "Ueber die Constitution und die Metamorphosen der chemischen Verbindungen," assumed that the first phase in chemical union consists in molecules attracting each other through their chemical affinity, and that a sort of loosely joined, larger molecule is thus formed. It is obvious that the formation of this "Kekulé polymolecule"[2] is due to the attraction between the free *chemical* energy in the constituent molecules, and that it proceeds with the conversion of more or less free into bound *chemical* energy and heat—the extent of this change determining its stability.

Let us represent the free *chemical* energy in an atom by a point and the bound by a line, and let the number of the points and the length of the lines be a rough indication of the changes in the energy values occurring during the reaction. If we assume that the energies of unlike character in a molecule of sodium and of chlorine are approximately equal in value, we may represent the energy relations in sodium and chlorine by

---

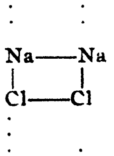
[1] *Ann.*, 106, 141

[2] Michael: *Ber.*, 34, 4028; 39, 2140, 2570. Am. Chem. J., 39, 3; 41, 120.

$\mathrm{Na{-\!\!-}Na}$

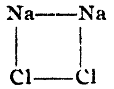
$\mathrm{Cl{-\!\!-}Cl}$

and the "polymolecule," representing the first phase in their interaction, by



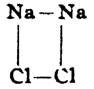
$\begin{array}{c}\mathrm{Na{-\!\!-}Na}\\ |\quad\ \ |\\ \mathrm{Cl{-\!\!-}Cl}\end{array}$

which indicates that some of the free has been converted into bound *chemical* energy. The free *chemical* energies of unlike character would then strive to neutralize each other as completely as possible, a phase of the reaction that may be represented by



$\begin{array}{c}\mathrm{Na{-\!\!-}Na}\\ |\quad\ \ |\\ \mathrm{Cl{-\!\!-}Cl}\end{array}$

and then, certainly facilitated by the enormous "internal maximum heat of reaction,"[1] the bound *chemical* energies between Na and Na and Cl and Cl would be converted into bound *chemical* energy between Na and Cl and Na and Cl; finally, to realize a phase which may be represented by



$\begin{array}{c}\mathrm{Na{-}Na}\\ |\ \ \ |\\ \mathrm{Cl{-}Cl}\end{array}$

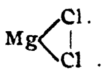
At this point, the bound *chemical* energy between the atoms of like nature may be inadequate to hold them together, and the complex would then break down into two molecules of NaCl.[2]

What happens if we substitute magnesium in the place of sodium; that is, an element the atom of which contains much less positive energy? The formation of a "polymolecule," then the conversion of the free *chemical* energy in the metallic and non-metallic atoms into bound between metal and halogen; but, although the energy in the sodium molecule suffices to neutralize that in the chlorine to an extent that the complex breaks down into two molecules, that in the much less positive magnesium molecule is insufficient to convert enough of the bound energy between the chlorine atoms into bound energy between metal and halogens, therefore the latter atoms separate. On the other hand, the greater energy in the chlorine atoms is capable of using up that in the magnesium to an extent that these fall apart. In magnesium chloride, therefore, the halogen has a considerably greater content of free *chemical* energy than it has in sodium chloride, and bound *chemical* energy exists not only between it and the metal, but between the chlorine atoms. We may represent these relations by:

---

[1] Wohl, *Ber.*, 40, 2290. That part of the free and bound *chemical* energy is converted into heat has not been indicated.

[2] The energies in two unlike atoms are never capable of exactly neutralizing each other, so that a certain content of free *chemical* energy is invariably present in the atoms of every molecule.



While the energy in a molecule of magnesium is not sufficient to separate the chlorine atoms, it obviously may be able to do so with the less negative oxygen, and, if the opposite energies in magnesium and oxygen approximately neutralize each other, two molecules of magnesium oxide should be formed. But, if we take oxygen and a metal with considerably more positive energy than magnesium, say lithium, the oxygen is not able to separate the metallic atoms, while the latter can separate the oxygen atoms, thus leading to the formation of Li_2O, in which the Li atoms are held together by bound *chemical* energy. The valency of an element, according to this interpretation, represents the resultant of the intramolecular chemical forces acting on the atom in terms of *bound chemical* energy, whether the action takes place directly, that is through direct union of the atoms or through space; or indirectly, that is, through other atoms. In as far as the free *chemical* energy in the atoms is not so converted into bound *chemical* energy, it will be able to exert readily a chemical attraction for such other atoms, either in the same or other molecules, for which it shows a chemical affinity.

Although a spontaneous chemical change can proceed only with increase of entropy, the increment depends on free *chemical* energy and chemical affinity existing between those atoms, which in the reaction enter into direct union with each other. The atoms in a molecule are held together *solely* by bound *chemical* energy and, if their chemical nature is such that their free *chemical* energy has very largely disappeared in the formation of the molecule, the substance must be chemically inert; if not, it will be more or less chemically active. Thus, the well neutralized condition of NaCl and Al_2O_3, the superabundant positive energy in Na_2O, and the negative in $AlCl_3$, is reflected in the properties of those substances.

Let us suppose that we could isolate and experiment with elements other than the noble gases in atomic condition, and could prevent the formation of molecules by the union of like, but not of unlike, atoms. In such a system free *chemical* energy would be amply present and chemical union would therefore depend alone on the affinity relations of the atoms. Moreover, if an isomeric substance could be formed, it would be that particular isomer which would represent the maximum entropy of the system under the prevailing conditions.

For instance, the present structure theory indicates the existence of two isomeric cyanogen chlorides, *i. e.*, ClNC and ClCN, but leaves us entirely in doubt why only one is known. So great is the uncertainty in regard to its constitution that this has long been a subject of active discussion and investigation.[1] Chlorine, nitrogen and carbon in atomic condition would possess ample free *chemical* energy for union and the question which isomer would be formed would depend on the increase of entropy connected with the affinity relations of Cl for N and for C. Since we know that the affinity between Cl and N is exceedingly slight, and that between Cl and C is large, it is absolutely certain that the isomer in which the halogen is united directly to the C, *i. e.*, ClCN, would be the direct product. Furthermore, a consideration of the energetic conditions enables us to predict the properties of the isomeric form (ClNC); it could exist only at a very low temperature and under ordinary condition the rearrangement ClNC ⟶ ClCN would occur so quickly, and with such a great increase of heat that the substance would be a violent explosive.[2] The matter we actually deal with is, however, in a molecular condition and all chemical changes that do not proceed *solely* through expenditure of free *chemical* energy involve an expenditure of energy due to overcoming bound *chemical* energy between atoms in the molecule. Chemical action is dependent, therefore, on a third factor, which constitutes a chemical hindrance, and it can proceed spontaneously only when the increase of entropy due to changes of free *chemical* energy and affinity is greater than the expenditure of energy necessary to overcome the chemical hindrance. That is, when the value of the equation: chemical affinity plus free chemical energy divided by chemical hindrance, is positive.

To ascertain quantitative values for the various factors that determine an organic reaction is at present impossible, but it is of the greatest importance for the development of organic theory to be able to connect changes in these values with modifications in structure. This done, we shall then be able to predict relative changes in the factors that contribute to the entropy values and thus be able to understand and explain organic reactions to a degree at present impossible.

---

[1] See Michael and Hibbert, *Ann.*, 364, 69.

[2] It is evident that the content of free *chemical* energy in ClNC would be vastly greater than that in ClCN, which implies a better condition of intramolecular neutralization of the chemical forces of the atoms in the latter structure. Since such chemical neutralization proceeds with increase of entropy, we may substitute chemical neutralization in the place of entropy in the second law of thermodynamics. Further, we may apply the Carnot principle to the activity of free *chemical* energy of unlike kinds, and conclude that the increase of entropy will be greatest when the chemical forces are able to neutralize each other exactly. This law of chemical neutralization has the advantage over that of entropy in a much wider application to organic reactions (Michael, *J. prakt. Chem.*, [2] 60, 293; 68, 489. *Ber.*, 38, 23).

What are the properties of carbon on which the existence of this wonderful and intricate organic world mainly depend? First, its capacity to polymerize, to form stable chains of astonishing length: second, the extreme sensitiveness of its properties to the influence of other elements,[1] which is shared in a like degree only by hydrogen, and which has been called its "chemical plasticity";[2] and third, its high valence combined with its marked affinity for hydrogen and for most of the non-metals, to form more or less stable derivatives.

The first of these properties stands clearly in a close relation to the position of the element in the periodic system. In the halogen group, the tendency to form greater than diatomic molecules is not shown, with the exception perhaps of iodine; in the oxygen group it is shown by that element, but in a far greater degree by the other members. From analogy, a similar tendency to form large molecules by conversion of free into bound *chemical* energy should be expected in passing from oxygen to nitrogen, but the latter element acts anomalously, although in the formation of its diatomic molecule its free is converted into bound *chemical* energy to a remarkable extent

The next member of this group, phosphorus, shows a marked capacity to polymerize to large molecules, and the conversion of ordinary into red phosphorus, which is accompanied by the evolution of only 19 calories, is one of the most salient illustrations in chemistry of how a change of free into bound *chemical* energy will radically change the properties of a substance. The very existence of organic life depends on carbon not sharing with nitrogen the property of polymerizing to a diatomic molecule, which is poor in free *chemical* energy. The actual change in passing from N to C is similar to that in going from N to P, but it is in a degree much more highly developed, and carbon represents among elements the greatest capability to use the free *chemical* energy in its atom to form molecules containing a large number of atoms. The midway position of carbon in the second series of the periodic system indicates that there is an approximate balance of positive and negative corpuscles in the make-up of its atom. And, as the polymerizing capacity of non-metallic atoms increases, generally speaking, with a tendency toward this constitution of their atoms, it seems reasonable to connect this all-important property of the carbon atom with its corpuscular composition.

A relation which is hardly less important for organic theory than the foregoing, is to what extent the polymerizing power of carbon is modified by the presence of other elements in the molecule, and the influence which they exert on the affinity of carbon for hydrogen and for non-metals. Without exception, every element joined to carbon decreases its polymerizing capacity, *i. e.*, its affinity for itself, and the influence is in the order, H, halogen, N, S and O. To the influence of the last element carbon is so exceedingly sensitive that, through direct union with a single atom of oxygen, the enormous combining capacity of the carbon atom for itself is completely destroyed.

---

[1] Van't Hoff, Ansichten über organische Chem., I, 280; II, 242.

[2] Michael, *J. prakt. Chem.* [2], 60, 325.

Notwithstanding the considerable content of free *chemical* energy in the atoms of CO, this substance shows practically no tendency to polymerize, but the characteristic property of carbon reappears at once, when the influence of oxygen is neutralized by the presence of other elements. Thus, the action of potassium on CO leads not to COK, but to a polymerized product, derived from benzene.

Not only does O decrease the affinity of C for C, but of C for H and for any non-metal to which carbon may be joined, whether the atoms are directly or indirectly joined. This is true to a degree directly proportionate to the extent of such negative influences acting on the atoms.[1] The capacity of hydrogen to decrease the affinity of carbon for carbon is far less than that of oxygen, but it plays, nevertheless, an important role in many organic reactions. Thus, the pinacone ⟶ pinacoline rearrangement: $(H_3C)_2=C(OH)-(HO)C=(CH_3)_2 \longrightarrow (CH_3)_3\equiv C-CO-CH_3+H_2O$, takes place on boiling with dilute mineral acid, and the reaction apparently should lead, with loss of water, to the formation of tetramethylethylene oxide.

---

[1] Michael, *J. prakt. Chem.*, 37, 473; 60, 286. *Ber.*, 38, 28, 3221. The writer is unaware of any facts in organic chemistry which are not strictly in accordance with the above stated rule. W. A. Noyes (THIS JOURNAL, 31, 1371) believes that the greater instability of acetoacetic acid ($CH_3COCH_2CO_2H$) over pyrotartaric acid (CH_3COCO_2H) "is some slight indication that the separation of the carbon atoms is ionic in character, taking place more readily when there is a greater contrast between the atoms united together." In the first-named acid, the group C- CO_2H is under the influence of H_2 and a negative, acidic radical (CH_3CO), in the second under a positive radical (CH_3) and O and it is quite in agreement with the above rule that acetoacetic acid splits off CO_2 much more readily than pyrotartaric acid. The writer, also, knows of no satisfactory evidence in favor of the view that any strictly organic reaction is ionic in character (see Michael, *Ber.*, 38, 29; *Am. Chem. J.*, 43, 322; Michael and Hibbert, *Ber.*, 31, 1090); or of any facts that are more easily understood than otherwise by such an assumption. The formation of ethyl chloride from ethyl alcohol and phosphorus pentachloride, while phenol gives partly chlorobenzene, partly phenyl phosphate, is mentioned by Noyes (*loc. cit.*, 1370) as confirming this view. However, when we consider that the chemical hindrance to the formation of a chloride, *i. e.*, the energy necessary to separate hydroxyl from the hydrocarbon radical, is much greater with phenol than with ethyl alcohol, it is obvious that such assumptions as that phenol can ionize to the phenyl and hydroxyl group, and that ethyl alcohol can ionize to ethyl and hydroxyl, do not contribute in any way to make the subject more clear.

This compound contains a three-membered, cyclic chain, which is formed under considerable tension, and, besides, a large number (12) of hydrogen atoms, exerting in a very important position (3) their positive influence on the cyclic carbons. Such a structure cannot represent a very stable substance. On the one hand, there is considerable tension, representing energy in a potential condition; on the other, an extremely insufficient, intramolecular chemical neutralization of the positive by the negative energy in its atoms. The compound may, indeed, be compared to sodium oxide, and shares with that substance a capacity to unite with water, most energetically, and with great increase of entropy. It is apparent that the oxide cannot possibly be formed from pinacone under the conditions of the reaction, but, if a rearrangement may lead to the formation of an intramolecularly well neutralized substance, this may be formed, provided the increase of entropy due to the intramolecular neutralization is greater than the decrease that is due to the chemical hindrance, *i. e.*, the energy necessary to effect the migration of a methyl group. These conditions are possible, for pinacoline represents a fairly well neutralized structure and has, consequently, a considerable heat of formation;[1] and the expenditure of energy accompanying the migration of a methyl in pinacone is comparatively small, owing to the *decrease of the affinity of carbon for carbon` by the influence of the numerous hydrogens.*

That phenyl exerts an extremely strong positive influence on any atom joined directly to it[2] is evident from the fact that two such groups united directly with iodine, give that non-metal a metallic character. It might, therefore, have been expected, that the accumulation of phenyl groups would facilitate rearrangements of the nature of the pinacone ⟶ pinacoline reaction, as this has been especially proven by the investigations of Tiffeneau. We have, moreover, direct experimental evidence that hydrogen diminishes the affinity of carbon for carbon in the observation of Acree,[3] that in the rearrangement with di-*p*-tolyldiphenylpinacone it is the more positive tolyl radical that migrates.

Another interesting illustration of this influence of hydrogen is found in that much-discussed substance "triphenylmethyl" (hexaphenylethane). Tshitshibabin[4] has shown that replacement of five of the hydrogens in ethane by phenyl groups materially lessens the affinity of the ethane carbon atoms for each other. It is, therefore, not surpris-

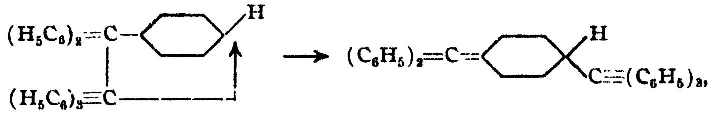
[2] Michael and Leighton, *Ber.*, 39, 2792.

[3] *Am. Chem. J.*, 33, 180.

[4] *Ber.*, 40, 367.

ing that when the remaining hydrogen is likewise replaced, the mutual affinity of these carbons is so greatly diminished that the substance easily dissociates into two molecules of triphenylmethyl,[1] and that these carbons, or the carbon, in "triphenylmethyl" joined to the three phenyl groups, have chemical properties similar to those of a very positive metal, for instance, sodium.[2] Nor is it surprising that hexaphenylethane may undergo easily a desmotropic rearrangement into the quinoid form:



or, since the difference in the entropy values of these two forms is slight, that the existence of one or the other form, or a derivative, will depend on the nature of a reagent or even of a solvent.[3]

The remaining fundamental properties of carbon, its high valency and its capability to combine not only with hydrogen but with most of the non-metals to form stable derivatives, are also related to the position of the element in the periodic system. An element acts as monovalent towards H, or Cl, when its energy suffices to neutralize that of H, or Cl, to an extent that the system is incapable of uniting with further atoms of these elements. In passing from F to O, from O to N, and from N to C, the valency for H, or Cl, increases, because the amount of energy in these atoms, able to neutralize that of H, or Cl, is successively decreasing. CH_4 or CCl_4 represent stable substances, because the energy and affinity relations between C and H, or Cl, are such that, in the combination of four atoms of hydrogen or chlorine among themselves and with one atom of carbon, comparatively little free *chemical* energy remains in any of the atoms.[1]

---

[1] Since the above was written Schlenk (*Ann.*, 372, 1) has shown that with a more positive radical than phenyl, *i. e.*, biphenyl, the affinity of carbon for carbon is reduced to such an extent that tribiphenylmethyl exists in solution in mono-molecular condition, which is a further confirmation of the above explanation.

[2] Michael, *J. prakt. Chem.*, [2] 60, 423, 428; 64, 107; *Ber.*, 39, 2791.

[3] Michael and Hibbert, *Ber.*, 41, 1091. A thermochemical investigation on *intramolecular* rearrangement will be published later; it may be stated that all our present experimental data on this subject confirm the view that the fundamental reason of the phenomenon is the increase of entropy proceeding with the change. In *intramolecular* changes it is the formation of an isomer with a greater heat of formation and in *intermolecular* rearrangements the increase of entropy is connected with a change in composition and the reagent uniting with a product of decomposition; in either case, slight chemical or physical forces may bring about the change, if the chemical hindrance is inconsiderable (see Michael and Hibbert, *Ber.*, 41, 1091). The rearrangements of camphor on treatment with P_4O_6 and H_2SO_4, to which W. A. Noyes (THIS JOURNAL, 31, 1372) recently called attention, may be understood from the point of view here presented. In camphor the affinity of the central carbon to those with which it is directly joined has been diminished considerably by the influence of hydrocarbon radicals and the central ring appears to exist in a condition of tension; moreover, such reduced benzene derivatives show a tendency to pass over into benzene derivatives, as the formation of the para-bonds in benzene is connected with a considerable increase of entropy (Michael, *J. prakt. Chem.*, [2] 79, 418). Phosphoric anhydride is a *powerful dehydrating agent* and the formation of a benzene derivative (cymene) with the elimination of water and rupture of a central carbon bond represents the maximum increase of entropy. In its action on camphor sulphuric acid acts not only as a *hydrolyzing*, but also as an *oxidizing agent*; the formation of *p*-acetyl-*o*-xylene undoubtedly represents the maximum entropy under such conditions.

Like the polymerizing capacity and the "chemical plasticity" of carbon, its power to unite not only with hydrogen, but with most non-metals, is due to the approximate balance of the positive and negative corpuscular energies in its atom. The direction in which the affinity of carbon for such elements will vary under the influence of other atoms in the molecule must be toward those of elements adjacent to it in the periodic system. Thus, the effect of increasing the influence of H on C in relation to H, or to a non-metal, joined to it, must be to shift its affinity values toward those of silicon, *i. e.*, there should be a decrease in the value for H and an increase for that of a non-metal. On the other hand, increasing the influence of O should shift them towards those of N, *i. e.*, decrease the values both for H and a non-metal. Further, the effect of such changes on the content of free *chemical* energy of C, and of any atom joined to it, must stand in a direct relation to the changes in the affinity values; in fact, the free must respond to such changes before the bound *chemical* energy.

According to van't Hoff,[2] two atoms in a molecule acting through direct union or through space, or indirectly, that is through intermediate atoms. This idea has been further developed[3] and shown to be of great importance in explaining organic reactions. If we number a certain atom in any fatty compound with a normal carbon chain by the figure 1, our present knowledge of the combined mutual influence between this atom and others in the molecule is expressed by the following "scale of combined influence," the numbers indicating the degree of removal and the extent of the influence decreasing in the order given: 2—3—5—6—4—7—

---

[1] Replacement of an H in CH_4 by Na gives a substance with preponderance of positive energy, and which is, therefore, poorly neutralized intramolecularly. Carbon, a weak non-metal, in uniting with very positive metals, tends to form compounds of the type C_2Me, in which the accumulated negative energy of several carbon atoms endeavors to neutralize the positive energy of the metal. Only with a weak positive metal like Al are metallic derivatives of methane formed, and it is doubtless owing to this relation between the energies of C and Al, the compounds of which are so widely distributed in nature, that we owe the occurrence of such enormous deposits of *saturated* hydrocarbons.

[2] Ansichten üeber die organische Chemie, I, 284–285; II, 252–254.

[3] Michael, *J. prakt. Chem.*, [2] 60, 331. *Ber.*, 39, 2138–2157, 2780–2790; 40, 141.

(9—10—11)—8. It is to be strongly emphasized that the effect of an atom in position 2 or 3 is *far greater* than that of any similar atom less closely connected, and, in the case of atoms farther removed, the influence must be largely direct, *i. e.*, spatial.

The principles developed above form a new basis for the theory of organic chemistry and may be applied to any problem arising in the science.

Several important organic questions will be discussed from the new point of view. One of the weakest sides of the present structure theory is that it indicates the existence of a countless number of compounds, which are incapable of existence. One instance, that of an isomeric chloride of cyanogen (ClNC) has been already discussed, but this question is of such importance that it will be considered with substances of a different type. Nitrosomethane (H_3CNO) does not exist, as it passes over spontaneously into the isomeric oxime: $H_3C—NO \longrightarrow H_2C=N(OH)$. If we add an oxygen to the nitroso group, we obtain nitromethane (H_3CNO_2), which is perfectly stable, but the tautomeric form of which ($H_2C=NO(OH)$) is so unstable, that its existence can be proven only by indirect means. The thermochemical equation, $2NO + O_2 = 2NO_2 + 26.9$ cal. proves conclusively that the nitroso group contains much more free *chemical* energy than the nitro, which is the reason why the nitroso group in nitrosobenzene is so much more reactive than the nitro group in nitrobenzene. In nitrosomethane, then, the following energetic and affinity relations exist: the oxygen has much free *chemical* energy and a strong affinity for the H of the methyl group, and by the change into the oxime, the great content of free *chemical* energy in the nitroso group is largely converted into bound *chemical* energy and heat. The transformation therefore proceeds with increase of entropy and the oxime represents an intramolecularly well neutralized structure, which agrees with its amphoteric properties and the slight additive capacity at the double bond. Since the nitro group in nitromethane has less free *chemical* energy than the nitroso in nitrosomethane, its oxygen has less capability to overcome the bound *chemical* energy holding the hydrogen to the carbon. A rearrangement to isonitromethane is barred for a second reason, *viz.*, that it would proceed with a degradation of entropy, for it is evident that the *neutral* nitromethane, the nitro group of which carries but little free *chemical* energy, is vastly poorer in such energy than the strongly *acidic*, unstaturated isonitromethane.[1]

In order that a rearrangement should proceed spontaneously, the atom which receives the migrating atom, or group, must have sufficient affinity for it to be able to overcome the bound *chemical* energy between the migrating atom, or group, and the atom to which it is already joined.

---

[1] See *Ann.*, 363, 21.

If we increase through a structural change the bound *chemical* energy more than we do the affinity and free *chemical* energy factor; or if we decrease the latter without essentially altering the former, we obviously increase the relative stability of the new derivative and it may show an existence in a free state. Through certain structural changes the difference between the entropy values of the isomeric forms may be lessened, and we may arrive in this way to desmotropic substances, the energy relations of which are so evenly balanced that the existence of one or the other form may be determined by a slight expenditure of extraneous chemical, or physical energy.[1]

Before 1887 the substitution process in organic chemistry was universally supposed to consist of the direct replacement of an atom, or group, by another. It was then shown, by an investigation on the constitution of acetoacetic ester and its sodium derivative,[2] that this view could be upheld no longer and that apparent substitution is often the result of a combination of an addition and elimination process. Subsequent researches[3] have shown that substitution, as represented by the old view is of comparatively rare occurrence, and that a rational interpretation of the process may be based on the entropy principle. Thus, by the use of a metal like sodium, which has considerable free *chemical* energy and a strong affinity for oxygen, the hydrogen in $CH_2=NOH$ attached directly to oxygen may be driven out, with the formation of $CH_2=NONa$.[4] This change is only apparently a direct replacement of hydrogen by sodium, for what actually occurs is, that the energy and affinity values of the metal are such that it is able to overcome the bound *chemical* energy between the oxygen and hydrogen and that the latter element is *driven out*, not replaced.

The distinction between replacing and driving out may seem from the above instance to be unimportant, but it is in reality of fundamental importance in organic reactions. Let us consider, for instance, the behavior of nitromethane and hydrocyanic acid towards sodium from the new point of view! In the system

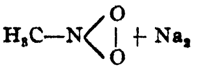
---

[1] Michael, *Ann.*, 363, 27.

[2] Michael, *J. prakt. Chem.* [2], 37, 473.

[3] Michael, *Loc. cit.*, 60, 316. *Ber.*, 33, 3739; 34, 4028; 38, 22, 1922–1938, 2083, 2097, 3218. *Amer. Chem. J.*, 43, 330.

[4] It does not follow from the formation of this sodium derivative that the change as represented by $CH_2=NOH \longrightarrow CH_2=NONa$ designates an increase of entropy; indeed, a consideration of the well neutralized, amphoteric character of the oxime and the strong basic, easily hydrolyzed character of the sodium derivative, leaves no doubt that the free *chemical* energy in the latter is much greater than in the former structure. In the reaction much of the free *chemical* energy in sodium is converted into bound; it is the total change ($2CH_2=NOH + Na_2 = 2CH_2=NONa + H_2$) that proceeds with increase of entropy.



$$H_3C{-}N\begin{matrix}O\\ |\\ O\end{matrix} + Na_2$$

the metal may be attracted either by the C or the O, but not only is the free *chemical* energy in the O larger than that in the C, but also the chemical affinity for Na. Moreover, according to the law of entropy, the system must strive to realize the maximum condition, which will be the formation of a sodium derivative, in which the free *chemical* energy existing in nitromethane and in sodium is converted as completely as possible into bound *chemical* energy and heat. This condition is realized by the direct union of Na with O, since then an almost neutral salt will be formed, while the derivative containing the metal joined directly to C would be strongly basic and have positive energy in great excess. Indeed, if such a derivative as $NaCH_2NO_2$ could be obtained at a low temperature, it would pass over at ordinary temperature spontaneously and with an enormous increase of entropy into $CH_2{=}N(ONa)O$.[1] The intramolecular hindrance, which nitromethane offers to attack, of the Na on the O is the energy necessary to overcome the bound *chemical* energy between a hydrogen and the carbon, which, owing to the strong negative character of the nitro group, is very considerably less than in methane and the reaction therefore proceeds readily.

According to the old substitution theory, the action of Na on HCN[2] proceeds by the direct replacement of the hydrogen by the metal, forming NaCN; according to the new theory, the Na may be attracted by the C or the N, and a salt may be formed if the metal is able to overcome the bound *chemical* energy between the H and the C and the reaction proceeds with an increase of entropy. The properties of the cyano group leave no doubt as to the existence of considerable free *chemical* energy in the C and the N, and there is also no doubt that Na has a greater affinity for N than for C: furthermore, N, being an element with more negative *chemical* energy than C, the energy of the metal in NaNC is much better neutralized than it would be in NaCN. The energy and affinity conditions permit, therefore, in the *direct* formation of $CH_2{=}NO(ONa)$ and NaNC, the maximum possible increase of entropy, and any other conception of the structures of these salts, is as inconceivable from the new theory, as the older view leaves us wholly in the dark in regard to them.

---

[1] Although a "double" bond is usually an indication of the accumulation of free *chemical* energy, its symbolistic use for this purpose would be misleading. The free *chemical* energy in an atom must vary with the extent of intramolecular neutralization; *i. e.*, in $CH_2{=}NO(ONa)$ the free *chemical* energy at C and N is used up indirectly to a very considerable extent in neutralizing the positive energy of the sodium. An approximate idea of the free *chemical* energy in the atoms of a molecule can usually be formed by a consideration of their chemical nature, the structure and the properties of the substance.

[2] Michael and Hibbert, *Ann.*, 364, 64.

We have seen that the positive energy in sodium has been largely converted into bound *chemical* energy, when the metal is introduced into nitromethane and that neither at the unsaturated carbon or nitrogen of $H_2C=N(ONa)O$ is there much free *chemical* energy. It follows from these energy conditions that this salt should not easily react with a reagent, unless the latter contains atoms with much free *chemical* energy and a large affinity value for certain atoms in the salt. Hence, sodium isonitromethane is comparatively inert toward methyl iodide: but, if we make a change in the structure of the salt, so that the metal is less well neutralized, we shall facilitate the reaction; for, by doing so, we increase not only the free *chemical* energy of the unsaturated atoms, but the difference between the heats of formation of sodium iodide and the sodium salt, which is one of the largest factors in determining the entropy of the reaction. The conditions for an easy reaction are fulfilled, for instance, in sodium acetoacetic ester ($CH_3—CONa=CH—COOC_2H_5$), for in this derivative the positive energy of the metal is very inadequately neutralized by the weakly acidic organic radical to which it is joined, and the unequal balance between the positive and negative chemical forces must leave considerable free *chemical* energy in the unsaturated atoms. The reaction may proceed in two directions:

I. 
$$\begin{array}{lcl} CH_3{-}CONa & \longrightarrow & I \\ \Vert & & | \\ H_5C_2OOC{-}CH & \longleftarrow & CH_3 \end{array} = CH_3CO{-}CH(CH_3){-}COOC_7H_5 + NaI.$$

II. 
$$\begin{array}{lcl} \quad H_3C \quad Na & \longrightarrow & I \\ \quad\;\; | \quad\;\; | & & | \\ H_5C_2OOC{-}CH\;C{-}O & \longleftarrow & CH_3 \end{array} = CH_3{-}C(OCH_3){-}CH \quad COOC_7H_5 + NaI.$$

It is of interest to analyze the energy and affinity relations of the unsaturated carbon joined directly to the carbethoxyl group and those of the oxygen joined to sodium, since they determine the course of the reaction. Sodium iodide is formed in either case, and, as the heat of formation of the C- is greater than that of the O-methyl derivative,[1] its formation represents the maximum entropy of the system. The introduction of sodium into acetoacetic ester ($CH_3—CO—CH_2—COOC_2H_5$) has the following effect on the energy and affinity relations of the carbonyl oxygen (in CO) and the methylene carbon (in CH_2):

First, the free *chemical* energy in the O has been greatly decreased through direct union with the metal, while part of the bound *chemical* energy of the C (used before in holding the eliminated H) has been converted into free; second, the affinity of the O for CH_3 has been greatly reduced by the positive influence of the metal, which, on the other hand, has neutralized the effect of the two negative radicals (CH_3CO and $COOC_2H_5$) and given the unsaturated α-C a large affinity value for methyl. It is evident that when we take the entropy, energy and affinity relations into consideration, the conversion of the O-sodium salt into the C-methyl derivative, *i. e.*, the reaction represented by I, is not an abnormal, but a perfectly normal, reaction,[1] as, indeed is every chemical change in which the condition of maximum entropy is realized.

---

[1] Experimental proof will be published later.

Finally, we shall discuss another fundamental organic process, that of addition, from the standpoint of the second law of thermodynamics.

If we remove one hydrogen from two adjacent hydrocarbon groups in propane a compound is formed ($CH_3—CH=CH_2$) in which part of the bound *chemical* energy previously holding the eliminated hydrogen atoms in chemical union appears as free *chemical* energy at the unsaturated C-atoms.[2] In the addition of a reagent to such a compound, the free *chemical* energy of the unsaturated atoms is more or less completely converted into bound *chemical* energy and heat, and the second law of thermodynamics compels the addition to take place in such a manner that the maximum entropy will be realized, unless there is some chemical hindrance, which prevents this attainment of the ultimate goal of free *chemical* energy.

The structure theory teaches us that in the addition of hydrobromic acid to propene, two isomers (propyl and isopropyl bromide) may be formed; but it fails altogether to give us any indication which of these products, or whether both of them, should result. The chemical hindrance in this reaction is the energy necessary to overcome the bound *chemical* energy between the H and the Br of HBr to the extent to which it exists between them in the bromopropane that will be formed in the addition.[3] This hindrance is obviously quantitatively the same in the formation of either isomer. The maximum entropy in this addition will be attained, therefore, in the formation of the isomeric bromopropane with the greater heat of formation.

Obviously, it is of great importance in this and in many other organic reactions to be able to trace the relation between the structure of isomers and their heat of formation. This is enabled by the following "thermochemical law of structure."[4] In isomers with normal chains and which contain a common negative radical as a nucleus, that isomer will have the largest heat of formation, the positive radicals of which to the greatest extent are under the influence—direct and indirect—of the negative nucleus. Thus, in propyl and isopropyl bromide the common negative nucleus is CBr, which in the last compound is under the direct influence of two methyl groups, while in propyl bromide only one methyl is directly, the other indirectly, joined. The intramolecular neutralization, which finds an expression in the heat of formation, is therefore larger in the iso than in the normal bromide, and, since the thermic value of direct is very much greater than that of indirect chemical union, the heat of formation of the former compound is considerably larger than that of the latter.

[1] Michael, *Ber.*, 38, 129.

[2] *J. prakt. Chem.*, [2] 60, 298.

[3] Michael, *Am. Chem. J.*, 43, 333 (footnote).

[4] Michael, *J. prakt. Chem.*, [2] 68, 499; 79, 418; *Ber.*, 39, 2140.

Not only does the system, propene and hydrobromic acid, realize its maximum condition of entropy in the formation of isopropyl bromide, but the affinity relations at the points of maximum concentration of the free *chemical* energy, *i. e.*, at the unsaturated carbons, are such as to favor the course of the reaction in this direction, since the influence of methyl in this substance is positive to that of hydrogen in the same position.[1] This relation causes in propene a greater accumulation of positive energy at the middle than at the end unsaturated carbon and the middle carbon must have, therefore, the greater affinity for the strongly negative halogen of the acid. It seems theoretically probable that this coincidence of affinity and entropy values should lead exclusively to the formation of the iso derivative, as, indeed, it would if chemical change depended solely on the free energy and the affinity values. When a mixture, containing an acid with a very large and a very small acidity constant, is brought together with a quantity of a strong base inadequate for complete neutralization of the acids present, there is always an appreciable amount of salt derived from the weak acid formed. The chemical force in each acid endeavors to its utmost capacity to contribute its share toward the increase of entropy, which depends not only on the values of the affinity constants but, although to a very much smaller degree, on the actual mass, by weight, of acid present.

If the formation of normal propyl bromide from propene and hydrobromic acid proceeds with an increase of entropy, which it undoubtedly does, we have in this addition reaction two chemical forces, each striving to increase the entropy, but, in this case, the mass by weight cannot be changed and the struggle is between energies.[2] Furthermore, since there is no difference in the chemical hindrance. to the addition in either direction, it is extremely probable that the relative amounts of salts, or isomeric bromides, formed will stand in a direct relation to the increase of entropy, and as this is very much greater with the formation of isopropyl bromide, it agrees with the theory that the normal bromide is formed only to a very slight extent.[3]

The principle here involved was first used by Thomson[4] to determine the relative acidity constants, and has been called the "*principle of*

---

[4] *Pogg. Ann.*, 138, 497.

partition";[1] it may be applied to every organic reaction where two or more isomers may be formed.[2] Let us take, as illustrations of the application of this principle, the addition of water by means of sulphuric acid to hexine–1 and –2. In hexine–1 ($CH_3—CH_2—CH_2—CH_2—C\equiv CH$), we have practically the same conditions as in propene, that is, the difference between the energy and affinity values of the unsaturated carbons are due to the difference between the direct influence of an alkyl group and a hydrogen; hexanone–2 ($CH_3—CH_2—CH_2—CH_2—CO—CH_3$) and probably a very slight amount of hexanal ($CH_3—CH_2—CH_2—CH_2—CH_2—CHO$) are formed. The relations in hexine–2 ($CH_3—CH_2—CH_2—C\equiv C—CH_3$) are quite different; the unsaturated carbons are both joined directly to alkyl groups, and the change in their energy values is due not to direct, but to indirect, influences, which are largely spatial. This relation must cause the heats of formation of the products that may result, hexanone–2 and –3, to be much nearer together than the isomers that may be formed in the addition to hexine–1; also an approximation in the energy and affinity values at the unsaturated carbons.

According to the "principle of partition," the relative amounts of hexanone–2 and –3 formed should not fall very far apart. Moreover, we can approximately estimate the energy values of the unsaturated carbons in relative terms by the use of the "scale of combined influence" mentioned above. Applying this scale to the relations in hexine–2, omitting those atoms the influences of which on the unsaturated carbons are equal,[2] or very nearly so, we find that Δ^β—C[3] (joined directly to methyl) is under the influence of one carbon in the 4th, one hydrogen in the 3rd, and three hydrogens in the 5th position, and Δ^γ—C (joined directly to butyl) has one carbon acting in the 3rd and 4 hydrogens in the 4th position. Since atoms in the 3rd and 5th positions exert a greater influence than those in the 4th, it is obvious that the positive energy at Δ^β—C is greater than that at Δ^γ—C, and that a larger proportion of that ketone should be formed, when the negative part of the addenda adds to it, *i. e.*, hexanone–2. A re-investigation[4] of the reaction shows indeed that about 60 per cent. of hexanone–2 to 40 per cent. of –3 are formed in the reaction.

The present structure theory has been, and always will be, of inestimable service to organic chemistry: it has taught us, until recently,[5] the possible number of isomers that may exist of a given formula, and it has been a guide in determining the constitution of most of the substances that have been discovered. But its weakness and limitations are inherent in its foundation on a mechanical conception of valency and an almost exclusive theoretical development along similar lines, for surely in nature there are no forces more intimately and indissolubly connected with changes in energy than the chemical.

---

[1] Michael, *J. prakt. Chem.*, [2] 60, 341–354; *Ber.*, 39, 2138–2156, 2569, 2786–2795; 40, 140.

[2] See *J. prakt. Chem.*, 60, 341. *Ber.*, 39, 2141.

[3] The capital "Delta" denotes unsaturation (Baeyer, *Ann.*, 245, 112).

[4] Michael, *Ber.*, 39, 2133.

[5] *Ber.*, 39, 203.

Largely for this reason, the structure theory fails to offer explanations for many of the simplest organic reactions and, for many years, it has failed in explaining and co-ordinating with theory much of the wonderful experimental progress that has been made in the science.

It is true that innumerable attempts have been made to amplify or change the idea of valency and the structure theory so as to remedy these deficiencies, but they have always been along mechanical lines and have led to such impossible theoretical conceptions as new brands of valencies, dissociated and partial valencies, oxonium and carbonium theories, steric hindrance due to size of the atoms, etc., etc.

All the forces in nature, whether mechanical or chemical, have the same goal in view, which is the realization of the maximum condition of entropy, and a scientific theory of chemistry must inevitably have this law as its basis. The present aim of organic theory is not to abandon the structure theory, but so to broaden and develop it that it becomes a consistent and harmonious part of nature.

NEWTON CENTRE, MASS

NEW BOOKS.

The Elements of the Science of Nutrition. By GRAHAM LUSK, Ph.D., M.A., F.R.S., (Edin). Second edition. W. B Saunders Company: Philadelphia, 1910. 402 pages, illustrated. Cloth, $3.00 net.

The science of nutrition attracts attention at the present time from the physiologist, the chemist and the practicing physician, but whatever his interest may be, the man who wishes to follow the developments of that science of to-day must have at his command a good knowledge of modern physiological chemistry. This truth is well illustrated in the book in question.

The science of nutrition, like many other sciences, goes back to Lavoisier for its beginning, and in an interesting introductory chapter Lusk traces the cardinal points in its growth down to the present time. The author is a well-known physiologist and has himself made valuable contributions to the field. He has condensed into some four hundred pages a very clear and interesting résumé of the noteworthy literature of the subject. The book is divided into fifteen chapters which discuss the uses and effects of various kinds of foods, the relations to temperature and to work, the products of metabolism and other questions which properly belong in such discussions. The treatment is much fuller and more satisfactory than is usually found in works on physiology which, in a way, cover the same ground. Very good literature references add greatly to the value of the explanations. Three chapters, the 12th, 13th and 14th, are devoted to the discussion of our present views on metabolism in diabetes, metabolism in fever and the purine metabolism in its relations to gout and other conditions. It is pointed out by the author that the rapidly accumulating data bearing on these topics may soon make possible rational theories as to the origin of these diseases. The interesting relation of the purine chemistry to this field of study is pointed out at length.

This book can be heartily recommended to any one who wishes a textbook guide with which to work into an understanding of the present status of the science of nutrition. J. H. LONG.

THE PROPERTIES OF SALT SOLUTIONS IN RELATION TO THE IONIC THEORY.

I. MOL-NUMBERS DERIVED FROM THE FREEZING-POINT LOWERING.

By A. A. Noyes and K. G. Falk

Received June 27, 1910

Contents.

Introduction. 1. Theoretical Considerations. 2. The Experimental Data. 3. Summary of the Mol Numbers Derived from the Freezing-point Lowerings. 4. The Mol Number in Relation to the Type of Salt. 5. Change of the Mol Number with the Concentration.

Introduction.

For a number of years one of the main lines of research pursued in this laboratory, with the aid of grants from the Carnegie Institution of Washington, has been the study of the properties of salt solutions with reference to the well-known anomalies of the ionic theory and with the view of establishing empirically the principles that must be substituted for the inexact theoretical laws ordinarily employed, and, if possible, of finding a rational explanation of the divergences. Such work has also been in progress in many other laboratories, partly with this general purpose, but oftener with more specific ends in view; and there has in consequence been accumulated a large mass of experimental material which has remained to a great extent uncorrelated. It seems therefore highly desirable to subject the existing data to a critical study from the standpoint just referred to; and the present paper is the first of a series of articles which are to be devoted to different phases of this subject.

The factors which according to the ionic theory directly determine the physical properties and also the chemical behavior of salts in solution are: (1) their degrees of ionization, or, in more general terms, the concentrations of the various ions and un-ionized substances present in the solution; (2) the mobilities or conductances of the separate ions; (3) the osmotic pressures of the ions and the un-ionized substances; (4) the so-called active masses or the (by Lewis more specifically defined) activities of the ions and the un-ionized substances; and (5) specific properties characteristic of the separate ions such as their molal volumes, refractive power, etc. Of these factors the first is involved in the interpretation of nearly all properties except those of a distinctly additive nature; the second in that of all phenomena connected with the passage of electricity, such as conductance and transference; the third in that of the so-called molecular or colligative properties, such as vapor pressure, freezing point, and boiling point, and in various thermodynamic relations; the fourth, in the determination of all chemical equilibria and many thermodynamic formulas; and the fifth, in the treatment of the additive and constitutive physical properties and of specific chemical effects, such for example as the catalytic power of the hydrogen ion.

The determination of the values of these separate factors is attended with the difficulty that at least two of them are simultaneously involved in any property of the salt solution that may be measured. From this it follows that a given factor can be determined only with the aid of some assumption in regard to the other factors, or indirectly through the combination of measurements of different properties or of the same property under different conditions. Thus the conductance of a salt depends both on its ionization and the mobility of its ions; and when the ionization is derived from the ratio of the equivalent conductance at the given concentration to that at zero concentration, it is assumed that the mobilities of its ions are the same in the two solutions. Evidence as to the correctness of this assumption may be obtained by the study of some other property dependent upon mobility, such as transference; or by a comparison of the ionization values calculated with its aid with those derived from some independent property, such as the freezing-point lowering.

The first paper of this series will be devoted to the consideration of the freezing-point lowering caused by salts, acids and bases, this being the property from which the total number of mols present in the solution can be most satisfactorily derived.

1. Theoretical Considerations.

In order to calculate exactly the number of mols i resulting from one formula weight of the solute, it is necessary to formulate accurately the theoretical relation between the freezing-point lowering and the molal concentration of the solute. The fact has been recently emphasized by several writers[1] that the most general and exact form of the law of solutions, judging especially from its applicability to non-associating liquids throughout the whole range of concentration, is that expressed by the Raoult vapor-pressure equation:

$$\frac{p}{p_0} = \frac{n_0}{n_0 + n} \text{ or } \frac{p_0 - p}{p_0} = \frac{n}{n + n_0} \qquad (1)$$

where p_0 and p are the vapor-pressures of the solvent ands olution respectively, and n_0 and n are the number of mols of solvent and solute respectively. The thermodynamically corresponding expression for the osmotic pressure P of the solution (neglecting the ordinarily insignificant compression term) is:

$$\log_e \left(1 - \frac{n}{n + n_0}\right) = \frac{PV_0}{RT} \qquad (2)$$

where V_0 is the volume of one mol of liquid solvent, R the gas constant, and T the absolute temperature. A solution which conforms to these laws has been called a *perfect solution.*

It has also been shown by Washburn[2] that the substantially exact numerical expression for the freezing-point lowering Δt which is thermodynamically equivalent to these relations when water is the solvent and the solution is not extremely concentrated is as follows:

$$\frac{n}{n + n_0} = 0.00969\Delta t(1 - 0.0043\Delta t). \qquad (3)$$

For the purposes of this article this may be given the following simpler form, which is obtained by placing $n_0 = 1000/18.01 = 55.5$, solving for n, and writing iN for it:

$$iN = \frac{\Delta t}{1.858}(1 + 0.0055\Delta t), \qquad (4)$$

where N represents the number of formula weights of solute associated with 1000 grams of water, and where 1.858 is the molal lowering in a dilute perfect solution. This expression is in concentrated solutions slightly less exact, but is accurate within 0.1 per cent. for solutions for which $N < 1$ or $\Delta t < 3°$, provided the imperfectly known effect of hydration is neglected.

This expression has been employed in calculating the values of i presented in this article; but in those cases where $\Delta t < 0.20$, and where therefore the parenthesis in the second member differs from unity only by about 0.1 per cent., the parenthesis has been ignored, and the simple formula $iN = \Delta t/1.858$ employed.

---

[1] Compare especially van Laar (Zwei Vorträge über nicht verdünnte Lösungen und über den osmotischen Druck (Vieweg & Sohn, 1906); Lewis, THIS JOURNAL, **30,** 673 (1908); Washburn, *Tech. Quart.*, **21,** 368 (1908).

[2] *Tech. Quart.*, **21,** 373 (1908); and *Jahrb. Radioakt. Elektronik.*, **5,** 493.

The value of i so calculated has a definite empirical significance which is independent of any assumption whatever. It represents, namely, the factor by which the number of formula weights N associated with 1000 grams of water must be multiplied, if the osmotic pressure, vapor pressure, or freezing point is to be correctly calculated by the laws of the perfect solution. The factor i therefore accounts not only for any difference between the number of mols actually existing in the solution and the number of formula weights taken, but also for any physical deviation from the laws of the perfect solution.

Assuming now that there is no such physical deviation—that is to say, that the ions and un-ionized substances are perfect solutes, exerting normal effects in accordance with the laws of the perfect solution, and that the quantity of solvent present is not appreciably diminished by combination with the solute, then evidently the value of i is equal to the number of mols in the solution resulting from one formula weight. Interpreted in this sense i will be called the *mol number* of the solute.

Since there is strong evidence that many salts in solution are hydrated, the assumption that the quantity of free solvent present is the same as that of the pure solvent used in making up the solution is almost always inaccurate. It is therefore important to consider what the magnitude of the error caused by neglecting the effect of hydration upon the value of the calculated mol number is likely to be at different concentrations. Its effect may be readily derived by reference to equation (4) through the following consideration. If, with the N formula weights of solute that are dissolved in 1000 grams or 55.5 mols of water, xN mols of water are in reality combined, the number of formula weights associated with 1000 grams of uncombined water is really greater than the assumed value N in the proportion $55.5/(55.5 - xN)$ or of $1/(1 - xN/55.5)$. The true value of i is therefore smaller than the calculated value in the same proportion; namely, by the following percentage amounts:

Percentage error =	$0.18x$	$0.36x$	$0.90x$	$1.8x$
For N =	0.1	0.2	0.5	1.0

Since x, the mols of water combined with one formula weight of salt, is probably often as large as 5 or 10, there is likely to be in many cases an error in i as large as 1 or 2 per cent. even at a concentration of 0.1 formal; and at much higher concentrations than this, the possible error arising from hydration becomes so large that the interpretation of the values of i as mol numbers has little significance, except perhaps in the case of substances which there is reason to believe are but little hydrated. Provided any independent determination of the true values of i can be found, the results would, however, be of great value in determining the degree of hydration.

The relation of the mol number to the degree of ionization may also be briefly considered. If the only substances present in the solution of a di-ionic[1] salt of the formula BA are the un-ionized substance BA and the ions B^+ or B^{++} and A^- or $A^{=}$, then evidently between the mol-number i and the degree of ionization γ there exists the simple relation

$$i = (1 - \gamma) + 2\gamma = 1 + \gamma. \tag{5}$$

And similarly, if the only substances present in the solution of a tri-ionic salt of the formula B_2A or BA_2 are the un-ionized substance B_2A or BA_2 and the ions B^+ or B^{++} and $A^{=}$ or A^-, then the following relation holds true:

$$i = (1 - \gamma) + 3\gamma = 1 + 2\gamma. \tag{6}$$

And in general for an n-ionic salt, we have

$$i = 1 + (n - 1)\gamma. \tag{7}$$

It is, however, to be noted that the assumption that the un-ionized salt and its simplest ions are the only substances present in the solution is by no means necessarily true in all cases. Thus in the case of tri-ionic salts, like K_2SO_4 or $Ba(NO_3)_2$, it may well be that the intermediate ion, KSO_4^- or NO_3Ba^+ is also present. And in the case of any salt, even of one of the di-ionic type, complex cations and anions and the corresponding complex salt may also be present; thus in a solution of magnesium sulphate there may be present not only $MgSO_4$, Mg^{++}, and $SO_4^{=}$, but also $Mg(SO_4)_2$ and the complex salt $Mg_2(SO_4)_2$; and in a lithium chloride solution not only LiCl, Li^+, and Cl^- but also $LiCl_2^-$ or Li_2Cl^+ and Li_2Cl_2 might be present.

The formation of new substances by reaction with the water is also to be considered; thus in the case of salts of a very weak acid or base (like KCN or ammonium acetate) the hydrolysis-products BOH and HA may be present in considerable quantity, especially in dilute solutions.

2. The Experimental Data.

It is the purpose of this section to bring together the values that have been obtained by various investigators for the freezing-point lowerings caused by salts, acids, and bases; and to derive through a critical consideration of these data what seem to be the best values to adopt. Owing to the many errors in freezing-point measurements, some of which have only gradually come to be recognized, it is in many cases only in this way that fairly reliable results can be secured. Such series of measurements as are obviously affected by unusually large errors have been disregarded.

The method of procedure employed has been to plot the values obtained by each observer for $\Delta t/N$ as ordinates against those of log N as abscissas, where Δt is the observed freezing-point lowering and N is the number of formula weights of salt associated with 1000 grams of water. In cases where the salt content was not so expressed it has been calculated over to this basis. The ratio $\Delta t/N$ will hereafter be designated the *formal freezing-point lowering.* The most representative curve was then drawn through the points representing the data of each observer; and the values of $\Delta t/N$ were taken from the curve at a number of definite concentrations. A mean of the values so obtained from the data of all the observers at each concentration was next derived, assigning to each observer's results a weight based upon the precautions observed in the experimental work, the number of determinations, and the accuracy of the results as indicated by their deviations from the curve. In general, the same weight is assigned to all the results of a given observer; but in a few cases this has been varied for the different substances. This method of assigning weight involves individual judgment and is to a certain extent arbitrary; but it is preferable to assigning equal weight to all the results. The average values so obtained were then plotted in the same way as before, the curve best representing them was drawn, and from this curve the final values of $\Delta t/N$ at definite concentrations were read off.

---

[1] The number of ions into which a salt dissociates will be indicated by the words *di-ionic*, *tri-ionic*, *etc.*; and the valence of the two ions to which the salt gives rise will be indicated by the words *uni-univalent*, *unibivalent*, *bibivalent*, *etc.* Thus $MgSO_4$ is a bibivalent, di-ionic salt; and $K_3Fe(CN)_6$ or $AlCl_3$ is a unitrivalent, tetraionic salt.

The limits of content which are considered are from 0.005 to 0.5 equivalents per liter. For those substances for which the value of $\Delta t/N$ passes through a minimum, the curves were not extended beyond this minimum.

A full discussion of the methods used by the various investigators in determining the freezing points of the solutions will not be entered into. Some of the factors influencing the accuracy of the results will, however, be considered, especially with reference to the relative weights assigned to the data of the different observers.

Passing over the older work as not suitable for the purpose, the investigation of H. C. Jones[1] may be mentioned as the first in which special precautions were taken. He employed a mercury thermometer with a very large bulb which was graduated in thousandths of a degree and could be read to one ten-thousandth, used a large volume (one liter) of solution, stirred moderately, caused a considerable proportion of ice to separate (namely, 1.5 per cent. or that corresponding to an overcooling of 1.2°), and corrected the concentration for the change produced in it by the ice separation. He states that his thermometer readings were reproducible with an average deviation of 0.0002°, but makes no statement as to the standardization of the scale of his thermometer. The concentration was determined synthetically, apparently with sufficient accuracy. His freezing-point vessel was surrounded above and below by felt and on the sides by an air space enclosed by a zinc vessel containing ice and salt. Error doubtless arose from this difference in temperature of the surroundings, but it was probably somewhat reduced by the large volume of solution employed and the fair proportion of ice separated. The results obtained by him with several organic substances in dilute solution are much higher (14–20 per cent. higher at 0.01 normal) than the theoretical values, and indicate the presence of an error doubtless due to failure to secure the true freezing-point. This error may well have influenced his results with the salts to a considerable, though evidently to a much less extent. The weight assigned to the results is therefore unity, this being the value here assigned to data of ordinary reliability.

---

[1] *Z. physik. Chem.*, 11, 110, 523; 12, 623 (1893).

In 1894 Nernst and Abegg[1] discussed the precautions which it was essential to observe in order to obtain the true freezing point of a solution; and a few series of results were published by them and later by Abegg alone.[2] Unfortunately, while the determination of the freezing-point lowerings was unusually accurate, that of the concentration of the solution involved an error, which according to Abegg's statement amounted to 2 per cent. in some cases. The weight assigned to the results is therefore 1.

The work of Loomis,[3] begun about the same time, extended over a number of years and included a large number of compounds. In the author's papers no correction was made for the change in concentration produced by ice separating from the solution. That is shown experimentally to amount to 0.3 per cent in the first paper; and the results for the substances there given (for sodium chloride, magnesium sulphate, and sulphuric acid) have therefore been corrected accordingly. In the work described in the other papers a larger quantity of solution was used; and the probable correction, which was small in any event, was not determined. This cause would tend to make the observed lowerings slightly too large. On the other hand, the method of working, which involved strong stirring and slight undercooling, would result in too small freezing-point lowerings. The inaccuracy in the final results would depend upon these two sources of error, the latter probably being the greater. A weight of 2 or 1 has been assigned to them according to the character of the curve. His results for sodium and potassium hydroxides are so irregular that they have not been included at all.

Barnes determined the freezing-point lowerings caused by sodium and potassium chlorides[4] and hydrochloric and sulphuric acids;[5] and Archibald,[1] using a similar method, determined those of sodium and potassium sulphates. The accuracy was apparently as great as that of the best results of Loomis, and a weight of 2 has therefore been assigned to their results. The results of Hebb[2] with very dilute solutions of potassium chloride were also obtained by a similar method; but a correction was introduced for the ice separating, and the thermometer readings appear to have been more accurate. A weight of 3 has therefore been assigned to them.

Ponsot[3] obtained results for a number of compounds, by determining the temperature and concentration of a solution in equilibrium with a large proportion of ice. For potassium bromide no representative curve could be drawn and the results were not employed. For potassium chloride any curve is unsatisfactory, and for potassium sulphate too few results are given within the required range of concentration so that a weight of only one-half was assigned. For the other substances, however, (sodium chloride, sulphuric acid, barium chloride, and lead nitrate), very fair curves are obtained, and a weight of 1 was given to the results.

Raoult[4] obtained two series of results with sodium and potassium chlorides. To his results a weight of 1 in one series and of ½ in the other was assigned as the results are so few in number and so scattered as to make it difficult to draw a satisfactory curve.

The greatest accuracy in determining differences in the freezing points of water and solutions attained up to the time of their publications appears to have been secured by Hausrath[5] and Osaka,[6] who, by measuring the electromotive force at thermoelectric junctions were able to measure differences of a few hundred-thousandths of a degree. That there were difficulties in these measurements is, however, seen from the irregularity of some of the results obtained at very great dilutions. Error in the preparation and standardization of the solutions probably is part of the source of these irregularities. The results down to 0.005 normal used here are fairly regular, except for a few substances; but since the results were not obtained for concentrations greater than 0.035 normal, a satisfactory curve could not be drawn and the experimental inaccuracies are still too large to warrant assigning a higher weight than 1 or in some cases 2 to the results. Their freezing-point lowerings have all been increased in the ratio 1.858/1.85, since 1.85 was used by them as the molal lowering in the standardization.

[6] *Z. physik. Chem.*, 41, 560 (1902).

A few of the results obtained by Biltz[1] are used. He took all ordinary precautions in his measurements, but worked to a great extent with concentrations greater than those considered here.

The most reliable research of an extensive character which has been carried out on the freezing-point lowerings of aqueous solutions is apparently that of Jahn.[2] He analyzed a portion of the solution in equilibrium with a large amount of ice after having determined the temperature, and he measured the latter independently by two mercury thermometers and in some cases also by the electromotive force at thermo-electric junctions. His results when plotted give regular curves, except in the case of lithium chloride, for which the curve is somewhat uncertain. A weight of either 5 or 4 has been ordinarily assigned to them except in the series in which the mercury thermometers alone were used, where a weight of 3 was assigned.

Results for the freezing-point lowerings of very dilute solutions of apparently high degree of accuracy have recently been published by Bedford.[3] Unfortunately the complete data are not yet available, the formal lowerings given by him being taken from a curve for a number of concentrations. This makes it difficult to judge the character of the results; but in view of the care and accuracy of the experimental work, a weight of 2 has been assigned.

A few series of results for single substances of considerable accuracy have been published. T. W. Richards,[4] using substantially the same method as Jahn, gives values at four concentrations for potassium chloride. A weight of 1 is given to these; for although the method was probably as accurate as Jahn's, few results are given, and temperatures were measured to 0.001° only. P. B. Lewis[5] also measured the freezing-point lowering caused by potassium chloride, reading his thermometer to 0.001°, using a large volume of solution, and introducing corrections for the ice separating and for pressure on the thermometer bulb. His results at practically four concentrations are given a weight of ½, since the point when plotted are too few and irregular to yield a reliable curve. The data obtained by Wildermann[6] for sulphuric acid have been included with a weight of unity. Of the freezing-point results published by Noyes and Johnston[7] only those for potassium ferrocyanide have been used, since the rest give either uncertain or improbable curves.

In two cases the results obtained in two independent series of experi-

ments by different observers have been plotted and combined in one curve. This has been done with Osaka's and Hausrath's results with sodium chloride, the individual experiments of the former showing a greater irregularity than those of the latter for this substance, although the same method was used by both; owing to the difficulty of drawing a satisfactory curve, a weight of 1 is given to the combined results. It has also been done with sodium sulphate, since the curves obtained from the data of Archibald and Loomis coincide; the final results are therefore given together, a weight of 4 being assigned to them.

Several other papers have been published in recent years presenting series of determinations of freezing-point lowerings extending up to very high concentrations. Only a few of the results in any of these series fall within the limits of concentration considered here; and they have, therefore, not been taken into consideration. In general, curves based upon only three or four results have been considered when the accuracy of the work justified their use or when more complete data are lacking.

Table I contains the separate values of the formal freezing-point lowering $\Delta t/N$ obtained by the various investigators and the means and best values derived from them in the way that has been described. The headings of the columns show the number of *equivalents* per 1000 grams water. The values of the mol number *i* given at the foot of each table were calculated by equation (4) of section 1.

3. Summary of the Mol Numbers Derived from the Freezing-point Lowerings.

The values of the mol number derived from the best values of the freezing-point lowering given in Table 1 are collected in Table 2. The concentrations, expressed in equivalents per 1000 grams of solvent, are shown at the heads of the columns. In the column headed "Wt." is given the sum of the weights assigned to the separate observations for each substance. These "weights" indicate roughly the relative probable accuracy of the mol numbers derived for the various substances, especially at the concentrations between 0.02 and 0.1 equivalents per liter.

4. The Mol Number in Relation to the Type of Salt.

The salts of the uni-univalent type may be divided for convenience into the two groups represented by the general formulas MX and MXO_3. The former includes seven chlorides and bromides of the alkali elements. The mol numbers for these at any concentration show only comparatively small differences among themselves, excepting those for lithium chloride and sodium bromide at concentrations greater than 0.02. Excluding these, the mean mol numbers and their extreme values at the different concentrations are:

Concentration	0.005	0.01	0.02	0.05	0.1	0.2	0.3	0.4	0.5
Mean	1.952	1.937	1.925	1.887	1.864	1.837	1.823	1.812	1.804
Limits	1.944	1.928	1.907	1.878	1.856	1.829	1.807	1.791	1.778
	1.963	1.943	1.943	1.892	1.875	1.850	1.838	1.830	1.824

Except for the chlorides at the two lowest concentrations the values for the sodium salts are somewhat higher than those for the potassium salts. This is a general rule, as will be seen later. The values for potassium chloride and bromide agree throughout, with a maximum difference of 0.7 per cent. at the concentration 0.5; and those for cesium and ammonium chlorides agree very closely with those for potassium chloride except that the former decreases more rapidly in the more concentrated solutions. Sodium bromide shows at all the concentrations values about 1 per cent. greater than those for sodium chloride.

The mol numbers for the salts of the general formula MXO_3 are less than those for the salts of the formula MX at the same concentration with a few minor exceptions where they are practically identical. The values for the separate salts are scattered through a considerable interval, thus from 1.860 to 1.765 at 0.1 normal, so that a mean value would have little significance. The relations between the various salts are most clearly shown by arranging them in the way shown in the following table, in which the mol numbers at 0.1 normal are given:

	Cl.	ClO_3.	BrO.	IO_3.	NO_3.
Na...........	1.875	1 860	1.844	1.773	1.830
K............	1.861	1.798	1.805	1.765	1.781

It will be seen that the values for the sodium salts are always larger than those for the potassium salts; that those for the chlorates are nearly equal to those for the bromates, and that those for the nitrates are somewhat smaller, and those for the iodates much smaller, than these. It should be noted, however, that in the more dilute solutions (0.01 to 0.02 normal) the values for the iodates do not differ much from those for the other salts.

The mol numbers for potassium permanganate appear to approach more nearly those for the salts MX than those for the salts MXO_3 at the same concentrations.

The results for sodium and potassium hydroxide are probably somewhat too large; but even making some allowance for this the values appear to be greater than those for the salts MX. The latter is also true of hydrochloric and nitric acids, for which the final values are more accurate. The acid HX has furthermore greater i values than the acid HXO_3, in analogy with the salts of the types MX and MXO_3.

The unibivalent tri-ionic salts consist of the sulphates, halides, and nitrates.

The mol numbers for sodium and potassium sulphates differ from each other only to a slight extent (less than 1 per cent. throughout the total range of concentration), but those for the sodium salt are again slightly greater. The mean value is 2.465 at 0.1 normal and 2.723 at 0.02 normal.

With respect to the halides the following facts may be noted. Excluding the cadmium salts, all the values are of similar magnitude (the range being 2.57 to 2.68 at 0.1 normal and 2.71 to 2.77 at 0.02 normal), but are distinctly higher than those for potassium and sodium sulphates. The values for the cadmium halides are much less than those for the other halides, and decrease rapidly in the order chloride, bromide, iodide (namely at 0.1 normal from 2.21 to 1.96 to 1.45).

The three nitrates, of cadmium, barium, and lead, have mol numbers which differ greatly among themselves, those for lead nitrate (*e. g.*, 2.30 at 0.1 normal) being the smallest for any unibivalent salt, excepting the cadmium halides.

Bibivalent Salts.—Those investigated consist of the sulphates of five bivalent elements. The mol numbers do not differ greatly among themselves (1.46 to 1.54 at 0.02 normal); but are all much lower than those for the uni-univalent salts.

5. Change of the Mol Number with the Concentration.

The ionization of the various substances derivable from the mol number by equations (5) and (6) and the change in it with the concentration will be considered in a later article, after other properties from which it can be derived have been discussed. It is the purpose here only to show empirically the extent to which a simple cube-root formula corresponding to that which was found by Kohlrausch to express roughly the change in the equivalent conductance of certain types of salt with the concentration, will represent the change of the mol number with it. The cube-root formula of Kohlrausch $\Lambda_0 - \Lambda = K'C^{1/3}$, in which C is the concentration and K' a quantity constant for a given salt, assumes the form $1 - \gamma = KC^{1/3}$, if the conductance ratio Λ/Λ_0 be taken as a measure of the ionization γ, and if this equation be combined with (5) or (6), the following expressions result:

$$2 - i = K\,C^{1/3} \text{ for di-ionic salts} \qquad (8)$$

and

$$3 - i = 2K\,C^{1/3} \text{ for tri-ionic salts.} \qquad (9)$$

By means of these expressions the values of i have been calculated at various concentrations, assuming a value of K corresponding approximately to the observed i value at 0.05 or 0.1 normal, and comparing the so calculated values with the observed ones. For the sake of greater simplicity the mol numbers (by taking the mean) for such substances as have approximately equal mol numbers have been combined. The results are presented in Table 3 for those salts to which a total weight of 3 or more has been assigned and for which the experimental values extend over a sufficient range of concentration.

The observed and calculated values up to 0.1 normal agree almost completely in the case of the halides of the alkali elements; and they

TABLE 3—CHANGE OF THE MOL NUMBERS WITH THE CUBE-ROOT OF THE CONCENTRATION.

differences not exceeding ½ per cent. in the case of the chlorates and bromates. In the case of the iodates and the tri-ionic salts, however, the differences at concentrations up to 0.1 normal frequently reach 1 per cent., but do not much exceed this. The bibivalent salts show deviations of several per cent., so that the principle can not be said to hold even approximately for them.

Attention may also be called to the fact that (since $K = -di/dC^{1/3}$) the value of the constant K furnishes an obvious measure of the relative rates at which the mol numbers of the various substances decrease with the increasing concentration. The regularities that exist will readily be seen by an examination of the values of K given in the table.

BOSTON, June, 1910.

SILVER NITRATE FORMED BY THE ACTION OF NITRIC ACID ON SILVER SULPHIDE.

BY HIPPOLYTE GRUENER.

Received May 30, 1910.

The statements which I have found concerning the products of the action of nitric acid on silver sulphide are incomplete and contradictory. The proportions of nitrate and sulphate formed vary widely with the conditions applied. Highly concentrated acid results in complete conversion to sulphate, while with the less concentrated acid there is formed a large percentage of nitrate. Besides concentration, temperature of the acid and time of action are influential.

In the experiments summarized in Table I, the precipitated sulphide

(0.2 g.) was treated with nitric acid (usually 15 g. of the pure acid) diluted to the proper concentration. The mixture was heated, or allowed to stand at the ordinary temperature. When the action had taken place, hot water was added to dissolve the nitrate and sulphate, the solution filtered from the sulphur and unchanged sulphide, and repeatedly evaporated to dryness. The amount of silver found in the residue determined the amount of sulphide dissolved. The nitrate formed was determined by the method of Gooch and Gruener.[1] The results are shown in Table I, which indicates the proportions of sulphide dissolved, and also the percentage of nitrate formed at different concentrations, *a*, with boiling acid, and *b* with cold acid.

TABLE I.

		a Acid boiling.			*b*. Acid cold

12.	5	30 min.	96.4	88.9	7 mos.	98.8	84.4
13.	2.5	4 hours	75.0	74.8	7 mos.	89.0	75.8
14.	1.25	20 hours	86.0	60.4	7 mos.	7.3	0

The complete conversion of the sulphide to sulphate by the strongest acid used suggests the other extreme, namely, complete conversion to nitrate. But the maximum formation of nitrate is found at about 20 per cent. acid, and with greater dilution the amount of nitrate is found to diminish. The advantage of the cold acid from the standpoint of the nitrate is apparent, for the average yield when the action takes place at ordinary temperature is about 10 per cent. greater than when the acid is heated.

The time of contact of the reacting substances is important. When the sulphur liberated by the first action is promptly removed, *i. e.*, by dilution and filtration, the percentage of nitrate is conspicuously greater than when longer contact is allowed. When the time of contact is lessened to increase the amount of nitrate, there is also a diminution of the amount of sulphide dissolved. These points are shown in Table II.

Summary.

Nitric acid, when of concentration above 5 per cent., dissolves precipitated silver sulphide rapidly. Very strong acid yields silver sulphate alone, while acid of lower concentration forms some nitrate in proportion to its dilution. 20–15 per cent. acid yields the maximum, about 95 per cent. nitrate, greater dilution again resulting in a smaller percentage. Heating the acid, or prolonging its time of action is unfavorable to the formation of nitrate.

CHEMICAL LABORATORY OF ADELBERT COLLEGE,
CLEVELAND.

GRAHAMITE, A SOLID NATIVE BITUMEN.

BY CLIFFORD RICHARDSON.

Received June 24, 1910.

Grahamite is a solid native bitumen, the type of which was first found in Ritchie County, West Virginia, in the early sixties of the last century. It was named for the Messrs. Graham, who were interested in the commercial development of the deposit, by Henry Wurtz. The early literature of the subject[1] is largely devoted to the origin of the material and to its relations to coal, asphalt and albertite, as the latter occurs in Nova Scotia.[2] It is largely controversial, which is not surprising in view of the fact that there had been little opportunity up to that time of studying and differentiating the native bitumens.

In 1890 Prof. Wm. P Blake, who had been interesting himself in the solid native bitumen found in such large amounts in veins in Utah and

[2] Wetherill, *Trans. Am. Phil. Soc.*, 1852, 353.

Colorado, presented a paper[1] before the American Institute of Mining Engineers at its Washington meeting entitled "Uintaite, Albertite, Grahamite, and Asphaltum, Described and Compared with Observations on Bitumens and its Compounds," in which he stated, after reference to preceding papers, that the grahamite of West Virginia is neither albertite nor gilsonite (uintaite) but that all of these bitumens are plainly differentiated from each other by definite characteristics, although he relied on the statements of his predecessors for his characterization of grahamite. His conclusions, we shall see from the data which are to be presented, were entirely justified.

Grahamite attracted no further attention until 1899 when J. A. Taff, of the U. S. Geological Survey, published a paper[2] on "An Albertite-like Asphalt in the Choctaw Nation, Indian Territory," in which he describes a deposit of solid native bitumen occurring in the Impson Valley. Dr. Wm. C. Day, who examined it for him, concluded that it "resembled albertite more than any other asphaltic substance" though "the solubility in carbon disulphide classes the material with the asphalts rather than the coals." Dr. Day should have known that the albertite is practically insoluble in carbon disulphide and that, consequently, the material he had in hand could not be an albertite. He, like many other writers, had not had a sufficiently wide experience with the solid native bitumens to recognize their relations to each other and to identify them.

In 1901 a voluminous paper on "The Asphalt and Bituminous Rock Deposits of the United States," by George H. Eldridge, was published in Part I of the Twenty-second Annual Report of the U. S. Geological Survey. Most of the occurrences of grahamite came under his observation but, strangely enough, he failed to recognize the relations and similarity of any of them to the type grahamite of West Virginia. He went so far as to give the name "impsonite" to the grahamite found in the Impson Valley and writes of that found in Middle Park, Colorado, as asphalt. It is but fair to say that Mr. Eldridge, when his attention was called to the matter by the writer, after the appearance of his report, recognized the fact that many of the bitumens which he had described were, actually, as will be seen later, grahamites.

The confusion as regards bitumens of the three types, grahamite, albertite and gilsonite and also, to a limited extent, manjak continued.

In 1909 there appeared a Bulletin No. 380 of the U. S. Geological Survey "Contributions to Economic Geology" in which, under the heading "Asphalt" two papers appear, one, "An Occurrence of Asphaltite in Northeastern Nevada," by Robert Anderson, and another, "Grahamite Deposits of Southeastern Oklahoma," by Joseph A. Taff. Anderson undoubtedly uses the term asphaltite in the sense proposed by Eldridge in the classification of the native hydrocarbons and allied substances which he gives in his "Report," where he includes under asphaltites, albertite, impsonite, grahamite, nigrite and uintaite (gilsonite) although not distinguishing them from the true asphalts which do not appear in his table in any form. Anderson, no doubt, intends to convey the idea that the Nevada bitumen is not an asphalt. He says: "The asphaltite found here would be commercially known as 'grahamite' but its characteristics show it to differ from the variety so known scientifically. A few tests revealed a close relationship to the variety from Indian Territory described by G. H. Eldridge as impsonite." Anderson shows, therefore, that he is not aware that impsonite is grahamite. Taff's description of the solid bitumens of Oklahoma in the pages immediately following Anderson's paper shows that he is in accord with the ideas advanced by the writer some years ago[1] that many, if not all of the solid bitumens of Oklahoma are grahamites, taking that from West Virginia as a type.

[2] *Am. J. Sci.*, [4] 8, 22

The confusion which has existed for many years as to what grahamite is becomes apparent from the preceding statement. It has arisen largely because no individual investigator has had in hand for comparison at one time, all of the very numerous deposits of solid native bitumen which are so widely distributed, particularly in North America and in the islands of the West Indies. Within the last fifteen years the writer has been so fortunate as to have referred to him specimens of nearly all the well-known occurrences of solid bitumen and of those which have been discovered during that period and was particularly fortunate in obtaining a large specimen of the original grahamite taken early in the seventies from the deposit in West Virginia, to which the name was originally applied and which must be regarded as the type. For this he is indebted to Prof. Charles F. Chandler, of Columbia University, whose identification of the material is, of course, authoritative.

In addition, specimens of this same bitumen, obtained when the vein was again worked for a short time in 1904–5 were available. The solid native bitumens which have been examined and which have the characteristics of grahamite are identified as to locality in the following list. Wherever possible reference is made to description of the deposits by geologists and others.

List of Occurrences of Grahamite.

WEST VIRGINIA.

No. 19,399 The type of material from Ritchie County, 25 miles a little north of east from Parkersburg, on McFarlan's Run near the South fork of Hughes River, taken from the vein at the time the mine was originally worked between 1868 and 1875. From the cabinet of Prof. C. F. Chandler.

TRINIDAD, B. S. I.

No. 61,726–8 From Vistabella mine, near San Fernando, Trinidad, B. W. I., put on the market as "manjak," specimens of 1902.

No. 80,659 Same—Specimen of 1905.

METAMORPHOSED GRAHAMITES.

No. 69,235 Unknown locality, Oklahoma.

No. 69,482 From the Choctaw Mining and Development Company.

No. 69,242 Black Fork Mountain, Oklahoma.

Two samples.

(*a*) Near top of outcrop.

(*b*) Entry running in on vein from side of hill at a point probably 15 ft. below surface.

It will be seen from the number of occurrences mentioned in the preceding list that, if we are justified in considering them all as the same material, that is to say, as native bitumens corresponding to the type originally found in West Virginia, grahamite is very widely distributed.

The results of the examination of the specimens which have been studied are given in Table I.

In considering the data given some consideration must first be given to the subject of native bitumens in general and especially to the solid native bitumens from which grahamite is to be differentiated.

The native bitumens consist of a mixture of native hydrocarbons and small amounts of their nitrogen, sulphur and, in some cases oxygen derivatives, the character of any bitumen being dependent on that of the different series of hydrocarbons of which it is composed and their state of aggregation. Natural gas, petroleum in its various forms, maltha, asphalt, gilsonite, ozokerite and grahamite are bitumens, the four last being solids. They are all characterized by being soluble in carbon disulphide, but are differentiated by their physical and chemical characteristics. They all originate in petroleum and are products of metamorphosis, depending for their character on that of the petroleum from which they are derived and the environment to which this has been exposed during the last periods of time during which the changes have been going on. Petroleums are known to be of various types and include the paraffin oils of the Eastern states, which contain but a small amount of sulphur derivatives, the more sulphurous oils of the Ohio and Canadian type, which are largely made up of the paraffin series of hydrocarbons, the semi-asphaltic oils of Illinois, Texas and the mid-continental fields, varying in character as they are more or less asphaltic in nature, and the asphaltic oils of California, Mexico and the West Indies, which are practically free from paraffin hydrocarbons. As yet no petroleum of the Russian type has been found in the western hemisphere.

Solid bitumens are, apparently, formed from all of these types of petroleum. Ozokerite consists of solid paraffins and is plainly derived from paraffin petroleum. The type grahamite of West Virginia is found where paraffin petroleums alone are available as its source. That occurring in Middle Park, Colorado, must have had its origin in petroleum of the type found in that State at Florence, which is a paraffin oil. The grahamite of Oklahoma must have been derived from oil of the type of the mid-continental field which contains a large amount of paraffin hydrocarbons, although it is also asphaltic. All of the grahamites of the United States originate, therefore, in petroleums which are more or less of a paraffin nature. The contrary is the case with the grahamite of Trinidad, where the petroleum is purely asphaltic, as far as we know it to-day, but in appearance it can hardly be differentiated from that of the West Virginia deposit. The Cuban grahamites must, likewise, originate in asphaltic oils. These facts may prove of some value in differentiating the grahamites which have been examined.

From the non-paraffin oils are formed the asphalts, gilsonite, manjak and glance pitch, all of which have physical properties and chemical characteristics which differentiate them from one another and from grahamite. Before attempting to characterize grahamite, therefore, and to differentiate it from asphalt and the other solid bitumens something must be known in regard to these latter bitumens. Some data in regard to them are presented in Table II for comparison with which similar data in regard to the type grahamite from West Virginia are presented.

The native bitumens, it will be observed, are soluble in carbon disulphide. This is an essential characteristic. If the material is not soluble and, nevertheless, has been derived from petroleum it is regarded as a

pyrobitumen. Such a material is represented in the table by albertite. This may be regarded as a bitumen in which the metamorphosis, beginning in petroleum and extending through maltha, asphalt and grahamite, has terminated in a material which is no longer soluble. On this ground grahamite is an intermediate material between asphalt and albertite. The extent of the metamorphism may be measured, it will be observed, by a comparison of the relative solubility of the bitumens in light petroleum distillates, and in the heavy petroleum residuals, known as fluxes, by the amount of residual coke which they yield on ignition and to a certain extent by their density and melting points. For this purpose data in regard to bitumens of the series extending from petroleums which are mobile liquids to grahamite and albertite are here presented.

				Solubility in			
						heavy residuals

Albertite	1.08	intum	29.8	6.0	1.5	insol	insol.

The preceding data present a fairly regular rate of metamorphism from petroleum to grahamite and illustrate very well the relation of grahamite to the other native bitumens, as well as the justification for its differentiation from asphalt and gilsonite. Grahamite does not melt. Asphalt, gilsonite and glance pitch become liquid on the application of heat. Grahamite is but slightly soluble in naphtha, whereas the other solid bitumens contain a considerable percentage which is soluble, corresponding in amount to the degree to which they have been metamorphosed. The grahamites yield a higher percentage of residual coke, this too corresponding to the extent of the metamorphism. The density of this form of bitumen is greater than that of the bitumens which melt readily.

Grahamite in its outward physical appearance is as a rule, and where it is not associated with mineral matter, characterized by a peculiar structure and fracture, which is found in no other form of solid native bitumen. While the material is homogenous or uniform as far as composition is concerned for any one specimen, the fracture is not conchoidal or that of a homogeneous solid such as gilsonite, glance pitch, manjak or the pure asphalts. On the contrary it presents a surface which shows that the bitumen has been subjected to pressure and to motion from movement of the vein walls which it is too brittle to resist. The result has been a fine fracture carried entirely through the mass, which results in a surface, when grahamite is broken, which is more or less schistose in structure. It has been described as hackly and also termed pencillate. It is found in all the grahamites occurring in the United States, in that from Trinidad and in the pure bitumens from Cuba. The deposit at Huasteca, Mexico, has a lustrous fracture like that of glance pitch while in some of the grahamites of Cuba the fracture is masked by the high percentage of mineral matter which is present.

In powder, grahamite, like asphalt and glance pitch, is black and it gives a black streak. This differentiates it sharply from gilsonite, which yields a light brown powder.

It does not melt readily, as has been said, and this alone differentiates it from all the other bitumens and justifies us in putting all the grahamites in a class by themselves. It intumesces and swells up at high temperatures with the evolution of gas, but softens to some extent so that it can be in part drawn out into threads. In this respect it resembles the pyro-bitumen albertite, although it differs entirely from it by its solubility in carbon disulphide.

In their ultimate composition the grahamites show some interesting differences from the other solid bitumens and among themselves, which are of importance and without which any consideration of this form of bitumen would be incomplete.

An ultimate analysis by combustion of the grahamite from West Virginia shows that it consists of

C, 86.56; H, 8.68; S, 1.79; undetermined, 2.97,

the preceding figures being calculated on a basis of bitumen free from mineral matter. For comparison with these figures data in regard to the ultimate composition of three well-known asphalts will serve.

	Pure bitumens. Trinidad.	Pure bitumens. Bermudez.	Waldorf, Cal.
Carbon	82.33	82.88	82.77
Hydrogen	10.69	10.79	10.62
Sulphur	6.16	5.87	6.47
Nitrogen	0.82	0.75	0.35
	100.00	100.29	100.21

The West Virginia grahamite differs from asphalt by containing a much smaller amount of sulphur derivatives, more carbon and less hydrogen. The relation of carbon to hydrogen, considering sulphur as an equivalent to two atoms of hydrogen, is as follows:

	Grahamite.	Asphalt.
Carbon	90.9	88.5
Hydrogen	9 1	11.5
	100.0	100.0

This relation and the presence of the larger amount of carbon may be regarded as explaining, to a certain extent, the differences between the two forms of bitumen as well as the larger yield of residual coke from grahamite and the fact that it does not melt readily.

Having shown the characteristics of the type grahamite, the next step is the differentiation of the various other deposits on the basis of their behavior with certain solvents, their purity or admixture with mineral matter and their ultimate composition; this with a view of determining whether they may all be properly included under the one designation "grahamite," whether they should be separated into classes, or whether specific names should be applied to some of the bitumens as has been done by some writers who were not familiar enough with the native solid bitumens to recognize grahamite when it was met in a new locality. Of course, in so doing, the material from West Virginia which was described in the early sixties of the last century must serve as the type.

This, it appears, contains 86.6 per cent. of carbon and 1.8 per cent. of sulphur. Some of the other grahamites have a similar ultimate composition, notably those from Middle Park, Colorado, and various localities in Oklahoma. The carbon in these occurrences lies within the extremes, 86.6 and 83.9, the latter figure for the Impson Valley material which was called impsonite by Eldridge. This approaches the amount found in asphalt and is smaller by 2.7 per cent. than the carbon in the type grahamite.

It is questionable whether this is sufficient to authorize a specific name, especially in view of the fact that the two materials in other respects are so strikingly alike, in their fracture and general appearance, in not melting and in their insolubility in light naphtha and dense paraffin residuums. From the writer's point of view the West Virginia, Colorado and Oklahoma bitumens may safely be recognized as all being grahamites.

So closely allied to these three occurrences that it cannot be distinguished from them in external appearance is the grahamite of Trinidad. It has the same hackly fracture as the type material, does not melt or flux smoothly with the paraffin oils, yields from 31 to 40 per cent. of residual coke and is readily recognized by the trained eye as a grahamite. It differs from the bitumen of this type as found in the United States only by the presence of nitrogen to the extent of over 2 per cent., in which it is unique, a higher percentage of sulphur, 3.83 as compared to 1.79, and its considerably greater solubility in light naphtha, 13.0–15.0 per cent. as compared with fractions of a per cent. in the Colorado and Oklahoma material and 1.4 to 9.4 in the original grahamite from West Virginia, the higher figure in the latter case being for the product of the operations in the sixties and the latter for material taken out in recent years. Further, the two materials differ in a marked degree in ultimate composition, as far as the percentages of carbon and hydrogen are concerned, the Trinidad grahamite containing but five per cent. of hydrogen whereas the West Virginia carries nine, and only 84 per cent. of carbon as compared with 86.5.

	West Va.	Trinidad.
Carbon	86.56	83.95
Hydrogen	8.68	5.66
Sulphur	1.79	3.83
Nitrogen	...	2.24
Difference	2.97	4.32

It may be held that the Trinidad bitumen differs sufficiently from the type grahamite to make it a distinct form, but the difference can be readily explained by the different character of the two petroleums from which the two deposits have been derived, the West Virginia grahamite originating in a paraffin oil and that from Trinidad in an asphaltic one. It is possible that grahamite must be considered as a class of bitumens, rather than a species, or genus, and this will be further confirmed as the characteristics of the other individual deposits are examined. There seems to be no reason, however, why the Trinidad bitumen should not be regarded as a grahamite. It is certainly not a manjak, although it has been put upon the market as such; a manjak being a bitumen which has a smooth fracture like glance pitch and melting readily. The comparatively high percentage of residual coke which manjak yields does, however, show that it is a material which, in its metamorphism, is somewhat related to grahamite. In this connection it is worthy of note that in Barbadoes, where alone manjak occurs, a continuous series of bitumens is found ranging from maltha to one of the hardest consistency.

If we look further into the ultimate composition of the remaining grahamites which have been examined, it is seen that they all contain more sulphur than those which we have had under consideration, from 5.4 to 8.7 per cent. as compared with 0.93 to 3.83 per cent. It is possible, therefore, to divide the grahamites into two classes, those containing less than four per cent. and those having more than five per cent. of sulphur. The presence of sulphur may be attributed in part to sulphur derivatives of hydrocarbons existing in the original oils from which the grahamites are derived, but we know of no petroleums which contain a sufficient amount of such components to account for the high percentage of sulphur found in the second class of grahamites. The assumption that this might be accounted for by concentration due to evaporation during the long period during which the metamorphosis has gone on will not serve, since this change has taken place, if we may judge from the location of the deposits, under conditions where volatilization could not occur, so that it must be adventitious in most, if not in all cases. The bitumen of Trinidad asphalt, however, contains 6.5 per cent. of sulphur and this may be considered as the source of grahamite of that island and of that of the sulphur which it carries, as the two bitumens are found not far apart. The bitumen of the asphalt, on the other hand, is associated with an asphaltic petroleum, issuing from wells sunk immediately adjoining the deposit, which contains only about 1.5 per cent. of sulphur. It is difficult, therefore, to say definitely what the source of the sulphur in grahamite is, but it must be in certain cases adventitious, as the bitumen found at the Le Grand deposit in Oklahoma contains quite large and well defined crystals of pyrite, visible to the naked eye, which have been deposited by infiltration through the fractures of the material.

In Cuba deposits of bitumen are found which carry a very considerable amount of adventitious earthy matter, resembling in this respect Trinidad asphalt, but the characteristics of the bitumens are such that they may be considered as grahamites, since these yield a high percentage of residual coke, over 30 per cent., and have a high density, although they are, like the Trinidad grahamite, more soluble in light naphtha than the type grahamite and, possibly, should be classed by themselves on this account, and because of their peculiar ultimate composition, as they contain, in addition to a high percentage of sulphur, much organic matter the nature of which is not revealed in the ordinary methods of combustion and which may be oxygen.

Very pure grahamites are also found in Cuba at Bahia Hondo and Campo Florida, equalling in this respect those from West Virginia, Colorado and Oklahoma, and differing from them only in their higher percentage of sulphur and greater solubility in light naphtha. The Bahia Honda bitumen resembles in outward appearance the type grahamite, having the schistose or hackly fracture.

The grahamite from Huasteca, Mexico, described by Kimball[1] is a unique one in that it resembles gilsonite in its high lustre and fracture and in that it melts. It is quite insoluble in light naphtha, however, yields a high residual coke and corresponds in ultimate composition with grahamite. Kimball seems, therefore, to have been justified in classing it as such.

In this connection it is not out of place to call attention to the resemblance of grahamite to that portion of the bitumen of the asphalts which is soluble in carbon disulphide but insoluble in light naphtha and which has been defined as a class as "asphaltenes" by the writer in distinction from the more soluble form which has been termed "malthenes" from their resemblance to natural maltha. The asphaltenes, like grahamite, do not melt, are not soluble in light naphtha, yield a high residual coke and have a similar ultimate composition, as can be seen from the following data:

---

[1] *Am. J. Sci.*, [3] 12, 277 (1876).

	Trinidad asphalt Asphaltenes.	Grahamite Bahia Honda.	Bermudez asphalt Asphaltenes	West Va. Grahamite
Specific gravity	1.121	1.157	1.110	1.130
Residual coke	32.00	40.00	37.00	36.80
Carbon	82.01	81.94	87.19	86.56
Hydrogen	7.82	7.45	8.47	8.68
Sulphur	10.86	7.65	4.83	1.79
Difference	...	2.96	..	2.97
	100.69	100.00	100.49	100.00

The agreement in the ultimate composition, specific gravity and yield of residual coke between the asphaltenes in the asphalts and the grahamites which contain larger and smaller amounts of sulphur is striking, and is evidence of the gradual metamorphosis of petroleum into grahamite.

In the table of analyses of grahamites data are given of several materials from Oklahoma under the heading "metamorphosed or altered grahamites." These are distinguished by their smaller solubility in carbon disulphide than that of the grahamites. They illustrate the intermediate stages between that bitumen and the pyrobitumens such as albertite and the transition of one form into the other, although it has not been positively shown that the type albertite, from Nova Scotia, is derived from petroleum, as are the solid native bitumens which have been described in this paper. There is a great probability that it is a type of coal.

The behavior of the grahamites with other solvents than those which have been mentioned is also of interest. Oil of turpentine and carbon tetrachloride do not have the same solvent power with all of them. In studying the solvent power of the former on various bitumens it was found that it dissolved when cold but 0.8 per cent. of the bitumen in the grahamite from the Impson Valley, 4.8 in that from West Virginia, and in all the others but little, as on standing in contact with them for twelve hours it was practically uncolored. With gradual rise in temperature the action was not increased and no solution takes place until the boiling point of the turpentine is nearly reached, when at a definite point the bitumen dissolves. On cooling the bitumen separates out. The amount dissolved at high temperatures varies, as can be seen in the following table:

SOLUBILITY OF GRAHAMITES IN HOT OIL OF TURPENTINE.

		Solubility in		Per cent. of total bitumen sol. in turp
		hot turpentine	carbon disulphide.	
35,901	Bahia Honda, Cuba	99.3	99.6	99.7
75,637	West Virginia	96.9	97.8	99.1
21,416	Mercedes Mine, Cuba	46.3	49.6	93.3
22,216	Bahia Honda, Cuba	89.6	99.4	90.1
21,657	Magdalena Mine, Cuba	51.2	58.0	88.2
44,626	Magdalena Mine, Cuba	47.2	54.8	86.1
55,195	Santa Clara, Cuba	66.4	77.8	85.3
25,131	Santa Clara, Cuba	66.0	79.1	83.4
52,000	Magdalena Mine, Cuba	47.8	58.2	82.1
21,415	Magdalena Mine, Cuba	51.6	58.1	81.9
47,615	Santa Clara, Cuba	58.4	77.4	75.4
	Impson Valley, Okla	48.9	91.8	53.2
	High	.	..	99.7
	Low	..	..	53.2
	Asphalt, Bermudez	94.9	95.6	99.2
	Gilsonite	99.7	99.8	99.9

On the ground of their relative solubility in turpentine the Impson Valley bitumen is differentiated from the West Virginia and the Cuban grahamites and all of them are more or less variable in this respect. This peculiarity should be further studied, including the bitumens from Colorado and Trinidad. In the case of the asphalts, it will be noticed, the bitumen is equally soluble in turpentine and in carbon disulphide, the lack of solubility in some of the grahamites undoubtedly being produced by changes due to environment and age.

It has been shown by the writer[1] that bitumens can be differentiated by the degree to which they are soluble in carbon tetrachloride, those showing the least solubility being the most metamorphosed by overheating, as in the preparation of residual pitches from asphaltic oils by distillation, or by age. The grahamites show decided differences in this direction. The proportion of bitumen in the several deposits examined varies, showing different degrees of alteration. The Colorado grahamite contains the largest amount of bitumen of this kind, over 80 per cent., the Oklahoma 58 and the Trinidad 39 per cent., while the Cuban deposits, with the exception of that at Bahia Honda, have but small amounts. This class of the components of bitumen has been called "carbenes" by the writer. A further study of this characteristic of the grahamites would prove of interest.

An interesting fact in connection with the mineral matter which is found in grahamite, and to which attention has been called by Messrs. Foster Hewitt and W. F. Hillebrand, is that, like the same component of some other bitumens, it contains vanadium, especially the ash of that from the Impson Valley, which contains from 11 to 15 per cent. of V_2O_5. The West Virginia grahamite contains 3.38 per cent., while Trinidad asphalt has 0.089, manjak a small amount and albertite a trace, according to determinations furnished by Dr. Hillebrand.

---

[1] *J. Soc. Chem. Ind.*, 24, 310 (1905).

From the facts and data given in the preceding pages grahamite can be characterized as a class of bitumens and further differentiated into sub-classes.

Grahamite may be defined as a brittle, solid native bitumen, the result of the metamorphosis of petroleum, generally pure but at times associated with adventitious mineral matter, characterized, when pure, by a peculiar schistose fracture, which has been termed hackly. It does not melt, but merely intumesces, on the application of heat, is soluble in carbon disulphide and only to a small extent in light naphtha and yields a high percentage of residual coke on ignition out of contact with air.

Various deposits of grahamite vary sufficiently to make it possible to divide them into several sub-classes:

1. Pure bitumens, 90 per cent. or more soluble in carbon disulphide.
2. Bitumens associated with adventitious mineral matter.

They may be subdivided again on a basis of solubility in naphtha, that is to say, the amount of malthenes which they contain, into:

3. Bitumens but a small proportion of which is soluble in light naphtha.
4. Bitumens of which a considerable part is soluble in naphtha, more than 15 per cent.

And still further, as regards the percentage of sulphur derivatives of the hydrocarbon which are present:

5. Bitumens with less than 5 per cent. of sulphur.
6. Bitumens with more than 5 per cent. of sulphur.

Individual grahamites can belong to more than one of these classes, but to only one in any group.

It is evident that the form of bitumen which we have had under examination is sharply differentiated from coal, asphalt and albertite and that there is no reason for confusing these minerals, as was done by the early writers. Whether there is any justification for further differentiating the grahamites and assigning names to special deposits, such as impsonite for the grahamite from Oklahoma, is a matter of opinion. From the writer's point of view this is, at present, hardly necessary. Particular grahamites have individual characteristics, but as a whole they are sufficiently alike to justify the application of the name to one class of bitumens, those which have been described in this paper, of which the original grahamite from West Virginia may be regarded as the type.

Eldridge, in his "Asphalt and Bituminous Rock Deposits of the United

States,"[1] classifies the solid native bitumens, excluding the melaterite and wurtzelite for some remarkable reason and giving no place whatever to asphalt, as asphaltite and coal, the former including albertite, impsonite, grahamite, nigrite and uintaite (gilsonite). Hofer has recently proposed to the writer that the solid native bitumens which are not asphalt shall be so denominated. It seems, however, that all these materials are so entirely different in character that we are hardly justified in putting them in one class, except for the fact that they are not asphalt, and the proposition does not, at present, commend itself.

In conclusion, the writer must acknowledge his indebtedness to the several assistants who have engaged in the investigation of the various grahamites and especially Mr. Kenneth Gerard Mackenzie, and Mr. J. S. Miller, Jr., for the study of the action of turpentine and tetrachloride of carbon on this bitumen. Prof. Jamieson and Mr. Ralph Langhy, of New Haven, have contributed ultimate analyses of several of the specimens, and have determined the presence of nitrogen, by the absolute method, in the Trinidad grahamite, Mr. Mackenzie has also aided in assembling the data and examining the cross references.

30 CHURCH ST., NEW YORK CITY

PROGRESS IN SYSTEMATIC QUALITATIVE ORGANIC ANALYSIS.[2]

BY S. P. MULLIKEN.

Received June 29, 1910

A general procedure in organic qualitative analysis that may be trusted to lead to the discovery of the proximate composition of any unknown organic substance whatever, whether this be a simple compound or a mixture, is demonstrably incapable of practical realization. Before proceeding to the discussion of the main subject of this paper, it therefore behooves us to pause for a moment to note certain limits which Nature seems to have set against the too curious advances of the analyst.

The most clearly insuperable of these limitations are associated with high molecular weight. If a paraffin hydrocarbon of the formula $C_{35}H_{72}$ were to be isolated in a state of perfect purity and in large quantity from some natural product, it would be impossible to absolutely identify it as a compound corresponding to any particular structural formula by any combination of methods of investigation now known, or whose future discovery appears probable. Such a hydrocarbon would not differ by one one-hundredth of one per cent. in its hydrogen or its carbon content from its adjoining homologues, while in chemical and physical properties there would be no measurable differences between it and thousands of its four million undiscovered structural isomers, which, according to the calculations of Cayley, are theoretically possible. Indeed, in the case of the discovery of such a high hydrocarbon by any process other than one of simple synthesis, no proof could be contrived which would show that the substance might not well be a mixture of many isomers and neighboring homologues; for all finite methods of purification by fractional separation based on differences in properties must inevitably fail when the numerical odds against them are so great, and we have no choice in such a case but to resign ourselves with the best grace possible to an inevitably partial solution of our problem.

---

[1] 22nd Annual Report U. S. Geological Survey, Part I, 209–452.

[2] An address delivered at the Second Decennial Celebration of Clark University, Worcester, Mass., Sept. 16, 1909.

But without having ascended to such an altitude in the homologous scale as in the instance just cited, it is often necessary or expedient to accept incomplete answers in qualitative inquiries because of our thralldom to the rule that unknown compounds in mixtures cannot in general be fully identified without previous isolation in a state of purity. It is for this reason that it is so common a practice in technical analysis to express the quantitative composition of familiar and important products in conventional or collective terms. Long and thoroughly as the animal fats have been studied, for example, there is probably no instance on record of a quantitative examination of any natural fat in which it could be safely claimed that the structural identity of all its fatty acids containing less than eighteen carbon atoms had been irrefutably established. Nor would it be surprising under the circumstances if such a result were never accomplished.

Thus handicapped, systematic qualitative organic analysis has developed slowly when compared with the simpler qualitative analysis of the inorganic elements and salts. Yet, if we contrast the difficulties to be overcome in constructing an orderly scheme for the separation and identification of the list of less than one hundred elements with the difficulties to be met in any corresponding scheme for the organic compounds, and then recall what has already been accomplished in overcoming them, and also the imperfections which present-day inorganic qualitative schemes still exhibit when the rarer elements are included, the organic chemist will find little cause for pessimism. The greater part of the contributions to organic qualitative analysis have been made, however, without much thought of the part which they might be made to play in any comprehensive scheme of procedure, and have often owed their origin to incidental observations made during the execution of investigations of broader scope and different purpose. Fischer's numerous characterizations of compounds in the sugar, purine and protein groups, by well chosen reactions and derivatives, and his ingenious separations for the amino acids formed in proteolysis are illustrations of this fact. Among the rather numerous handbooks of organic analysis, although many devote much space to qualitative testing, the speaker recalls only one whose author (Barfoed, 1878) has been sufficiently venturesome to incorporate the phrase "Organic Qualitative Analysis" in its title. Of the many commendable partial schemes for the isolation and identification, or the detection in certain classes of mixtures, of carbon compounds belonging to restricted groups, we owe the origin of a large proportion to an acute need of special analytical assistance in some department of industry, research, or governmental control. To such cause we owe much of what is most valuable in "Allen's Commercial Organic Analysis," Posts's "Chemisch-technische Analyse," and the works of Vortmann, Dragendorff, Hoppe-Seyler, König, Leach, Sherman, and others. The investigation of methods for the detection and determination of constituent radicals has also proved a fruitful source of valuable material, much of which has been made accessible for ready reference in H. Meyer's "Analyse und Konstitutionermittelung organischer Verbindungen."

The resolution of mixtures is usually the first, and often the most difficult part of a qualitative analysis. Definite plans for correlation in a broad general procedure of the methods of separation that have proved effective in the study of restricted classes of mixtures have yet to be proposed. The speaker is not in accord with the rather prevalent view that it is useless to strive for broader and more systematic separation procedures. But, on the other hand, as he is unprepared to play the prophet's rôle, it may be more profitable for him to confine the following discussion to the topic of systematic procedures for the identification of pure compounds, this being an important division of the qualitative problem whose solution seems nearer accomplishment.

Prior to 1831, the date of the inauguration of those revolutionary improvements in organic combustion methods by Liebig, which rendered it possible to determine the percentage composition of any carbon compound with considerable accuracy and comparative convenience, it does not appear that any comprehensive systematic methods for identifying previously described organic compounds had been formulated, or that the lack of them had been felt as a serious inconvenience. The number of pure compounds that had been described was comparatively small, the possibility of laboratory syntheses for organic compounds having only just become recognized, and the descriptions of such compounds as were known were not scattered as to-day through an almost endless list of special journals and treatises. A chemist of this earlier period, if a man of extended practical experience, well read, and having access to a good library, rested more or less content in the knowledge that he could probably accomplish by a purely eclectic procedure based on his miscellaneous sources of information, ingenuity, and common sense, all that was then analytically possible.

Thanks to Liebig's writings and the influence of the students who passed from his Giessen laboratory, his simplified methods of ultimate analysis were not long in becoming widely known. In scientific laboratories they were everywhere welcomed and adopted. This welcome was richly deserved; for, besides serving as a means to determine percentage composition values—which will perhaps always remain the most fundamental of chemical constants—their use, in connection with the later widely adopted vapor density molecular weight determination methods, furnished all information required for the calculation of empirical formulas. These, if we add knowledge of genetic relations and chemical behavior, become structural formulas with all the added information as to chemical characteristics and individuality which are inherent in the latter. The vapor density molecular weight determination methods reached their climax for the organic chemist in the air displacement form proposed by Victor Meyer in 1878. The prestige of the empirical formula as an aid in compound identification was soon still further enhanced by the discovery of Raoult's principle, followed by the invention of the Beckmann thermometer in 1888, these aids to molecular weight determination finally enabling the inclusion among the compounds of directly determined empirical formulas of a large share of the non-volatile compounds. Other causes about to be mentioned also conspired to bring the analytical importance of the empirical formula to extreme prominence.

During the two decades closing in 1880, the unprecedented increase in newly described organic compounds had already begun to assume the dimensions of a threatening deluge. The synthesist responsible for the creation of a new species, being aware of its genetic relations, and having determined its empirical formula, was usually in a position to correctly interpret the chemical identity of his progeny; though to prove that his discovery was really an original one by a search through the swollen literature had become a task to be undertaken with fear and trembling. The time rapidly approached when the healthy future development of organic research seemed likely to receive a serious check from the confusion and discouragement in store for investigators who could only hope to escape plagiarism in recounting their alleged discoveries by well-nigh interminable bibliographical delvings. Those of us in the younger generation of organic chemists are not in a position to even faintly appreciate the sigh of relief that must have been breathed by hundreds of workers in many lands when these chaotic conditions were ameliorated in 1882 by the completion of the first edition of Friedrick Beilstein's great handbook of organic chemistry. With rare foresight Beilstein had in season anticipated the mission which this remarkable work had to fulfil, and its publication after twenty years of incessant labor, occurring as it did at this critical period in the development of organic chemistry, is of epoch-making importance to organic qualitative analysis as well as to all other departments of the science.

Beilstein's "Handbuch" was a digest of the complete literature of the modes of formations, properties and reactions of all the analyzed compounds of carbon. It did not purport to be an analytical guide, and in its introduction the possibility of a qualitative organic analysis at all comparable to the inorganic is categorically denied. Nevertheless, because of the completeness and orderly arrangement of its concise descriptions, its importance as an aid in the identification of organic compounds may be fairly estimated as greater than that of all the special analytical treatises which have ever been issued. Its general classification for the compounds has some times been criticized as clumsy and confusing, but the division of species according to chemical function, saturation, and in homologous series, has, on the whole, served the interests of the analyst well; and the invention of a simple device for locating in its pages the description of any desired compound of known empirical formula, which has been more recently made available through the ingenuity and coöperation of M. M. Richter, the manager of the Prinz Dye Works in Carlsruhe, has now long served in case of compounds of this class to greatly facilitate their identification.

Richter's "Tabellen der Kohlenstoff-Verbindungen" with its 20,000 brief references to the literature and properties of the analyzed organic compounds was issued in 1884. The first volume of the second edition appeared in 1900 under the altered title of "Lexikon der Kohlenstoff-Verbindungen." In its present completed form this edition registers more than one hundred thousand compounds of determined empirical formulas, and gives direct access to the full description and literature of each by citation of the proper volume and page number of Beilstein. As a bibliographical index for compounds of known empirical formula it is hard to imagine anything simpler or more complete than the Richterian classification. The exact position of every possible compound (if we exclude the arrangement of isomers with reference to one another) is automatically fixed by its formula alone, and is as easily found, and in much the same manner, as a word in a dictionary through a knowledge of the relative positions of its letters in the alphabet. The completeness of the tabulation is suggestively indicated by the author's remark that his guiding thought during its preparation was "Das Unwesentliche, d. h. die weniger bekannten Verbindungen, stets in erster Linie und vollstandig hervorzuheben." On the other hand, its use as the basis for a method of identification for unknown organic compounds is often attended with serious or prohibitive difficulties.

It has been already pointed out that an absolute determination of species among the carbon compounds is theoretically impossible by any combination of tests in the case of compounds of extremely high molecular weight, and that the unavoidable errors of ultimate organic analysis with such substances are large enough to prevent analysts from making any selection between a large number of seemingly possible and equally probable empirical formulas. This unfortunate circumstance prohibits the use of the Richterian system in large and important fields where quantitative investigation by other methods may be conducted with good prospect of success. For example, the dyestuff tables of Schultz and Julius describe a hundred distinct tetra-azo dyestuffs having molecular weights above 500, and some of them exceeding 1000. These colors are many of them important, their constitutions well established by synthesis, and their identification through their physical and chemical properties, or at least their approximate identification--which is often all that is required—is not especially troublesome. The absurdity of an attempt to identify an unknown color of this class through its empirical formula—which would usually involve the quantitative determination of at least six elements with an impossible degree of precision—is so patent from the mere mention of the stoichiometric conditions that it may be hoped it has never been made by any rational being.

A second defect in the method of the empirical formula, which in the ordinary laboratory curtails its actual application even more than the absolute limitation just mentioned, is the fact that much special manipulation, skill and apparatus are necessary to ensure trustworthy results in elementary organic analysis, and that so much time is always consumed in the preliminary arrangements for a combustion and in its conduct. In the larger organic laboratories where the combustion of new synthetic products is an almost daily incident of the routine of investigation, and the equipment of the combustion room is maintained at all times in a state of perfect preparedness for emergency calls, so that no time need ever be lost in the mobilization for an analysis, the organic combustion is not formidable to the initiated. But under other circumstances—and they are the prevalent ones—chemists do not resort to the method of the empirical formula except under rather strong compulsion, and many identifications which ought to be made are not even attempted.

In view of these defects and inconveniences, it is natural to inquire whether there is hope of securing in the future any scientific substitute for the method of the empirical formula. In the comprehensiveness and simplicity of its classification of compounds, it must be admitted that it will be vain to expect anything but loss from radical changes in the Richterian arrangement; but, if we accept the logician's definition of a scientific classification as "Nothing more than a system of division carried out in such a way as to best serve a given purpose," and if our purpose is convenience and effectiveness in general qualitative investigation, the possibility of other and more scientific classifications is not to be denied; and it has seemed to the speaker that the discovery of such methods of classification is at present one of the important and attractive fields for organic chemical research. What the final outcome of this quest will be—if we have the right to speak of a final outcome in a problem which from its nature permits of only progressive partial solution—no one can as yet speak with full authority. Some of the general considerations bearing on the subject may, however, be brought to your attention.

Scientific classifications are chiefly concerned with relations of resemblance and contrast. To answer the question what points of resemblance and contrast must be regarded, and in what order, if we are to make a classification scientific, is to say that no basis of classification ("*fundamentum divisionsis*") is *per se* better than any other. All depends on the ultimate object. If the object of a classification is ready diagnosis of natural objects, it is evident that the characteristics used as *differentiae* for distinguishing between groups should permit of easy as well as certain determination; and it is also a good quality in such a division to collect individuals in the lowest group for comparison which are on the whole most alike. Methods of subdivision which aim at discovering something without regard to whether the resemblances of adjacent species are fundamental or accidental, like the classification of words in a dictionary according to the accidental alphabetical sequence of their letters, are called artificial systems. The Linnæan and Richterean systems belong to this category. No comprehensive system of division in natural science is free from many artificial features. But these are more likely to be prominent in the early than in the later stages of the development of a classification; the pioneer in such work having to first bridge his rivers with such structural materials as lie nearest at hand.

To the observant mind the discovery of possible *differentiae* for the classification of natural objects is an easy and fascinating pastime, though to make a wise selection may often be quite the reverse. Thus we read in the quaint diary of the botanist Linnaeus under the date of June 12, 1632, in his "*Lapland Observations*": "Close to the road hung the under jaw of a horse, having six front teeth, much worn and blunted, two canines, and at a distance from the latter twelve grinders, six on each side. If I knew how many teeth and what peculiar form, as well as how many udders, and where situated, each animal has, I should perhaps be able to contrive a most natural methodical arrangement of quadrupeds." As with Linnaeus' quadrupeds, so with organic compounds—we find a multitude of easily determined properties from which we may choose the *differentiae* for our classification, and by the exact coincidence of a sufficient number of these characteristics of different orders with those of an unknown compound, the identity of the latter may be proved. Qualitative elementary composition, color, melting and boiling point, specific gravity, odor, taste, solubility, refractive index, specific optical rotation, electrical conductivity, absorption spectra, color reactions, precipitations, and general chemical behavior—especially simple chemical reactions that throw light on the nature of dominant atomic groups and structural peculiarities—may all be thus used.

Regarding the chemical compound, or individual, as the *species* of a chemical system, it appears most natural to group these species in such a way as to make the next higher unit or *genus* contain species which are most similar in general chemical behavior. This would, for example, tend to make congeners of members of all homologous series containing the aldehyde radical, provided we could find sufficiently reliable and simple chemical tests for showing the presence of the CHO group. Recent chemical literature abounds in suggestions for tests suitable for generic *differentiae*, though much additional work will be required in every instance to determine the real value and exact boundaries of the genera that their employment would create, there being ever-present danger that overconfidence in the constancy of behavior of a reagent towards a given radical in different structural environments may lead to false conclusions. Thus, it is not safe to assume that under certain specified conditions all ketones will form oximes; all acids and phenols will dissolve in alkali; all esters will be saponified; or all unsaturated compounds will add bromine. In first delimiting a genus such assumptions may be adopted, after preliminary experiments, as tentative working hypotheses; but the contents and existence of the genus must be held to be strictly provisional and dependent on the positive outcome of the proposed genetic reaction when applied to a larger number of its carefully selected species, and to its negative outcome when tried with numerous members of all genera of higher numerical designation in the same classificatory *order*. It will also be the duty of the classifier to indicate, in a manner that will leave no doubt in the minds of readers, all descriptions, or parts of descriptions, for which he is personally responsible; for unless some means is given for distinguishing between data which he has verified, and others which he has not, the authority is liable to be more or less implicated in the mistakes of others for which he need have assumed no responsibility, but which will now tend to vitiate the value of his classification as a whole.

It would be premature at this time to present in all its minutiae any plan for such a classification as has just been suggested in its outlines. Details in illustration of the speaker's original conception and partial execution of such a plan are to be found in the already published first and third volumes of his "*Method for the Identification of Pure Organic Compounds.*" All that is desired here is to lead to a discussion of the advantages in the plan for Chemistry; and, if it is sound, to arouse interest with a view to eventually bringing about a wider coöperation for furthering its future development. The difficulties to be overcome are considerable. Recorded descriptions of organic compounds, while frequently very complete for a few properties like melting and boiling points, are commonly equally deficient concerning others—especially in exact data showing the extent of the influence of slight variations in chemical constitution on the results of the selected differential tests. The occasion hence arises for an investigation or partial reexamination of a considerable proportion of the species receiving locations. If one has the pure compounds with which to experiment, the tests are easily made. But as only a few thousand pure compounds can be procured through commercial channels, and most of these require some purification, success in the construction of a comprehensive diagnostic classification implies assistance from private collections throughout the world; for to synthesize any considerable part of the rarer species would overtax the facilities of the largest and best equipped of laboratories.

To bring a majority of the carbon compounds referred to in Richter's Lexikon into an essentially "natural" classification of the kind suggested would, assuming the study of tests and revision of constants to be thoroughly done, perhaps involve a labor as great as the transformation of the "artificial" botanical classification of Linnaeus into the modern "natural" system as it was left by de Candolle. An undertaking of this magnitude and character might presumably in the present century be accomplished with greater benefit to science under the direction of some such organization as the committee entrusted with the periodical revision of Beilstein's "Handbuch" and the Richter "Lexikon" than under private auspices.

SYNTHESIS OF THE α,α'-DIMETHYLADIPIC ACIDS, AND SEPARATION OF THE RACEMIC ACID INTO OPTICAL ISOMERS.

BY WILLIAM A. NOYES AND L. P. KYRIAKIDES.

Received June 24, 1910.

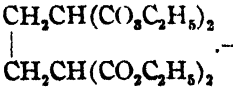
The α-α'-dialkyl-dicarboxylic acids are described in the literature as existing in two stereomeric forms—known as maleinoid and fumaroid. As far as we know none of these acids have been resolved into optical isomers. Bischoff and Walden[1] have failed in the resolution of the succinic acids. And because of this failure, the view has been entertained, that in such cases even saturated molecules are fixed in space, so that the singly-bound group or atom can not rotate.[1]

---

[1] *Ber.*, 22, 1814.

By glancing at the structure of α,α′-dimethyladipic acid, we see that this acid, like tartaric acid, has two asymmetric carbon atoms, and consequently, according to van't Hoff's theory, it ought to be resoluble into optical isomers. As will be seen later, we have succeeded in effecting this resolution.

Ethyl Ester of Butanetetracarboxylic Acid,



$$\begin{array}{l} CH_2CH(CO_2C_2H_5)_2 \\ | \\ CH_2CH(CO_2C_2H_5)_2 \end{array}$$

.—At first we prepared this compound in toluene. The best yield was obtained by using an excess of sodium, about one and one-half times that required theoretically in the malonic ester condensation. The sodium was shaken to granules in boiling toluene. The mixture was cooled, and equivalent portions of ethylene bromide and malonic ester were added. After three hours' cooling, the mixture was heated on the steam bath for about 15 hours. In this way from the pure malonic ester as well as from the recovered malonic ester, about 27–30 per cent. of the theoretical yield of butanetetracarboxylate boiling between 230–250° at 40 mm. was obtained.

Meunier[2] has described the use of magnesium in the form of amalgam instead of sodium in the preparation of mono- and diethylmalonic ester. We have tried this method in the preparation of butanetetracarboxylate, and find it better, in this case, than the use of sodium.

Ten grams of clean magnesium ribbon were put in a 500 cc. round-bottomed Jena flask, 400 grams of mercury added, and the mixture heated and shaken until the amalgamation was complete. The flask was then provided with a protected reflux condenser, 100 cc. of absolute alcohol was added, and the mixture heated on the steam bath for three hours. Occasional shaking of the flask, vigorously, hastens the formation of the magnesium ethylate by breaking the crust that clings to the sides of the flask. The flask was then cooled somewhat, and 100 grams of malonic ester were added, care being taken that the liquid did not boil too vigorously. When the reaction subsided, the flask was heated on the steam bath for three hours more. The alcoholic solution of the magnesium malonate was then cooled somewhat, 58 grams of ethylene bromide added, and after a short time the mixture was heated on the steam bath for 10–14 hours.

The alcohol was distilled off as much as possible under reduced pressure and the reaction mixture was treated with water and hydrochloric acid

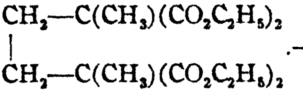
[1] Lean, *J. Chem. Soc.*, 65, 1001.

[2] *Compt. rend.*, 137, 714.

until the liquid separated into two layers. Ether was then added, the mixture shaken, and the ethereal solution separated and washed twice with dilute hydrochloric acid in order to wash away any magnesium held by the butanetetracarboxylate. After drying with sodium sulphate the ether was evaporated off, and the residue fractionated under reduced pressure. In this way 40–43 grams of the butanetetracarboxylate were obtained, boiling between 210–230° at about 10 mm. A low pressure is essential for successful fractionation of the product.

From each condensation about 40 grams of malonic ester were recovered, and used in subsequent condensations. The yield is, therefore, from 65 to 70 per cent. of the weight of malonic ester used or from 60 to 65 per cent. of the theoretical. The method is much less troublesome and, so far as we can judge from his statements, gives better yields than the method of Perkin.[1]

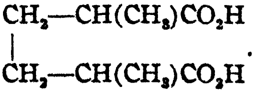
Ethyl Ester of Dimethylbutanetetracarboxylic Acid,



$$\begin{array}{l} CH_2—C(CH_3)(CO_2C_2H_5)_2 \\ | \\ CH_2—C(CH_3)(CO_2C_2H_5)_2 \end{array}$$

.—Ten grams of sodium were dissolved in about 120 cc. of absolute alcohol, the solution was cooled in ice water, and a mixture of 70 grams butanetetracarboxylate and 64 grams of methyliodide was added drop by drop, while the flask was continually shaken to keep the mixture from getting warm. It was found that the yield in the product was much greater when the mixture was kept thoroughly cooled. After the mixture had stood in the cold about half an hour it was warmed on the steam for an hour or two, while the flask was connected with an upright condenser. The alcohol was then evaporated off under reduced pressure. Water and a little hydrochloric acid were added. The ester was taken up in ether, washed with dilute potassium hydroxide, dried, the ether evaporated off, and the ester left to crystallize. The ester was purified by recrystallization from petroleum ether.[2] The yield of the recrystallized product was about 85 per cent. By working with smaller amounts we have succeeded in obtaining as high as 95 per cent. of the theoretical.

α-α'-Dimethyladipic Acids,



$$\begin{array}{l} CH_2—CH(CH_3)CO_2H \\ | \\ CH_2—CH(CH_3)CO_2H \end{array}$$

.—These were prepared from the pure crystallized dimethyl butanetetracarboxylate by the method of Lean[3] by boiling for 16 hours with a mixture of 350 cc. each of water and concentrated sulphuric acid. 165 grams of the dimethyl butanetetracarboxylate gave the theoretical amount of the adipic acids. The separation of the mixture into the two modifications, known as the fumaroid, and maleinoid, was carried out by a combination of the methods of Zelinsky[1] and Lean,[2] that is, by crystallizing from water and benzene. The final crystallizations were from water.

---

[1] *J. Chem. Soc.*, 65, 578.

[2] Lean, *J. Chem. Soc.*, 65, 1004.

[3] *Loc. cit.*

The dried acids melted at 143 and 70°. The lower melting modification begins to soften at 65°. Zelinsky gives the melting points as 140–141° and 74–76°. Lean gives 142° and 70–72°.

Separation of the Racemic α,α'-Dimethyladipic Acid into its Optical Isomers.—Twenty-seven grams of the acid melting at 70° were dissolved in 450 cc. of water, and 32 grams of brucine were gradually added to the hot solution. 131 grams brucine are necessary to neutralize completely the 27 grams of the acid. We have used about one-fourth of the weight of brucine, theoretically required, with the object of forming the acid-salt of the less soluble optically active acid. The solution, while hot, was inoculated with a few crystals of the brucine salt from a former preparation, and the liquid left overnight. The crystals were collected on a filter, and washed four times with about 15 cc. of water each. They were then dissolved in 250 cc. of hot water and crystallized. One more crystallization from 150 cc. of water is all that is necessary.

The salt was dissolved in about 150 cc. water, decomposed with sodium hydroxide, cooled in ice, the solution of the sodium salt of the acid filtered off from the alkaloid, and the latter washed several times with cold water.

The aqueous solution was treated with hydrochloric acid, a little in excess of the amount required to neutralize the sodium hydroxide used. The acid was then extracted 5 times with ether, the latter evaporated off, and the acid crystallized once from a little water. The acid thus obtained gives a positive rotation of $(\alpha)_D^{28°} = +31.3°$ in 10 per cent. alcoholic solution. It begins to soften at 103.5° and melts completely at 105.5°. Yield, 7 grams A sample of the acid (0.1741 gram) titrated required 20.02 cc. 0.1 *N* potassium hydroxide. Theory, 20.00 cc. For the *l*-acid the mother liquor from the first crop of the brucine salt, in the preparation of the *d*-acid, was extracted with ether. The acid thus obtained melted at 70–95°.

Ten grams of this acid were dissolved in 150 cc. water and 11 grams of brucine added. The crystals that separated were recrystallized from diminishing amounts of water four times. The acid that was liberated and purified as in the case of the dextro acid, melted at 85–103° and gave a rotation of $(\alpha)_D^{28°} = -23.4$ in 10 per cent. alcoholic solution. A sample titrated required 4.02 cc. 0.5 *N* potassium hydroxide. Theory, 4.00 cc. The rotation in comparison with that of the dextro acid indicates that this acid still retained about 12 per cent. of the dextro form.

---

[2] *J. Chem. Soc.*, 65, 1006.

Lack of time and material prevented us from carrying the purification of the levo form further.

An attempt to separate the fumaroid form of the α-α′-dimethyladipic acid (m. 143°) into optical isomers by means of its brucine salt was unsuccessful. It is undoubtedly a "meso" form, optically inactive by internal compensation.

Summary.

By using magnesium amalgam for the preparation of magnesium ethylate and condensing ethylene bromide with malonic ester by means of the latter the yield of butanetetracarboxylic ester has been greatly improved and this compound is now rather easily accessible.

The *dl*,α,α′-dimethyladipic acid (m. 70°) has been resolved into its optical components, of which the dextro form has been obtained in a state of purity. It melts at 104–105° and has a rotation $(\alpha)_D^{28°} = +31.3°$ in a 10 per cent. alcoholic solution.

The levo form was only obtained in a relatively impure form, melting over a wide range and given a rotation $(\alpha)_D = -23.4°$.

The "meso" form of α,α′-dimethyladipic acid (m. 143°) gave no indication that it could be separated into optically active components by crystallization with brucine.

The separation of the racemic α-α′-dimethyladipic acid into its optically active components definitely disproves the view expressed by Lean[1] that the carbon atoms are so united in this and similar cases that optical isomerism is impossible. These acids exist in four forms in close analogy with the four tartaric acids and in strict accord with the theory. The synthesis of laurolene from α-α′-dimethyladipic acid will be described in a subsequent paper.

MOLECULAR REARRANGEMENTS IN THE CAMPHOR SERIES. III. OXIDATION PRODUCTS OF *l*- AND *d*-LAUROLENE.[2]

BY WILLIAM A. NOYES AND C. G. DERICK.

Received June 24, 1910.

Levo-laurolene.

In a previous paper[3] it was shown that laurolene, when prepared from the nitroso derivative of aminolauronic anhydride by boiling with sodium hydroxide solution, always gave an optically negative hydrocarbon,

---

[1] *Loc. cit.*

[2] Abstract of one part of a thesis presented by Mr. Derick to the Graduate School of the University of Illinois in partial fulfilment of the requirement for the degree of Doctor of Philosophy.

[3] Noyes and Derick, THIS JOURNAL, 31, 670.

C_8H_{14}. This work has been repeated and the hydrocarbon from different preparations gave $(\alpha)_D^{29°} = -15.72$ and $(\alpha)_D^{27°} = -18.13$. The value of the negative rotation changes with the method of preparation, as Crossley and Renouf[1] have previously shown. The higher value of the rotatory power was found when the hydrocarbon was distilled from its sodium hydroxide solution as rapidly as it was formed. It would seem that longer contact with the alkaline solution causes the racemization of a part of the laurolene.

This product upon oxidation gave the diketone mentioned in the first article. Contrary to the statement made at that time, the diketone does not easily condense. In fact it gives very constant boiling point determinations with no evidence of decomposition. The boiling point,[2] under 750 mm. pressure, is 204° (cor.). The optical activity was found to be $(\alpha)_D^{36.5°} = 0.53°$ while that of the previous preparation[3] was found to be $(\alpha)_D^{25°} = -8.47°$. Hence it is evident that the diketone, like the hydrocarbon, possesses an optical rotation which varies with the method of preparation.

The diketone forms an oily dioxime, which gave upon analysis:

Calculated for $C_8H_{16}N_2O_2$: N, 16.27; found: N, 15.45.

An oily monophenylhydrazone was obtained which gave upon analysis:

Calculated for $C_{14}H_{20}ON_2$: N, 12.07; found: N, 12.72.

Although these analyses were made with products which could not be carefully purified they are sufficiently accurate to show that the oxidation product of *l*-laurolene is a diketone.

In the case of the semicarbazone, more satisfactory results were obtained in the form of a white crystalline product melting at 194° (cor.) The substance separates very slowly from the solution in which it is prepared. It was not found possible to recrystallize it. The portion used for the melting point and analysis was washed thoroughly with warm water (about 60°) till free from chlorides. The analysis gave:

Calculated for $C_{10}H_{20}O_2N_6$:	C. 46.87	H, 7.82	N, 32.81
Found:	46.50	8.80	31.71

These analyses were made with very small amounts, since the yield of the disemicarbazone was very small and much time is required for the preparation. But the results prove beyond a doubt that the oxidation product of laurolene is a diketone.

Attempts to condense the diketone by heating alone and with sodium hydroxide were unsuccessful. Phosphorus pentoxide gave a very small yield of a product, boiling at 143°, which could not be further investigated.

---

[1] Crossley and Renouf, *J. Chem. Soc.*, 89, 38.

[2] This was determined by Sivolobov's method, *Ber.*, 19, 795, as modified by Mulliken, "A Method for the Identification of Pure Organic Compounds," p. 222.

[3] Noyes and Derick, *Loc. cit.*

A diketone of the formula $C_8H_{14}O_2$ must necessarily be an open chain compound. This view of its structure receives strong confirmation from the synthesis of laurolene (see the following paper) and from the boiling point and specific gravity of isomeric diketones.

	Boiling point.	Specific gravity	
2,3-Octanedione $CH_3(CH_2)_4COCOCH_3$.	172–173°	732 mm.	. . . . .[1]
3,4 Dimethyl 2,5-hexanedione, $CH_3COCH(CH_3)CH(CH_3)COCH_3$	210°	. . . .	. . . . .[2]
3-Methyl-2,4 heptanedione, $C_3H_7COCH(CH_3)COCH_3$	89-90°	20 mm.	0.955[3]
3 Methyl-2,6-heptanedione, $CH_3COCH(CH_3)CH_2CH_2COCH_3$	203–204°	750 mm.	0.988[4]

In general the specific gravities and boiling points increase as the carbonyl groups are further apart.

The presence of the acetyl group in the diketone was also demonstrated by the formation of bromoform when it is treated with sodium hypobromite. The diketone reduces a neutral solution of potassium permanganate instantly, as acetone does.

Dextro-laurolene.

In our previous article on laurolene, we stated that the direct decomposition of the hydrochloride of aminolauronic acid by means of sodium nitrite always gave an optically positive hydrocarbon, C_8H_{14}. Similar results have been obtained since the publication of the above article. The rotation of laurolene prepared in this manner being $(\alpha)_D^{26.2°} = +28.15°$. The rotation of the hydrocarbon varies, therefore, with the method of preparation as was found to be the case with the optically negative laurolene. The density of the optically positive laurolene was found to be $d_{4°}^{15°} = 0.8030$ and $d_{20°}^{20°} = 0.7991$. The boiling point was 120.3–121° at 750 mm. Thus levo- and dextro-laurolene possess the same composition, boiling points and density.

Oxidation of dextro-laurolene by the same method employed with levo-laurolene gave a diketone. It was also purified by fractional distillation with a Sprengel pump and distilled from 70–80° under ½ to 1 mm. pressure. The product gave upon analysis:

Calculated for $C_8H_{14}O_2$: C, 67.60 ; H, 9.86 .
Found: C, 66.53, 66.50, 67.9; H, 9.90, 10.15, 10.60.

The analysis of the diketone was very difficult. If burned in an open boat the results were uniformly too low, while if burned in a bulb with copper oxide it was exceedingly hard to burn the last traces of carbon. Extra long burning with some copper oxide in the bulb with the diketone gave the last analysis, which is within the limits of experimental error for carbon. The results show that a diketone is formed which boils at the same temperature as the diketone from levo-laurolene.

Several determinations of the optical activity of the diketone from dextro-laurolene, as above prepared, showed it to be optically inactive. Experiments were performed with the diketone in the pure form as well as in 20.5 per cent. ethereal and alcoholic solutions.

As in the case with diketone from levo-laurolene, the diketone from dextro-laurolene gave an oily oxime and phenylhydrazone.

The semicarbazone was a white crystalline product which separated from water after long standing. It melted fairly sharply at 192° (cor.) and appeared to resolidify and again melt at 225° (cor.). A very recent preparation gave a semicarbazone which melted at 228° (cor.) with no evidence of a preliminary melting. The analysis of the product melting first at 192° gave:

Calculated for $C_{10}H_{20}O_2N_6$: N, 32.81. Found: N, 33.25

It is evident that the oxidation product of dextro-laurolene is a diketone identical with the diketone obtained from levo-laurolene. Therefore dextro- and levo-laurolene are mixtures of optical isomers, but the *d*- and *l*-forms occur in different proportions. In the levo-laurolene the *l*-form predominates while in the dextro-laurolene the *d*-form is in excess.

Structure of Laurolene.

The experiments described in this paper give further confirmation of the structure of laurolene first proposed by Eijkman[1] on the basis of refractometric studies and advocated by us in our previous paper.[2] They have shown, also, that both *d*- and *l*-laurolene give a diketone by oxidation and that the semicarbazones of the ketones from the two hydrocarbons are, apparently, identical, indicating that the two hydrocarbons differ only in configuration and are otherwise identical in structure. The formula established for laurolene is,

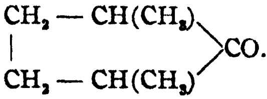
for this hydrocarbon.

Noyes and Derick[1] have given experimental evidence in favor of the formula proposed by Eijkman. They oxidized laurolene, and obtained an active diketone. The only formula for laurolene—an active body itself—consistent with this behavior on oxidation is that proposed by Eijkman.

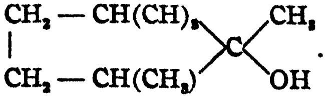
The object of the present investigation has been to establish the constitution of laurolene by synthesis. As will be seen, we have verified experimentally the constitution of laurolene, as given above.



Preparation of 2,5-dimethylcyclopentanone.—The separation of *dl*,α,α'-dimethyladipic acid into its optically active components[2] was undertaken in the hope that this might be the starting point for the preparation, synthetically, of an optically active laurolene. When the dextro-α,α'-dimethyladipic acid was mixed with lime and distilled, the resulting dimethylcyclopentanone proved to be optically inactive.

Having failed to secure an optically active ketone, in our further experiments the mixture of "meso" and racemic α,α'-dimethyladipic acids obtained by the saponification of dimethyl ketonetetracarboxylic ester (see preceding paper) was used. Portions of 12 to 13 grams of these acids were mixed with about 25 grams of calcium oxide and the mixture placed in a small distilling bulb, of such size that it was nearly filled. The bulb was placed in a bath of Wood's metal and heated until the ketone was formed and distilled away.

By this method 73 grams of the α,α'-dimethyladipic acids gave 33 grams of the purified ketone boiling at 146–149°, the main portion at 147–148°. This is about 70 per cent. of the theoretical yield. Zelinsky and Rudski[3] give the boiling point as 145–147°. Better yields of the cyclopentanone are obtained by distilling the acid in portions of 6 grams each.



1,2,5-Trimethylcyclopentanol-1. — This compound was prepared from the dimethylcyclopentanone by means of the Barbier-Grignard reaction. Eight grams of clean magnesium ribbon were put in a flask, with 25–30 cc. absolute ether and 50 grams of methyl iodide were added, the flask being provided with a protected reflux condenser. As soon as the reaction became vigorous, the reaction mixture was cooled. Towards the end, it was heated gently on the steam bath. When the solution of the magnesium was complete, the solution was cooled in ice water, and shaken continuously, while 30 grams of the cyclopentanone were added drop by drop, on account of the violence of the reaction. The mixture was left in the cold for about a quarter of an hour and then warmed on the steam bath for an hour. The reaction product soon separated out as a solid.

[1] This Journal, 31, 669.

[2] *Ibid.*, 32, 1057.

[3] *Ber.*, 29, 304.

The ether was then mostly evaporated off, and the product added slowly to crushed ice, while the latter was being stirred. Local heating is to be avoided, as the alcohol has a strong tendency to decompose.

Ice-cold acetic acid was slowly added until the liquid separated into two clear layers. The upper layer was separated, washed once with dilute acetic acid, twice with dilute potassium hydroxide, and dried quickly over sodium sulphate. The cyclopentanol was then fractionated under a very low pressure.

The substance boils at 56–60° in the neighborhood of 8 mm. Yield about 65 per cent.

Analysis:	Calculated for $C_8H_{16}O$:	C, 74.98	H, 12.68
	Found:	C, 74.44	H, 12.74

The specific gravity was $d_{4°}^{15°} = 0.9121$.

The refractive index as read on the Abbé refractometer and corrected was $n = 1.4554$ at 16.7°.

Synthetic laurolene, C_8H_{14} or  $\begin{array}{l} CH(CH_3) - C-CH_3 \\ | \qquad\qquad\quad \| \\ CH_2-CH_2-C-CH_3 \end{array}$.—Simply heating the cyclopentanol at ordinary pressure induces the breaking off of a molecule of water. However, complete dehydration in this way is a tedious process. In order to obtain the pure unsaturated hydrocarbon, we have usually used Zelinsky's method.[1]

Eleven grams of the cyclic alcohol, which had lost most of its water by two distillations at ordinary pressures, were mixed with 10 grams of powdered anhydrous oxalic acid, heated at 100–110°, and distilled. Repeating the heating with oxalic once more, and subjecting the distillate to steam distillation, drying the product over calcium chloride, and fractionating, we obtained the hydrocarbon boiling at 119–122°. The specific gravity was $d_{4°}^{15°} = 0.8039$.

Analysis of the hydrocarbon after it had stood a month:

Calculated for C_8H_{14}:	C, 87.27 ;	H, 12.72
Found:	C, 87.06, 87.16;	H, 13.15, 13.03.

---

[1] *Ber.*, 34, 3249.

In the last preparation of the hydrocarbon we used phosphorus pentoxide as a dehydrating agent. It was necessary to dry the cyclopentanol over phosphorus pentoxide and distil several times before the dehydration was complete. The final fractional distillation gave a product that disti[illegible]mostly at 121.6°. The hydrocarbon prepared in this way was foun[illegible] oxidize rapidly in the air, so that the substance two weeks after its preparation gave 73.86 per cent. carbon instead of the theoretical 87.72 per cent.

In order to free the hydrocarbon from the oxidation product, the mixture was fractionated, and the fraction boiling up to 125° collected. This was then subjected to steam distillation, until the volume of the distillate was about 10 cc. This was dried, and fractionated, when about 5 grams of the hydrocarbon boiling at 120–122° was obtained.

Analysis of the product immediately after distillation:

Calculated C, 87.27, H, 12.72. Found: C, 86.90; H, 12.94

The refractive index of the hydrocarbon was = 1.4464 at 16.5°.

In the purification of the alcohol and hydrocarbon we observed the same characteristic green coloration which was observed by Walker and Henderson[1] and which we have often noticed in working with lauronolic acid and laurolene.

The hydrocarbon was oxidized with the theoretical amount of a 2 per cent. solution of potassium permanganate in the cold. The oxidation product was extracted several times with ether, directly from the oxidation mixture On fractionating the product, about 0.6 gram of substance was obtained boiling at about 75° in the neighborhood of 5 mm.

Analysis: Calculated for $C_8H_{14}O_2$. C, 67.60; H, 9.86
Found. C, 69.79, 70.09; H, 10.42, 10.36.

The substance that was obtained as oxidized in the air, was treated with a little 2 per cent. solution of potassium permanganate and purified. It was analyzed, and gave: C, 71.93; H, 10.59. Working with about 5 grams of the hydrocarbon and the yield in the oxidation product being so poor, we could not expect a very pure product. However, comparison of this oxidation product, with that obtained by Noyes and Derick[2] by the oxidation of the laurolene from the decomposition of aminolauronic acid, shows that they are the same. Noyes and Derick give as the boiling point of their diketone 203.6°. (See the preceding paper). Two samples of our oxidation product, prepared from two distinct preparations of the hydrocarbon, gave 203° and 204° as the boiling points of the oxidation products, respectively.

Noyes and Derick give 0.9844 as the specific gravity of their pure diketone. The one last prepared by us gave 0.9733 at 20°. Both the lower specific gravity and the analyses indicate that the diketone retained a small amount of the hydrocarbon from which it was impossible to separate it owing to the small amount available.

---

[1] *J. Chem. Soc.*, **49**, 749.

[2] THIS JOURNAL, **31**, 669.

Comparison of constants of the hydrocarbons:

	Boiling point.	Sp gr. at 15°.	n at 16.5°.
C_8H_{14} from aminolauronic acid	120–122°	0.8030	1.[illegible]
C_8H_{14} synthetic.......................	120–122°	0.8039	1.[illegible]64

The structure of laurolene as Δ′-1,2,3-trimethylcyclopentone must therefore be considered as fully established.

Professor Eijkman has kindly determined the refractometric constants of our synthetic laurolene. He finds the refractive index slightly less than that of the laurolene from camphor, as we have done. He also finds the dispersion somewhat less and suggests that the synthetic laurolene may contain some *pseudolaurolene*, , which would account for the difference. We hope to publish Professor Eijkman's results with laurolene and with some of the other compounds later.

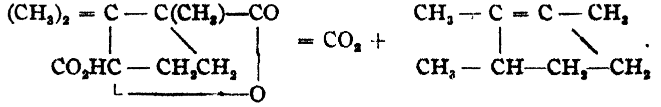
MOLECULAR REARRANGEMENTS IN THE CAMPHOR SERIES. V. MECHANISM OF THE REACTIONS BY WHICH LAUROLENE IS FORMED.

BY WILLIAM A. NOYES.

Received June 24, 1910.

Having established the structure of laurolene (see the preceding papers) it is now possible to discuss intelligently the reactions by which it is formed. The most important of these are the following:

1. By the slow distillation of camphanic acid[1] or by distilling calcium camphanate[2]



The yield is 53 per cent. of the theoretical (Aschan) and the hydrocarbon is sometimes levorotatory and at other times dextrorotatory.

2. By the distillation of lauronolic acid[3] (allocampholytic acid):

$$C_8H_{13}CO_2H = C_8H_{14} + CO_2.$$

---

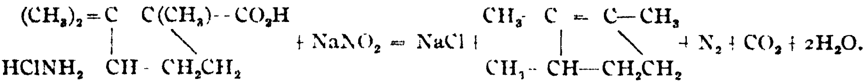
[1] Wreden, *Ann.*, 163, 336; Aschan, *Ann.*, 290, 187; Zelinsky, *Ann.*, 319, 311; Crossley and Renouf, *J. Chem. Soc.*, 89, 27.

[2] Rupe and Maull, *Ber.*, 26, 1202.

[3] Walker and Henderson, *J. Chem. Soc.*, 69, 749.

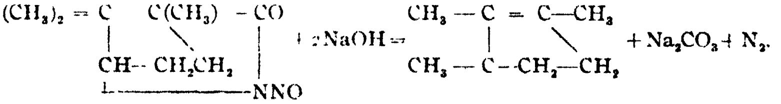
The yield is not given and there is some indication that the allocampholytic acid used was a mixture. The hydrocarbon obtained was levorotatory. The shifting of the methyl group in this case may have occurred either during the formation of the lauronolic acid or during its decomposition to form laurolene. On the basis of refractometric measurements Eijkman concludes that the former is the case[1] and that the structure of lauronolic acid is  It is our intention to study this question further from the chemical side.

3. By the interaction of sodium nitrite and the hydrochloride of aminolauronic acid.[2]



The yield is 19 per cent. of the theoretical[3] and the hydrocarbon is dextrorotatory.

4. By heating the nitroso derivative of aminolauronic anhydride with sodium hydroxide.[4]



The yield is 53 per cent. of the theory and the hydrocarbon is levorotatory.

A consideration of these reactions leads us to the conclusion that the decompositions which take place lead to the formation of the complex  which is, of course, incapable of an independent existence. Under these conditions one of the "gem" methyl groups shifts to the lower carbon atom giving an opportunity for the formation of a double union between the two upper carbon atoms of the ring. Erlenmeyer[5] suggested the intermediate formation of a trimethylene ring in such cases but the fact that phenyl groups may shift their places as easily as methyl and that atoms in the para position in such phenyl groups remain para,[6] has rendered this explanation almost untenable. It seems much simpler to assume that one of the methyl groups is momentarily detached only to combine at once with the adjacent carbon atom.

[6] Montague, *Rec. trav. chim.*, 24, 105; 25, 413.

The loosening of the affinity of the "gem" methyl groups for the carbon atom to which they are attached through the free valences of the two carbon atoms to which that carbon atom is attached is probably an important factor in the reaction.[1] About the only apparent objection to the view here expressed is the ordinary experience with carbon compounds that carbon atoms do not readily separate from each other. But we know that at higher temperatures or in the presence of negative groups such separations do frequently occur. That the parts which separate may recombine to a more stable grouping is to be expected. For the pinacone-pinacolin rearrangement and also for the α- and β-campholytic acids it has been shown that the shifting of the methyl group may be reversible, which points strongly to the probability that separation between carbon atoms may be much more frequent than we have supposed. Only in those cases where an opportunity is presented for a more stable grouping will the separation result in a rearrangement. The fact that laurolene has a higher specific gravity and boiling point than isolaurolene makes it extremely probable that its heat of combustion is also higher and that the shifting of the methyl group is accompanied by a dissipation of energy. Isolaurolene, of course, more nearly retains the structure of camphor. It is, perhaps, worth while to call attention to the fact that in the decompositions of camphanic acid and of the nitroso compound, in both of which cases the two carbon atoms of the ring are associated by a cyclic grouping, the loss of carbon dioxide and formation of laurolene occurs in much larger amount than it does in case 3 where the primary decomposition affects the amino group only.

It may also be remarked that if we assume that these reactions are ionic in character the free valences in the intermediate product will be positive and negative respectively and that the methyl group which shifts its place would be negative as it does so. This is in accord with the hypothesis first proposed by the writer in 1901[2] that atoms of the same element may in different cases assume either positive or negative charges. Essentially the same fundamental idea has been proposed quite independently by Abegg[3] and, from a wholly different point of view, by J. J. Thompson.[4]

The loss of carbon dioxide in these reactions is probably closely related to the loss of carbon dioxide by any ion of an organic acid when it loses its negative charge at the anode in electrolysis.

THE HYDROCARBONS OF THE WOOL GREASE OLEINS. FIRST PAPER.

BY AUGUSTUS H. GILL AND LAURENCE R. FORREST.

Received June 30, 1910

In 1904 Gill and Mason showed how these hydrocarbons might be distinguished from mineral oil.[1]

The hydrocarbons were obtained by saponifying the distilled wool grease oleins with an excess of alcoholic potash. The unsaponifiable matter was extracted with redistilled petroleum ether, treated with acetic anhydride to remove any cholesterol, and if more than 0.2 cc. of 0.5 *N* alcoholic potash per gram of oil were required for the saponification of the neutral oil present, these operations repeated until an oil of this quality resulted.

The oil obtained has the following characteristics (for comparison those of some mineral oils are herewith shown).

		Bromine			
	Sp gr at 15°.	Addition	Substitution	Optical rotation in 200 mm. tube.	Refractive index at 20°.
	0.896	28.8	14.2	+17° 58′	1.4967
Mineral oils	0.848-0.863	4.4-5.9	5.6-8.4	+ 1° 2′	1.4662-1.4750

From the large bromine addition number these hydrocarbons would seem to be unsaturated compounds, and according to the investigations of Smith[2] to have been formed by the breaking down of an ester, like cetyl palmitate, into the corresponding acid and the double-bonded hydrocarbon of a similar name, $C_{15}H_{31}COOC_{16}H_{33} = C_{15}H_{31}COOH + C_{16}H_{32}$. Between two and three liters of these hydrocarbons were prepared from the olein as above described. Some of this was distilled at a pressure of 17–44 mm. giving boiling points from 270° to 315°; good separations were not obtained, it being impracticable to use a bead tower, five or six inches of vertical height being as much as the liquid could be raised by boiling.

Fractionation under these circumstances being difficult, a rotary vacuum pump, the rotator running in oil, was used; this was similar to those used in evacuating incandescent lamps and afforded a pressure during distillation as low as one millimeter. Richards'[3] method of heating was used with excellent results, the current being regulated by wire and carbon rheostats. With a coil of platinum wire 0.25 mm. in diameter and 50 cm. long a current of 4–6 amperes at 220 volts was found sufficient to distil the hydrocarbons.

The distilling flask held but 200 cc., consequently many distillations were necessary. Six complete fractionations were made between the following temperatures, 95–100°, 100–110, 110–125, 125–130, 130–140, 145–150, 150–155, 170–176, 176–182, 186–193° and a quantity of each portion of fairly constant boiling point was obtained.

---

[1] THIS JOURNAL, 26, 665.

[2] *Ann. chim. phys.*, (3) 6, 40 (1842).

[3] T. W. Richards, THIS JOURNAL, 30, 1282.

The hydrocarbons were next subjected to purification by crystallization from acetone. Those having boiling points of from 95° to 135° would not separate out in crystalline form even at 0°, coming out of solution simply as oils; but the separation was repeated three times with these as with those of higher boiling point, since any change in composition which might be thereby affected tends toward purification. The remainder of the hydrocarbons were obtained as crystallized white solids from the acetone solutions, and crystallization from fresh acetone was effected three times in each case. The hydrocarbons which were last separated from the acetone were heated on the water bath to remove all traces of solvent. All except the one, crystallizing from acetone, which had the boiling point 130–140° were solid at the ordinary temperatures. The solvent was also distilled from the total mother liquor left from the three crystallizations leaving the hydrocarbon which is soluble in acetone at 0°. All of these soluble hydrocarbons, to the end of the list, were liquid at ordinary temperature.

By this means there were obtained, from the original single series of hydrocarbons, two series, one insoluble after three separations from acetone solution at 0°, and the other soluble in acetone at that temperature.

The molecular weights by the Beckmann method, in benzene, and the iodine absorption values by the Hanus method were now obtained for all the hydrocarbons of each of these series, both solid and residual; these are shown in Tables I and II.

From a study of these tables it would seem that in these distilled wool grease oleins we had hydrocarbons of the olefin series, that is with but a single double bond, and of formula from $C_{20}H_{40}$ to $C_{30}H_{60}$.

These hydrocarbons are now under investigation, with the idea of determining some of their physical constants with greater accuracy, more particularly their boiling and melting points, their index of refraction and, if possible, the position of the double bond.

BOSTON, MASS

[CONTRIBUTIONS FROM THE HAVEMEYER LABORATORIES OF COLUMBIA UNIVERSITY, No. 177.]

STUDIES ON AMYLASES. I. AN EXAMINATION OF METHODS FOR THE DETERMINATION OF DIASTATIC POWER.

BY H. C. SHERMAN, E. C KENDALL AND E D CLARK.

Received June 28, 1910.

The enzymes being known by their activities it is scarcely possible to make satisfactory progress in the isolation of any enzyme for investigation of its chemical nature until we have accurate knowledge of methods and conditions for determining quantitatively the increase of its activity or power with the progress of the purification. This may be illustrated by a reference to the papers of Osborne[1] and of Wroblewski[2] on the chemical nature of the amylase of malt.

In the case of the amylases there are also extremely important applications, both biochemical and economic, awaiting the development of reliable and comprehensive methods for the measurement of diastatic power. The fact that the salivary digestion of starch may continue much longer in the stomach than was formerly supposed not only emphasizes the value of accurate measurements of the diastatic power of the saliva, but also adds interest to the use of both plant and animal amylases as aids to this part of the digestive process. The U. S. Pharmacopoeia standard for pancreatin has been changed so that the primary requirement now relates to amylolytic instead of to proteolytic power and recent food and drug legislation naturally suggests a more accurate standardization as well as a more comprehensive standard or standards which shall apply also to malt diastase and taka-diastase, both of which are likewise marketed as pharmaceutical preparations.

---

[1] Osborne, THIS JOURNAL, 17, 587 (1895); Osborne and Campbell, *Ibid.*, 18, 536 (1896); Osborne, *Ber.*, 31, 254 (1898).

[2] Wroblewski, *Ber.*, 30, 2289 (1897); 31, 1127 (1898).

Malt extracts are now being purchased by bakers on the basis of diastatic power and with the economic completion in the production of tax-free industrial alcohol it is to be expected that the determination of diastatic power will soon become an important factor in the valuation of commercial American malts.

In consequence of the very different points of view from which investigators have approached the subject of diastatic power, many methods or modifications of methods have been employed for its measurement and the descriptions are widely scattered in chemical, physiological, and technical literature. In the interest of brevity anything like a comprehensive review of such methods must be omitted here and attention confined to those which appear to have been most used.

These are of two main types: (1) the so-called "liquefaction" methods which aim to measure the power of the enzyme to completely convert a known amount of starch into products which no longer give the characteristic color reactions with iodine; (2) the saccharification methods which measure by means of alkaline copper solutions the amount of reducing sugar produced by the enzyme when acting under known conditions upon a sufficient excess of starch.

It will be convenient to refer to these two types as "iodine methods" and "copper methods" respectively.

Evidently the result obtained by either type of method will depend upon the conditions under which it is applied and further it may be expressed in a number of ways, for example, the amount of change produced by a given amount of enzyme in a given time, the amount of enzyme required to produce a given change in a given time, or the time required for a given amount of enzyme to produce a given change.

Kjeldahl[1] determined the reducing sugar formed by the action of a known amount of malt extract or saliva upon an excess of starch during 20 minutes at 57–59°, and considered that this was directly proportional to the amount of actual amylase present, or in other words, was a true measure of the diastatic power, so long as the digestion was not carried beyond the point which corresponds to a conversion of about 40 per cent. of the original starch into maltose. This is frequently referred to by other writers as "Kjeldahl's law of proportionality" and has had considerable influence upon subsequent work.

---

[1] Mittheilungen aus dem Carlsberger Laboratorium, *Dingler's Polytechn. J.*, 235. 379, 452 (1880).

Roberts[1] working with pancreatic extracts, saliva, and malt extract defined diastatic power as the number of cubic centimeters of a standard starch paste which could be converted by one cubic centimeter of the active solution during 5 minutes at 40° into products giving no color reaction with iodine.

Jungk[2] used a similar method for malt extract but determined the time required for 10 cc. of the extract to convert 10 grams of starch which he considered in the case of a good extract should not exceed 10 minutes at 40°.

Lintner[3] modified Kjeldahl's method in such a way as to ensure that the calculations of diastatic power should be based upon the production of a constant quantity of maltose by the action of the malt extract upon a definite amount of soluble starch. This was accomplished by measuring 10 cc. of a 2 per cent. starch solution into each of the several test tubes and adding to each tube a different amount of a malt extract, *e. g.*, 0.1, 0.2, 0.3, 0.4, 0.5 cc., etc. After standing for 1 hour at 21° the action was stopped by the addition of 5 cc. of Fehling solution to each tube, the tubes placed in boiling water for 10 minutes, and then examined to determine the first tube in which the copper was all reduced, *i. e.*, the smallest amount of extract which had produced sufficient maltose to reduce 5 cc. of Fehling solution. Lintner prepared a sample of diastase, of which 0.12 mg. produced under these conditions the maltose necessary to reduce the 5 cc. of Fehling solution. This preparation was rated as having a diastatic power of 100 and the diastatic powers of other preparations were calculated as inversely proportional to the amount of sample required to produce this fixed amount of reducing sugar. Thus, if 0.3 mg. were required $0.3 : 0.12 : : 100 : X \; . \; . \; . \; . \; X = 40$, the diastatic power of the preparation tested.

In applying this method to malt, however, 25 grams of the dried, ground sample are digested with 500 cc. of water and portions of the clear, filtered extract are employed as described for the diastatic solution. Then if V = the volume of extract required to give complete reduction of the Fehling solution

$$V : 0.1 : : 100 : \text{"diastatic power of malt."}$$

Since 0.2 gram starch are used in each test tube and the weight of maltose required to reduce 5 cc. of Fehling solution is only about 0.04 gram, it follows that the diastatic power is determined by this method for a point at which only about 20 per cent. of the starch has been converted into maltose. Hence the retarding effect of the maltose formed must act, if at all, to the same extent in all cases and so can not vitiate comparative determinations. On the other hand, if ten tubes containing 0.1 cc. to 1.0 cc. of the extract are used in testing a sample, there are only 10 points on Lintner's scale at which an accurate determination could be had in the first operation. If, as usually happens, the correct amount lies between the successive amounts taken, it is necessary to assume that the required volume is midway between the two, or to repeat the test with smaller increments of the extracts. Moreover, the probable error of the method increases rapidly with the diastatic power of the sample. If the end point falls between the last two tubes (0.9 cc. and 1.0 cc.) the diastatic power will be between 10 and 11.1, but if it falls between the first two tubes (0.1 cc. and 0.2 cc.) the diastatic power may be anywhere between 50 and 100.

Kjeldahl,[1] Chittenden and Ely,[2] and later Brown and Glendenning,[3] Ford[4] and other investigators have estimated gravimetrically by copper reduction the extent of the diastatic action.

Sykes and Mitchell[5] introduced a method which they held to be interchangeable with Lintner's while giving a closer result in a shorter time, especially when dealing with malt of high diastatic power. In this method 100 cc. of 2 per cent. starch solution are treated with 1 cc. of malt extract or diastase solution (of the concentration used by Lintner) for 1 hour at 21°, 50 cc. of Fehling solution added, and the whole heated rapidly to 98° and then placed in a boiling water bath for 7 minutes, after which the reduced copper is determined. The weight of copper found, divided by 0.438 (the quantity of copper in 50 cc. of Fehling solution) and multiplied by 100, gives the diastatic power in terms of the Lintner scale. The results obtained by this method on 10 samples of malt having diastatic power of 5 to 77 (Lintner scale) averaged 2 units (about 8 per cent.) higher than those by the Lintner method with extreme variations of —1.7 to +5.8 units and of —34 to +30 per cent. This was accepted by Sykes and Mitchell as a satisfactory agreement of results.

Francis[6] improved the iodine method by extending the time of digestion to one-half hour, and specified exact conditions for the determination of the end point.

Takamine[1] determines diastatic power in comparison with a permanent standardized sample of taka-diastase by finding the relative amount of the standard sample and the sample under test which are required to accomplish the same conversion in the same time as judged by the iodine color reaction.

Vernon[2] in his study of pancreatic amylase used a method essentially like that of Roberts.

Johnson[3] has recently published a new form of color method in which different amounts of the sample under examination are added to a fixed amount of starch paste, the mixture held at 40° and portions withdrawn and tested with iodine at the conclusion of 8 minutes and each minute thereafter. The operation is repeated with smaller increments of sample, if necessary, until that amount is found which just suffices to digest the starch in 10 minutes to products which give no color with iodine. Working mainly with samples containing commercial pancreatic amylase, Johnson concluded that diastatic values which were equivalent to each other as indicated by this method were also equivalent as measured by the production of reducing sugar.

The first object of our experimental work has been to ascertain, if possible, the relative value of some of the methods in use for measuring diastatic power, the consideration which should determine the choice of a method, what modification, if any, is necessary to ensure reliability of results, and how generally applicable is any one method to the examination of amylases of different origins. Much work having already been done by others upon malt diastase, we have confined our experiments almost entirely to taka-diastase and pancreatin.

In reaching the results given below we have been very greatly aided by the extended and able preliminary work on this subject which was carried out by the late Arnold William Meyer in conjunction with one of us in this laboratory in 1907–'08. We have also profited by the experience of Mr. Robert Schwarz and Miss M. I. Alley, who during the course of the investigation have carried out in this laboratory a considerable number of experiments on certain phases of the work.

Experiments upon Taka-diastase.

Three samples of taka-diastase have been used: No. 1, a one-ounce sample purchased in 1907; No. 2, a mixture of 4 one-ounce samples purchased in 1908; No. 3, a specially prepared sample of much greater activity which was kindly furnished us directly from the laboratory of Dr. Takamine.

[3] THIS JOURNAL, 30, 798 (1908).

Lintner's method was carried out with all precautions which we had found suggested by any previous workers, using carefully prepared[1] and neutralized[2] soluble starch and neutralized[2] distilled water in specially cleansed Jena glass apparatus and working in a room kept free from laboratory fumes.

Taka-diastase No. 1 showed a diastatic power of 11.4 on Lintner's scale at 21° and 24.5 at 40°. No. 2 showed 7.8 at 21° and 17.5 at 40°. No. 3 showed 38.9 at 21° and 95.1 at 40°.

The gravimetric method showed with taka-diastase No. 1 (when 2.5 mg. of enzyme acted for 1 hour at 21° upon 100 cc. of 2 per cent. soluble starch) an amount of reducing sugar corresponding to a Lintner figure of 11.1. This result is in substantial agreement with that of the Lintner method. The difference between maximum and minimum in 9 successive determinations by this method was about 4 per cent. while in Lintner's method it was about 15 per cent., probably because of the errors involved in measuring out the very small amounts of enzyme solution required.

Johnson's method, while a great improvement over the Pharmacopoeia test, did not in our hands yield definite or satisfactory results because of the difficulty experienced, when following Johnson's directions, in securing a homogeneous starch paste and in determining the end point with sufficient accuracy.

A new iodine method seemed desirable which should differ from those of Roberts, Jungk, and Johnson in combining the use of a more dilute and homogeneous starch paste, a large volume of digestive mixture, and a fairly long time of digestion (as recommended by Francis) in order to secure a better mixture and more uniform action and diminish the proportional error involved in the determination of the end point.

The starch paste is prepared as follows: Enough clean air-dry potato starch to contain 10 grams of water-free substance is suspended in about 100 cc. of cold distilled water; enough more distilled water to make one liter was poured into a 2 to 3 liter flask immersed in a brine bath and connected with a reflux condenser. The bath is then heated and if the water boils the heating is stopped so that the water may cool somewhat, then the suspension of starch is poured *very carefully* into the hot water, the heating resumed and the paste boiled 2 hours under the reflux condenser. This long boiling renders the starch paste less viscous, more homogeneous and transparent, and more easy of digestion by the amylase.

[1] The small reducing power which the starch still retained after 65 careful washings on a Buchner funnel was determined and the proper correction applied.

[2] Rosolic acid was used as the indicator of neutrality in both cases.

In order to determine how long the boiling of the starch paste should be continued, experiments were made in which 250 cc. portions of the paste were treated with 40 mg. of taka-diastase No. 2 dissolved in 20 cc. of water and the time required for digestion to products giving no color with iodine was determined as follows: Boiled ½ hour, required 50 min.; 1 hour, required 46 min.; 1½ hours, 36 min.; 3 hours, 33 min.; 6 hours, 30 min. Hence boiling beyond 1½ hours had little effect upon the digestibility of the starch as thus determined. Moreover, it was noted that up to 2–3 hours the solutions remained colorless while on 3–6 hours' boiling they became slightly yellowish. Two hours was therefore decided upon as the best length of time for boiling the starch paste.

The paste at a temperature not above 40° is weighed out in 250-gram portions (equivalent to 2.5 grams anhydrous starch) into Erlenmeyer flasks of 350–400 cc. capacity and immersed in a water bath kept at 40°. The desired amount of enzyme is then introduced along with 20 cc. of water (in which the enzyme may be dissolved, or which may be used to wash it into the flask), the contents of the flask well mixed and the temperature of 40° carefully maintained. The digestion is considered completed when 0.25 cc. of the contents of the flask removed and mixed with 5 cc. of the dilute iodine test solution[1] in a test tube shows, when viewed against a white background, no color which can be distinguished from that of the untreated iodine test solution. The experiment is repeated with different amounts of enzyme, if necessary, until that amount is found which completes the digestion in 30 min. (± 1 min.). The result may then be conveniently expressed by dividing the weight of starch (2.5 grams) by the weight of enzyme required to digest it under these fixed conditions.

The results obtained with the three samples of taka-diastase were as follows, the times required with different amounts of sample being given to show the probable error of the method.

No. 1 — 37 mg. required 34 min., 40 mg. 27 min.; 43 mg. 22 min.; 38 mg. 31 min.

No. 2 — 40 mg. required 40 min.; 43 mg. 37 min.; 46 mg. 33 min.; 49 mg. 31 min.

No. 3 — 7 mg. required 34 min.; 9 mg. 30 min.; 11 mg. 27 min.

If the weight of starch, 2.5 grams, be divided in each case by the weight of taka-diastase which digested it in 30 or 31 min. the following values for diastatic power are obtained: No. 1, 66; No. 2, 51; No. 3, 278.

If these values be compared with the Lintner figures given above for the same samples at the same temperature we find the ratio of the Lintner figure to the value as found by the new iodine method to be for No. 1, 1 : 2.7; for No. 2, 1 : 2.9; for No. 3, 1 : 2.9.

---

[1] Two grams of iodine and 4 grams of potassium iodide are dissolved in 250 cc. water. For use, 2 cc. of this solution are diluted to 1 liter and 5 cc. of this dilute solution are employed for each test.

Hence as expressing the comparative diastatic powers of the three samples of taka-diastase, the results by the new iodine method ran approximately parallel to the results obtained by the Lintner method at the same temperature.

Experiments upon Pancreatin.

Five commercial preparations of pancreatic amylase representing the products of the principal American makers were used in the experiments here described.

The Lintner method was applied to these as to the samples of taka-diastase, but with much less satisfactory results. Duplicate determinations often showed wide divergence and lower results were obtained at 40° than at 21°.

The gravimetric copper method also gave unsatisfactory results. The amount of reducing sugar formed by a given amount of enzyme was less here than in Lintner's method and there was not a fixed relation between the amount of enzyme used and the weight of cuprous oxide formed.

Thus the 46 mg. of cuprous oxide in five cc. of Fehling solution were obtained in a Lintner test from 1.7 mg. of pancreatin. The same weight of pancreatin under the conditions of the gravimetric copper method gave only 14.4 mg. cuprous oxide, and increasing amounts of enzyme gave the following results:

Pancreatin, milligrams........	2.5	5.0	10.0	12.0	15.0
Cuprous oxide, milligrams....	27.0	62.8	202.6	270.0	379.0

In these experiments where only a small proportion of the starch was converted into maltose in any case, a given weight of pancreatin had a greater effect in 10 cc. than in 100 cc. of starch solution, while with different weights of pancreatin in the same volume (100 cc.) of starch solution the effect increased in greater proportion than the weight of pancreatin added. In both cases dilution appears to have injured the activity of the pancreatin.

The influence of dilution was studied directly by conducting experiments in pairs so arranged that the amounts of starch and enzyme and the conditions of time, temperature, etc., were exactly the same while the amount of water in which the action took place differed. At the end of the digestion enough water was added to the more concentrated solution to make the volumes the same for the determination of the reducing sugars which had been formed.

MILLIGRAMS CUPROUS OXIDE FROM REDUCING SUGARS FORMED BY 5 MILLIGRAMS ENZYME PREPARATION.

Enzyme and starch	In 55 cc	In 110 cc.
Taka-diastase No. 1, 2 grams starch	328	332
Taka-diastase No. 1, 4 grams starch	361	361
Pancreatin No. 1, 0.5 grams starch	170	115
Pancreatin No. 2, 3.0 grams starch	273	185
Pancreatin No. 4, 0.5 gram starch	110	68
Pancreatin No. 5, 0.5 gram starch	94	66

Here the taka-diastase produced the same effect when working in different amounts of water, but the pancreatins produced much less in 110 cc. than in 55 cc.—the activity of the pancreatic amylase was evidently diminished by its dilution with neutralized distilled water.

From these results and those above given it is evident that the diastatic power of pancreatic amylase was largely influenced by the ratio of amylase to water. Under these conditions, therefore, the testing of fixed amounts of commercial preparations containing varying amounts of actual amylase cannot be expected to give reliable results. This is because of the influence of electrolytes in activating the amylase.

In these experiments no electrolyte was added other than the small amounts of salts accidentally present in the soluble starch and the neutralized distilled water, hence there was insufficient electrolyte present either to fully activate the enzyme or to protect it from deterioration on standing in water solution. Hence the greater the amount of water present the less favorable the condition for enzyme activity. The optimum conditions as worked out for pancreatin and which permit of the accurate determination of its diastatic power by the grav metric method were not worked out until after our experiments with the iodine methods and will, therefore, be described later.

Johnson's iodine method gave us even less satisfactory results with pancreatin than with taka-diastase for the reason that as the digestion proceeds the test portions from the digestion mixture, when they no longer give a blue color with iodine, do give a red color which on continuing the digestion persists for a comparatively long time and disappears by almost imperceptible degrees so that it is extremely difficult to decide when the digestion should be considered finished.

The new iodine method showed in our experiments upon pancreatin the same advantages over Johnson's method as were noted in the experiments with taka-diastase, but still did not give a very satisfactory end point because of the rather long duration and gradual fading of the red color reaction. That the activity of the commercial pancreatin may be greatly increased by addition of a small amount of salt was shown almost as prominently by this iodine method as by the determination of the reducing sugar formed. Each of the four samples of commercial pancreatin tested digested 2.5 to 7 times as much starch under standard conditions in a solution containing 0.1 per cent. of added sodium chloride as in one to which no electrolyte was added. The stronger two preparations were tested in 0.3 per cent. salt solution and showed the same apparent activity as in the 0.1 per cent. solution.

By these and many other analytical data which must here be omitted for the sake of brevity, we became convinced that it is illogical and misleading to attempt to determine the diastatic power of pancreatin by its action upon pure starch in pure water because such a medium is too poor in electrolytes to permit the amylase to function normally, and that the conditions necessary for the amylase to function normally should be worked out and incorporated in the method to be used in the future for the determination of diastatic power. This led to a somewhat extended study of the action of pancreatic amylase the main results of which will be given in the next paper. The analytical procedure employed in that study and the optimum conditions for pancreatin as there found are included in the following description. Under these optimum conditions we obtain in testing commercial pancreatins results about 20 times as high as when no electrolyte is added.

PROPOSED GRAVIMETRIC METHOD.

Materials and Conditions.

Starch.—The starch for careful gravimetric work should be Lintner soluble starch, which gives a perfectly clear solution with boiling water. Ford[1] discusses very fully the preparation of such a starch. It should have a reaction with rosolic acid equivalent to less than 0.5 cc. of 0.01 normal acid or alkali per gram of anhydrous starch. In the anhydrous state it is quite hygroscopic; air-dry it contains about 15 per cent. of moisture. The lower the reducing power the better, but a reduction of 30 mg. of cuprous oxide per gram of anhydrous starch is not too large for accurate work.

Water.—The water used must be as nearly pure and as constantly uniform as is possible; redistilled and practicaly neutral to rosolic acid.

Temperature.—We prefer a temperature of 40° for all diastatic power determinations. This is obviously most suitable for the amylases of animal origin and there are important advantages and no important disadvantages in the use of the same temperature for the vegetable amylases. The solutions and flasks should be as near 40° as possible at the time of actually mixing the enzyme and the starch. The temperature should remain constant during the entire time of reaction, as a variation of one degree causes about 10 per cent. error in the result.

Time.—Since the time must in any case be somewhat arbitrarily chosen, we have decided upon 30 min. as best meeting the requirements of accuracy and convenience of working.

---

[1] *J. Soc. Chem. Ind.*, 23, 414 (1904).

Enzyme.—The enzyme may be dissolved in pure water if its power is to be tested immediately. If it is to stand, it should be dissolved in water containing 4 cc. of fiftieth-molar disodium phosphate per 100 cc. The test should be made within an hour in any case. The amount of enzyme to be weighed out will depend entirely on its strength.

One may dissolve the enzyme in a small amount of water and use a very small volume, or use a larger volume for the solution of the enzyme and measure larger amounts for the determination. We employed the former method, using a special 1 cc. pipette which was very accurately graduated. The actual weight of enzyme added to the starch solution varied from 0.1 to 1.0 mg.

Activating Agents.—These will doubtless differ with the different amylases. For pancreatic amylase acting on two per cent. starch, add 300 mg. sodium chloride and 7 cc. of fiftieth-molar disodium phosphate per 100 cc. (final volume) of reaction mixture.

Procedure.—Prepare 400 cc. of 2 per cent. soluble starch solution and the enzyme solution of such a strength that 1 cc. will contain from 0.4 to 1.0 mg. of enzyme. By means of a 1 cc. Mohr's pipette, accurately calibrated in hundredths, measure into four 200 cc. Erlenmeyer flasks such volumes of the solution as will contain 0.2, 0.5, 0.8, and 1.0 mg. of enzyme, respectively.[1] Now 100 cc. of the starch solution previously warmed to 40° is poured into each flask and the digestion allowed to proceed for 30 minutes, the temperature being accurately maintained at 40°. At the expiration of the 30 minutes, stop the reaction quickly by mixing at once with 50 cc. of Fehling solution and immerse the flask in a large bath of boiling water for 15 minutes. See that the water of the bath is kept boiling and that it stands above the level of the contents of any of the flasks. At the end of this heating filter quickly and determine the reduced copper by any accurate method. We prefer to filter through Gooch crucibles having thick felts of specially prepared asbestos, wash the cuprous oxide thoroughly with hot water, then twice each with alcohol and ether and weigh it as such after drying for at least 20 min. in a boiling water oven. The weight of cuprous oxide must not exceed 300 mg.

Correct the weight of reduced copper or cuprous oxide found for the reducing power of the soluble starch by subtracting from it the weight obtained in a "blank" test in which the starch solution is treated directly with the Fehling reagent.

Under the conditions here described the reducing power of maltose was found to be approximately the same as in Defren's method, so that the weight of cuprous oxide may be calculated to cupric oxide and the corresponding weight of maltose taken from Defren's table.

---

[1] The quantities suggested are such as were suitable for the pancreatins which we have tested. In testing other substances larger or smaller quantities may be necessary.

To express the results in terms somewhat comparable with those of Lintner's scale, multiply the weight of cuprous oxide by 0.2415, divide by the time in hours, and by the weight of enzyme preparation in milligrams. Results so obtained cannot, however, be considered as interchangeable with those found by Lintner's method because of the conditions of the determination and the form of the velocity curve of the reaction.

As will be more fully shown in the next paper, the rate of the amylolytic action is not constant up to a conversion of a considerable percentage of the original starch as Kjeldahl and others have held, but decreases as the conversion proceeds from the start, so that whatever the method of procedure the differing weights of cuprous oxide cannot be taken as standing in simple proportion to the actual diastatic power. However, if the velocity curve of the amylolytic action be plotted with time as abscissas and yield of reducing sugar as ordinates a scale may be established which will permit of an expression of true diastatic power based upon the weight of cuprous oxide obtained as above described. If 300 mg. of cuprous oxide be taken as 100 on such a scale the value on this scale of any lesser weight of cuprous oxide is obtained by expressing the abscissa corresponding to such weight as percentage of the abscissa for 300 mg. cuprous oxide. Calling the series thus obtained values of *K*, the diastatic power of the sample under examination is determined by dividing the value of *K* corresponding to the weight of cuprous oxide found by the number of milligrams of sample used to effect this conversion.

In the next paper in the consideration of the velocity of the reaction the mathematical relation between time and extent of conversion will be shown. From this relation an integral equation is deduced making it possible to establish this series by a mathematical means. The use of this equation verifies the experimental results and gives a convenient method for establishing values of *K*.

The accompanying table was constructed by finding the value for *K* from the equation for the action of pancreatic amylase upon 2 per cent. starch for every 10 mg. of cuprous oxide up to 300 mg.

VALUES FOR *K* FROM CUPROUS OXIDE FOUND.

Cuprous oxide. Mg.	*K*.	Cuprous oxide. Mg.	*K*.	Cuprous oxide. Mg.	*K*.	Cuprous oxide. Mg.	*K*.
30	9.1	100	31.2	170	54.1	240	78.3
40	12.2	110	34.4	180	57.5	250	81.8
50	15.3	120	37.6	190	60.9	260	85.4
60	18.4	130	40.9	200	64.3	270	89.0
70	21.6	140	44.2	210	67.8	280	92.6
80	24.8	150	47.5	220	71.3	290	96.3
90	28.0	160	50.8	230	74.8	300	100.0

In the equation, amounts of enzyme and time are reciprocal quantities. It is therefore evident that diastatic powers may still be compared when determined under different conditions of time as well as of amounts of enzyme employed.

The following example will illustrate how much more closely the results thus found correspond with actual amylolytic power than do the mere weights of cuprous oxide. In a set of determinations under uniform conditions 0.15, 0.30, 0.45, 0.60 mg of pancreatin yielded respectively 76, 147, 217, 286, mg. of cuprous oxide.

From the table we find the corresponding values of *K* to be 23.5, 46.5, 70.2, 94.8. Dividing these values by the respective weights of enzyme we obtain 156, 155, 156, 158. If we did not use the table, but divided the weights of cuprous oxide by three times the number of milligrams of enzyme, we would obtain 169, 163, 160, 159.

Furthermore, by application of this table, results obtained with different times of conversion may still be expressed on the same scale. With the proper activating agents present, any time of conversion from 15 minutes to two hours may be employed; and, if the amount of cuprous oxide does not exceed 300 mg., the results may be calculated as follows: Divide 30 (the standard time for the method described above) by the actual time of conversion in minutes, and multiply by the value of *K* as found in the above table. The product will equal the value which would have been obtained for *K* under standard conditions.

The procedure of the Lintner method may likewise be used and from the known weight of cuprous oxide in the tube in which the 5 cc. of Fehling solution is just reduced one may (after correcting for the reducing powers of the starch used) make use of the above table and express the results on the new scale of diastatic values.

Summary.

1. There seems to be no good reason for the diversity of conditions of temperature and time which have been given by different writers in the past, and it seems desirable that in all determinations of diastatic power the amylase be allowed to act at 40° and that 30 minutes be adopted as the standard time.

2. The Lintner method is sound in principle but does not prescribe optimum conditions, is not very delicate, and does not give a satisfactory degree of accuracy when applied to preparations of high diastatic power.

3. The gravimetric method as here described is capable of much greater accuracy and gives results which can either be stated in terms of cuprous oxide actually weighed, or of maltose, or in terms comparable with those of the Lintner scale, or on a new scale based upon the velocity curve of the reaction.

4. The new iodine method is believed to increase considerably the practicable accuracy of this type of determination and while it probably cannot be made as delicate as the improved gravimetric method, yet for those cases in which a satisfactory end point can be obtained, it has the practical advantage of simplicity and the theoretical advantage of marking the completion of a fairly definite step in the digestive process, whereas the copper reduction method measures the amount of a substance or substances produced by successive steps through intermediate products which are but imperfectly known.

5. With the three samples of taka-diastase examined, the end point in the iodine method was fairly satisfactory, consisting in a change from light blue to nearly colorless, and the results by the method were consistent with those by the Lintner method. It remains to be determined by examination of a larger number of samples under a variety of conditions whether the two types of method will give parallel results with taka-diastase throughout, or whether each method is capable of giving information which the other does not.

6. In the case of pancreatin, the iodine method does not seem capable of great accuracy because of the uncertainty in judging the point of change from a blue to a red reaction with iodine, and the comparatively long duration of the stage which gives the red color and which fades almost imperceptibly into the faint straw color of the iodine test solution itself.

7. With the copper reduction methods also, much more difficulty was experienced with pancreatin than with taka-diastase. In spite of all efforts to eliminate interfering impurities, irregular results were persistently obtained. This fact indicated the need of a detailed study of the action of pancreatic amylase, the results of which study are described in the paper which follows.

8. In the absence of added electrolytes the pancreatic amylase was so incompletely activated that it could not behave normally and was extremely susceptible to slight variations in the amounts of salts, acids, or alkalies accidentally present, so that the results were both misleadingly low and irregular. It is evident that in testing amylolytic power it is not the presence of electrolytes but their absence or insufficiency that constitutes the disturbing condition, and that reliable results are obtained only when the enzyme is properly activated so that it can function normally.

9. A gravimetric method is proposed which utilizes the results of a quantitative study of the action of pancreatic amylase, which study is described in the following paper. By this method, employing optimum amounts of salt and alkali for activation, we obtain in testing commercial pancreatins, results about 20 times as high as when no electrolyte is added.

STUDIES ON AMYLASES. II. A STUDY OF THE ACTION OF PANCREATIC AMYLASE.

By E. C. KENDALL AND H. C. SHERMAN.

Received June 28, 1910.

In an examination of methods for the determination of diastatic power[1] it was found particularly difficult to obtain concordant results with pancreatin, and the peculiar behavior of the pancreatic amylase made plain the desirability of a special study of its action. The main results of this study are here given in as condensed and systematic a form as possible and not necessarily in the chronological order of the experiments.

Materials and Methods.

Enzyme Preparations.—In the experiments described in this paper the pancreatic amylase has been used in the form of commercial pancreatin. Seven samples purchased in New York City at various times during 1907–9 showed, when tested in the favorable conditions worked out during the investigation, the following relative diastatic powers: No. 1, 16; No. 2, 151; No. 3, 9; No. 4, 105; No. 5, 75; No. 6, 78; No. 7, 66. The stronger preparations which presumably contained the smaller amounts of impurities were used in the experiments described beyond.

Starch.—The soluble starch used was prepared by the Lintner[2] method with attention to the details discussed by Ford.[3] After completion of the acid treatment and removal of most of the acid by washing, the starch was transferred to a large glass bottle and washed about 65 times by decantation with about twice its bulk of water. At each washing the starch was vigorously mixed with the water by rolling the bottle back and forth on a table, after which the starch was allowed to settle thoroughly and the water siphoned off. This was repeated 3 or 4 times daily for about 3 weeks. The starch was then brought upon a Büchner funnel and the wash water removed as thoroughly as possible by suction, the slight acidity of the starch determined by titrating a weighed portion with $N/100$ alkali, using rosolic acid as indicator. The starch was then given a final washing with water containing the very small amount of sodium hydroxide calculated as necessary for its neutralization, filtered with thorough suction and air-dried. Four different preparations made in this way showed 12 to 17 per cent. of moisture, required 0.1 to 0.3 cc. of N/100 acid or alkali per gram for neutralization, and showed reducing powers of 27 to 30.5 mg. cuprous oxide per gram of anhydrous starch.

[3] *J. Soc. Chem. Ind.*, 23, 414 (1904).

Water.—Ordinary distilled water was found to be a cause of irregular results, especially when working without added electrolyte, nor did neutralization of such water render it satisfactory. In all subsequent work we used water which had been redistilled from alkaline permanganate, the steam being passed through a long column of glass wool to filter out any possible spray.

Procedure.—Unless otherwise stated the procedure was that of the gravimetric method for diastatic power proposed in the preceding paper except for the activating agents. The results are expressed in milligrams of cuprous oxide weighed, corrected for the reducing power of the particular soluble starch used in each experiment. In case it was impossible to determine at once the reducing sugars formed in an experiment, so that a means of stopping the enzyme action and preserving the solution was necessary, the addition of hydrochloric acid enough to make 0.1 per cent. stopped the action of the amylase at once and did not affect the reducing power of the solution, even on standing 24 hours. In cases in which the amylase acted more than one hour, a mixture of toluene and chloroform was added to prevent bacterial growth and evaporation. This was effective and had no influence upon the amount of copper reduced.

Influence of Added Electrolytes.

Neutral Salts.—As early as 1875, Nasse[1] held that there is an important and specific dependence of the activity of ferments upon the presence of salts. In his experiments the addition of chlorides, nitrates, and sulphates of sodium, potassium, and ammonium raised the diastatic power of pancreatin by 7 to 31 per cent.

Grützner[2] compared the effects of sodium chloride, bromide, iodide, and fluoride.

Vernon[3] found that pancreatic extracts suffered less loss of diastatic power when diluted with tap water than with distilled water and that the addition of a small quantity of salt increased the activity, and also diminished the reduction of activity occasioned by dilution. The activity of his preparation was 30 times as great in 0.1 per cent. salt solution as in distilled water.

Preti[4] reported that the amylases obtained from the pancreas, urine, blood serum, malt and cryptogams were all rendered practically inert by dialysis and restored to activity by the addition of a neutral electrolyte.

Bierry and Graja[5] working in conjunction with Victor Henri found a similar result with pancreatin.

[2] *Ibid.*, 91, 195 (1902).

[3] *J. Physiol.*, 27, 174 (1901); 28, 156, 375 (1902).

[4] *Biochem. Z.*, 4, 1 (1907).

[5] *Compt. rend. soc. biol.*, 60, 479; 62, 432 (1906–7); *Compt. rend.*, 143, 300 (1906).

Slosse and Limbosch[1] also confirmed Preti's observations.

We have confirmed the observation that if both the pancreatin and the starch be first dialyzed in collodion sacks the pancreatic amylase becomes inactive but is reactivated by the addition of salt. Further experimentation showed that if the starch was dialyzed so that the only salts present were those of the enzyme preparation a small amount of high grade pancreatin was inactive; but was rapidly activated by the addition of very small amounts of salt.

Thus 0.35 mg. of pancreatin No. 2 in 50 cc. of 1 per cent. dialyzed starch at 40° for 1 hour showed after various additions of salt the activities indicated by the weights of cuprous oxide found as follows:

Sodium chloride milligrams .. .	0.01	0.1	1.0	10	30	60	90	121
Cuprous oxide milligrams... .	0	10	51	87	91	86	85	85

In another series of experiments 1 mg. of pancreatin No. 4 acted for 1 hour at 40° upon 100 cc. of 2 per cent. starch which had not been dialyzed with the following results:

NaCl. Mg.	Cuprous oxide Mg.	NaCl Mg.	Cuprous oxide. Mg.
0	13	60	183
0.1	34	100	182
0.5	90	200	182
1	119	400	167
5	171	600	168
10	178	800	158
20	186	..	..
25	180	..	..
30	187	..	..
35	193	..	..
40	194	..	..

Similar though less extended experiments upon four other samples of pancreatin gave confirmatory results.

If the enzyme preparation does not contain sufficient neutral electrolyte to completely activate the amylase, and no salt is added, a peculiar relation between rate of conversion and amount of enzyme is found. Doubling the amount of enzyme will more than double the rate of conversion, because doubling the amount of enzyme at the same time doubles the electrolyte in solution. Some results obtained with neutral solutions containing no added salt are:

Mg. Enzyme.	Mg. Cuprous oxide.
10	42
20	86
30	137
40	204
60	283
90	418

---

[1] *Bull. soc. roy. sci. med. nat. Bruxelles*, 1908, 80.

It is evident that salt not only helps the diastatic action but is essential to it. The salts accidentally present in commercial pancreatin and in very carefully prepared soluble starch are sufficient to enable the amylase to act to some extent, but any results so obtained are abnormal and entirely misleading as indications of real diastatic power, since pancreatic amylase acts in nature in a medium containing salt and must have an appreciable amount of some salt in order to function normally.

Experiments with potassium and ammonium chlorides gave similar results.

Alkalies.—Several investigators[1] of pancreatic and other amylases have reported alkalies harmful and some have found activity increased by the presence of a minute amount of acid, while others maintain that strict neutrality is the best condition for amylolytic action.

Tested without added electrolyte 5 mg. of pancreatin No. 5 acting upon 100 cc.[2] of 2 per cent. undialyzed starch for 1 hour at 21° gave the following results:

Cubic centimeters 0.01 N NaOH added. . .	0	1	2	3	4	6	8[1]
Milligrams cuprous oxide found .	71	61	49	42	24	14	4

These results were obtained by Meyer in the preliminary part of this study. No further experiments were made upon the influence of alkali alone because it was felt as already explained that any results obtained in the absence of sufficient salt to activate the enzyme must be regarded as abnormal.

Addition of Salt and Alkali.—Ebstein, in 1893,[3] showed that a degree of alkalinity which would otherwise stop the action of pancreatic amylase did not prevent a vigorous action when "blood salts" were present in the solution and this helpful influence of the blood salts appeared to be due chiefly to the sodium chloride. This observation does not seem to have been appreciated or followed up.

Our work has included a considerable number of observations of the same enzyme working in solutions containing sufficient salt but of varying alkalinity. In the following table are brought together results obtained at different times but which are fairly comparable in representing in each case the mg. of cuprous oxide reduced by the sugar formed from the action of 0.125 mg. of pancreatin No. 2 upon 0.25 grams of soluble starch[1] at 40° for the length of time stated.

EFFECT OF ADDED ACID AND ALKALI ON SOLUTIONS CONTAINING NEUTRAL ELECTROLYTE

Added acid or alkali.	Time.						
	10 min	30 min.	1 hr.	2 hrs	3 hrs.	5 hrs	25 hrs
8 cc 0.01 *N* H_2SO_4 per 100 cc			0		.	.	.
6 " " "			0		.		
4 " " "			3		7	..	..
3 " " "			87	151		222	277
2 " " "			153	218		251	272
1 " " "			223	242		254	271
Neutral			227	243		254	270
1 cc 0.01 *N* NaOH per 100 cc	143	207	235		240	252	..
2 " " "	156	204	226		244	250	
3 " " "	124	191	214		241	244	..
4 " " "			200	223	.	239	256
6 " " "			154	196		232	250
8 " " "			124	186		227	250
20 " " "			19		40	163	
30 " " "			11		18	40	
40 " " "			3		9	11	
50 " " "			0		4	6	

It will be seen from the data in the above table:

(1) That in solutions sufficiently acid, where the concentration of hydroxyl ion may be regarded as practically zero, there was no action; (2) that in passing from acid through neutral to faintly alkaline solutions the increasing concentration of hydroxyl ion is accompanied by an increased amylolytic activity up to the degree of alkalinity obtained by adding 2 cc. of 0.01 *N* sodium hydroxide per 100 cc. of solution; (3) that greater additions of alkali have a retarding effect but the action is not stopped except by the addition of relatively large proportions of 0.01 *N* solution; (4) that although the alkalinity of the solution has a great influence upon the speed of the reaction still there is a tendency toward a constant final yield of reducing sugar provided sufficient time be allowed.

In other experiments where a larger excess of starch was present the optimum amount of added alkali was found to be higher.

Experiments were also made in which varying amounts of sodium chloride and sodium carbonate were added. The following table shows the milligrams of cuprous oxide obtained by the action of equal amounts of pancreatin No. 2 upon equal volumes of 2 per cent. starch solution for 1 hour at 40°.

---

[1] One-half milligram pancreatin acted on 100 cc. of 1 per cent starch solution (containing the indicated amount of acid or alkali) of which 25 cc. were withdrawn and diluted to 100 cc. before treating with Fehling solution. The amount of added salt varied from 125–300 mg. and was sufficient in each case to activate the enzyme.

EFFECT OF ADDED SODIUM CHLORIDE AND SODIUM CARBONATE.

Sodium chloride. Mg.	Sodium carbonate, 00.1 N solution. 1 cc.	2 cc.	4 cc.	5 cc.	6 cc.	7 cc.	8 cc.	9 cc.	15 cc.
60– 100	234	248	280	290	284	278	250	244	84
120– 200	..	253	..	292	289	279	..	..	..
300– 400	..	..	..	290	291	278	256	261	96
500–1000	.	.	..	280	..	263	241	230	81

Comparison of these data with those previously given indicates that the amount of salt necessary to activate the enzyme is comparatively small (in none of these cases was it over 0.3 per cent.) and that moderate variations in the amount of salt added do not materially influence the optimum alkalinity so that even in alkaline solutions the helpful effect of the salt appears to be due to a direct activation of the enzyme rather than to its influence upon the ionization of the alkali.

If, however, the salt is insufficient to fully activate the amylase, the optimum alkalinity[1] rises with the concentration of salt. In a case of this sort the following results (expressed in mg. of cuprous oxide) were obtained:

EFFECT OF SALT UPON OPTIMUM ALKALINITY.

Added NaOH.	0.	1.	2.	3.	4.	5 cc. 0.01 N.
1 milligram NaCl	110	103	85	61	.	..
5 milligrams NaCl	214	243	233	202	..	..
500 milligrams NaCl	..	.	400	427	430	296

That the optimum alkali was higher here than in the preceding table is due to the fact that more starch was used. This relation will be fully explained later in this paper.

The results of some of the experiments made to compare the effects of different alkalis in the presence of a uniform amount of salt are shown in the following table.

As would be expected the optimum is reached more quickly and the retarding effect of excess is more pronounced with carbonate that with phosphate and with hydroxide that with carbonate. The activity at optimum concentration is, however, very nearly the same in all cases except with ammonia where the lower results may very probably be due to a solvent effect upon the cuprous oxide. It should also be noted that the unit of comparison is fiftieth-molar for phosphate while the hydroxide and carbonate solutions were 0.01 N by titration with standard acid.

---

[1] The above results show plainly the increase of activity produced by adding alkali in the presence of sufficient salt. Since Cole (*loc. cit.*) has shown that the activity of ptyalin is increased by acid it is suggested that some amylases may use the hydroxyl and others the hydrogen ion to accomplish the hydrolysis of starch. This point should be studied further upon other amylases sufficiently activated by salt.

The conditions for all these determinations were: One-half mg. pancreatin No. 4. Sodium chloride, 700 mgs. Temperature, 40°. Time, 60 min. Starch, 2 per cent.

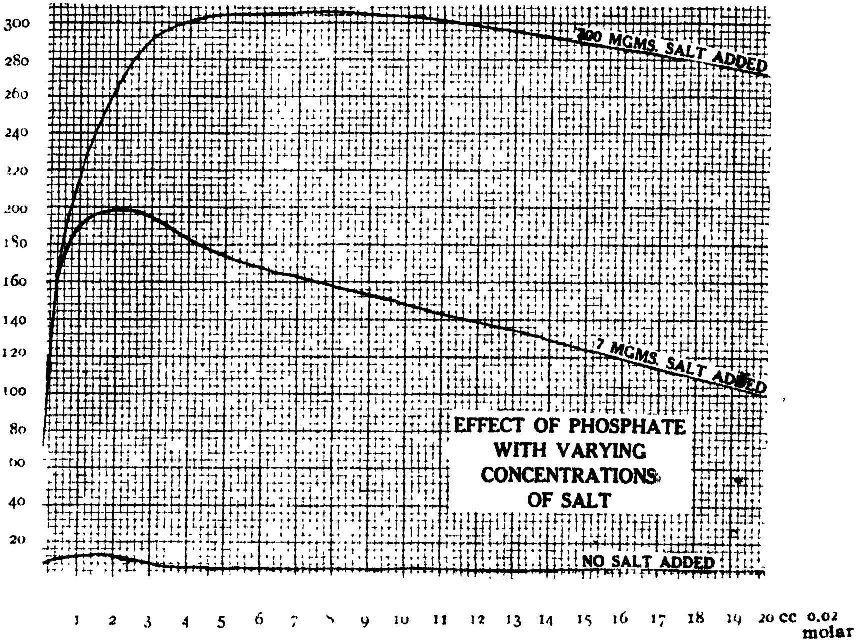
30..............	..	77	264
40..............	35	69	236

Where no salt was added 20 times as much enzyme was used for the experiment in order to get a comparable yield of reducing sugar, hence the partial activation by the salts accidentally present.

Since the figures in one column are for a much larger weight of pancreatin than in the others, the effect may be more readily seen from the following curves:



When the phosphate alone was added in small amount it caused a rapid rise in speed of conversion but in slightly larger amounts its effect was depressing. At the optimum concentration of the phosphate alone the enzyme was very incompletely activated.

With the addition of a small amount of salt, sufficient largely, but not completely, to activate the enzyme, small additions of phosphate greatly increased the speed of the reaction while slightly larger amounts had a marked retarding action.

With the addition of an abundance of sodium chloride (0.7 per cent.) the phosphate continued to increase the speed of the reaction up to a much greater concentration, giving a maximum much higher than with the smaller amount of chloride, and beyond the maximum there was only a very gradual retardation as the additions of phosphate were still further increased.

The following results were obtained with 0.35 mg. of pancreatin 2, with 5 cc. of 0.01 normal sodium carbonate in 100 cc. of a solution of 2 per cent. starch.

EFFECT OF SALT ON THE TIME CURVE.

Quantitative Relations of Enzyme, Starch Salt and Alkali.—In the experiments described in this paper we have usually employed (as will be seen from the descriptions accompanying the data) from 0.1 to 1 mg. of high grade commercial pancreatin. Our recent experiments upon the purification of pancreatic amylase give evidence that the pancreatin here used contained at least 90 per cent. of material other than actual amylase and as the volume has usually been 100 cc., we have a concentration not greater than 1 : 1,000,000 to 1 : 10,000,000 of actual amylase in the solution. Considerations of actual quantities relate, therefore, to starch, salt and alkali.

In discussing the influence of added salt and alkali, experiments have already been described in which the diastatic action was seen to rise rapidly at first with increasing concentrations of salt, after which a much greater increase of salt had very little effect. As further examples the following three pairs of determinations may be cited:

All other conditions being the same for the two tests in each set,

50 milligrams of salt gave 280 milligrams cuprous oxide.
1000 milligrams of salt gave 270 milligrams cuprous oxide.

100 milligrams of salt gave 84 milligrams cuprous oxide.
1000 milligrams of salt gave 81 milligrams cuprous oxide.

90 milligrams of salt gave 238 milligrams cuprous oxide.
2000 milligrams of salt gave 228 milligrams cuprous oxide.

It is also apparent from the table of results showing effect of added sodium chloride and sodium carbonate that the optimum alkalinity did not increase with increasing additions of salt. On the other hand there is an evident tendency to a higher optimum of alkalinity with an increasing concentration of starch. Thus 1.05 mg. pancreatin No. 2 acting for 20 minutes at 40° upon 100 cc. solutions containing 500 mg. salt and different amounts of starch and alkali gave the following results expressed in milligrams of cuprous oxide.

These results, as well as other data obtained under different conditions, including smaller and larger concentrations of starch, indicate that the amount of alkali to be added in order to obtain the most rapid conversion (*i. e.*, the optimum addition of alkali) increases with the concentration of the starch and that this optimum alkalinity is rather sharply defined for low concentrations of starch and becomes much less sharply defined as the concentration of the starch is increased.

Alkali added. Cc. of 0.01 *N* NaOH.	Starch, grams.			
	0.5	1 0	2.0	3.0
2	203	271	276	269
3	87	170	285	271
4	45	86	245	293
5	35	47	115	259

Thus the quantity of starch not only influenced the optimum of added alkali, but the enzyme was largely protected from the retarding effects of alkali in excess of the optimum by moderate increase in the concentration of the starch, whereas a proportionate increase in the amount of salt added had no noticeable effect.

Velocity and Equilibrium of the Reaction.

Influence of Concentration of Starch.—The following experiments bear upon the relation between amount of starch and the speed of its hydrolysis. Different amounts of pancreatin No. 6 were allowed to act at 40° upon a uniform volume (100 cc.) of starch solution whose strength was varied in the different cases from 0.1 per cent. to 4 per cent. In all cases 700 mg. of sodium chloride and 10 cc. of 0.02 molar disodium phosphate per 100 cc. of solution were added. The time of reaction was one hour. The figures are mg. of cuprous oxide reduced by the sugar formed under the given conditions.

Starch Per cent.	Pancreatin. mg.			
	0 15.	0.30.	0.45.	0.60
4	78	156	235	313
3	78	152	225	299
2	76	147	217	286
1	69	132	196	259
0.5	66	123	172	223
0.3	60	108	145	177
0.2	58	100	125	142
0.1	48	70	78	83

In another series the amount of starch present was so small that in no case was the increase in speed of conversion directly proportional to the weight of enzyme used, but it is seen that the rate of conversion is more nearly proportional to the enzyme in the higher concentrations of starch. The conditions were: Time, 5 minutes. Temperature, 40°. Disodium phosphate, 1.5 cc. 0.02 molar and sodium chloride, 200 mg. per 100 cc.

Starch. Per cent.	Pancreatin, mg. 0.1	0.2	0.3	0.4
0.1	12	19	28	35
0.2	12	19	28	37
0.5	12	23	33	41

It will be seen from the above tables that with sufficient amounts of starch the speed of conversion was directly proportional to the amount of enzyme present, while with less starch the increase in speed was not in proportion to the increase of enzyme. The sufficiency of the starch is not a matter of the percentage strength of the starch solution, but of the ratio of starch to enzyme. This point will be considered more fully below.

Influence of Alkalinity.—It has been pointed out that the effect of increasing alkalinity is, first to accelerate the speed of conversion and then to retard it. It has also been shown that the optimum alkalinity varies with the percentage of starch and for this reason the effect of a given amount of alkali on the time curve may be, first, acceleration, and then retardation. Therefore, if the time curve was determined, *e. g.*, for a solution of 2 per cent. starch containing the optimum concentration of alkali at the start, as the conversion proceeded, the alkali, which would remain constant, would have a greater retarding influence as its ratio to the amount of starch present increased.

If, on the other hand, the concentration of hydroxyl ion were much below the optimum at the start the speed of conversion would be greatly retarded, but as the action continued there would be a constantly accelerating influence (due to the diminishing percentage of starch) and finally the rate of conversion in this solution would equal, or exceed, that of solutions having a greater initial concentration of hydroxyl ion. The following data and chart illustrate this effect of alkali on the time curve, the results being given in mg. of cuprous oxide.

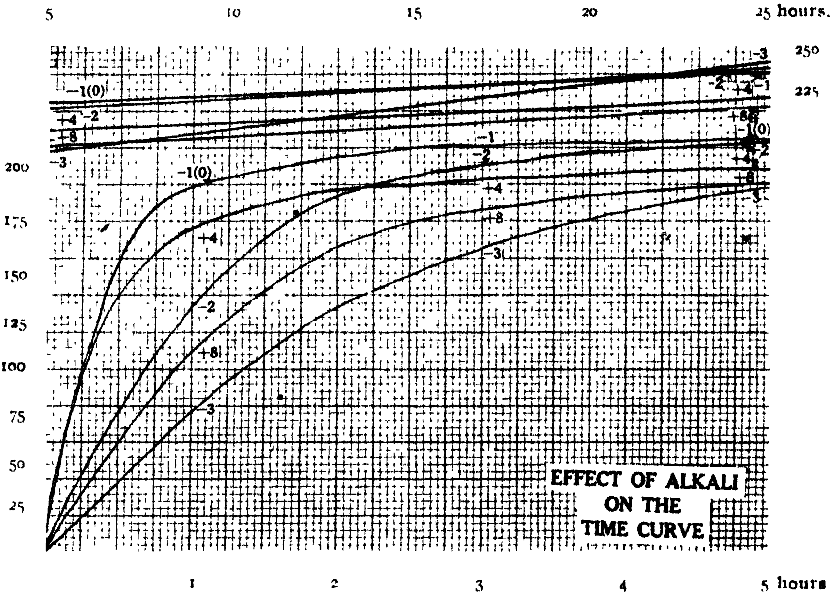
EFFECT OF ALKALI ON THE TIME CURVE.

Added acid or alkali.	Time, in hours. 1	2	5.	25.
3 cc. 0.01 *N* H_2SO_4	77	133	198	246
2 cc. 0.01 *N* H_2SO_4	135	193	222	242
1 cc. 0.01 *N* H_2SO_4	198	214	225	240
Neutral	201	215	225	238
3 cc. 0.01 *N* NaOH	199	212	218	230
4 cc. 0.01 *N* NaOH	177	196	211	227
6 cc. 0.01 *N* NaOH	136	173	205	221
8 cc. 0.01 *N* NaOH	109	165	201	221

The conditions for these determinations were: Starch, 1 per cent. Temperature, 40°. Volume (inclusive of added acid or alkali), 113 cc. Salt, 125 mg. Pancreatin No. 2, 5 mg.

This accelerating and retarding action of the alkali depending on the percentage of starch and therefore on the amount of conversion, explains one cause why previous investigators have found such varying conditions of alkali and acid for the optimum conversion of the starch.

An example taken from our work will show the great variation which may exist. When 4 per cent. starch was used and the time of conversion was limited to 20 minutes, 5 cc. of 0.01 *N* alkali per 100 cc. of solution were required for maximum speed of conversion. When 1 per cent. starch was used and 25 hours allowed for the time of conversion the greatest amount converted was in a solution containing 3 cc. of 0.01 *N* acid per 100 cc. of solution.



In discussing the curves we will designate the cc. of 0.01 *N* acid used as minus alkali; *e. g.*, —1, —2, or —3 will mean 1, 2, or 3 cc. of 0.01 *N* acid and +3, +4, +8 will mean cc. of 0.01 *N* sodium hydroxide.

The chart shows that a relatively high concentration of hydroxyl ion is required at first to give maximum speed to the reaction, but that a much lower concentration of hydroxyl ion will eventually cause the rate of conversion to equal, and finally exceed, that of the higher concentration. This is shown in the accompanying curves. At the end of 1 hour the amount of conversion is in the order 0, +3, —1, +4, +6, —2, +8, —3 cc. 0.01 *N* alkali. At the end of 5 hours the order is 0, —1, —2, +3, +4, +6, +8, —3, and at the end of 25 hours the order is —3, —2, — 1, 0, +3, +4, +6, +8.

The following set of determinations with varying amounts of alkali also illustrate this fact.

	5 min.	16 hrs.
0 cc. of 0.01 normal NaOH per 100 cc.	13	261
1 cc. of 0.01 normal NaOH per 100 cc.	15	251
2 cc. of 0.01 normal NaOH per 100 cc	17	245
3 cc. of 0.01 normal NaOH per 100 cc.	11	240

If we take the amount of the conversion in the first stages of the reaction we find the greatest speed in the solution containing 2 cc. of hydroxide per 100 cc., while after 16 hours the neutral solution shows the highest result.

A series of results where the time interval was less shows the effect of alkali in the first part of the conversion. The total time of digestion was only 5 hours, so the last set of figures does not represent the final equilibrium.

EFFECT OF VARIOUS CONCENTRATIONS OF ALKALI.

	Cc 0.01 *N* NaOH per 100 cc.			
Minutes.	0	1.	2	3
10.	124	143	156	124
20	185	195	194	177
30..	195	207	204	191
60	217	235	226	214
120	222	240	235	231
180.	229	241	244	241
240	231	248	246	243
300.	232	252	250	244

The conditions were: Temperature, 40°. 5 mg. of pancreatin 2. 300 mg. of sodium chloride per 100 cc. 1 per cent. starch.

Here, although the increments of alkali were very small, their influence was apparent throughout the five hours of the experiment.

To test the effect of a less caustic alkali sodium hydroxide and disodium phosphate were compared with the following results (expressed in mg. of cuprous oxide) in experiments on 1 per cent. starch containing 300 mg. sodium chloride per 100 cc.

Time. Minutes	With NaOH [1]	With Na_2HPO_4.[2]
5	48	49
10	85	88
15	119	124
20	145	151
25	164	170
30	174	180

The depressing effect of the alkali as the reaction proceeds is shown to be less with the phosphate than with the hydroxide.

---

[1] 2 cc. 0.01 *N* NaOH.

[2] 2 cc. 0.02 molar disodium phosphate.

Our results indicate that the point of final equilibrium in the conversion of starch by pancreatic amylase is but little influenced by variations in hydroxyl ion concentration within the limits which permit the action to take place with measurable speed. In the experiments already described in which the conditions varied from an addition of 3 cc. of 0.01 N H_2SO_4 to 8 cc. of 0.01 N NaOH the great difference of hydroxyl ion concentration was accompanied by a difference of only ten per cent. in the amount of reducing sugar found at the end of 25 hours.

In another series of experiments 10 mg. of pancreatin were allowed to act upon 4 grams of starch in 350 cc. of water containing 125 mg. salt per 100 cc. for about 16 hours. The solution was then divided into four equal parts, 5 mg. more of enzyme and the desired amounts of alkali were added to each part, and the reducing sugar found in the different flasks. The amount of conversion was found after the flasks had stood 1, 5 or 45 hours.

While the results do not agree exactly they show that there was no decided change in any of the flasks. The results are expressed in mg. of cuprous oxide.

	Cc 0 01 N NaOH per 100 cc.			
	0	10.	20.	30
When divided.	255	255	255	255
1 hour later	257	259	256	255
5 hours later	261	259	255	253

Another set with larger amounts of alkali gave:

	Cc. 0 01 N NaOH per 100 cc			
	20	30	40.	50
When divided	250	250	249	246
45 hours later	258	253	255	254

While there was a slight change in these solutions, still there was no decrease in reducing sugar to indicate reversion and within the limits of experimental error they all attained the same equilibrium.

Further, the equilibrium was not influenced by the amount of enzyme present. After standing 20 hours a solution containing 3 mg. of enzyme reduced 264 mg. of cuprous oxide and the same solution with 12 mg. of enzyme reduced 266. Two other solutions containing 3 and 12 mg. of enzyme reduced 246 and 249 mg. cuprous oxide respectively.

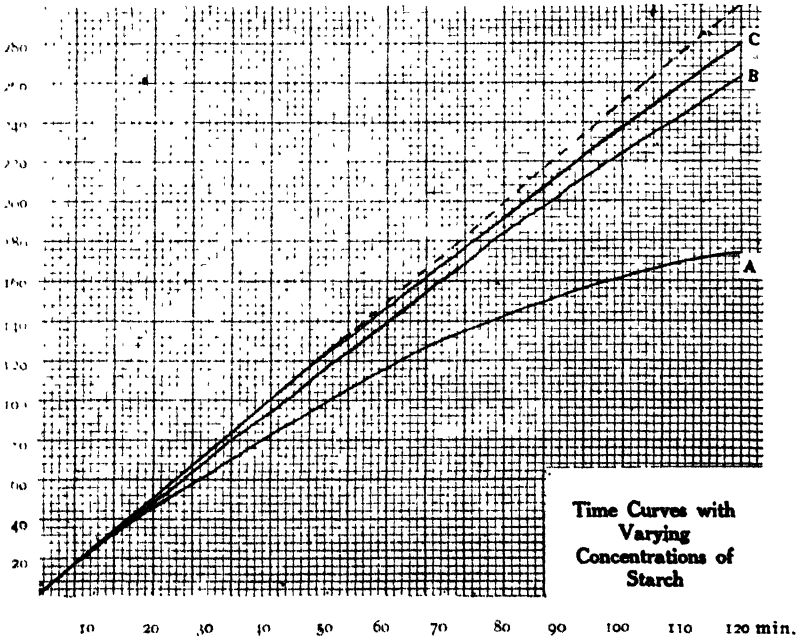
Velocity of Reaction.—Our principal data bearing upon the velocity of the reaction for different concentrations of starch were obtained in 4 series of experiments. In each experiment of the first 3 series (A, B, C) 0.6 mg. pancreatin No. 6 acted for the time indicated upon starch solutions the strengths of which were for series A, 0.5 per cent.; for B, 2 per cent.; for C, 4 per cent.; and which contained in all cases 700 mg. sodium chloride and 10 cc. of fiftieth-molar disodium phosphate per 100 cc. In series

D 5 mg. of pancreatin No. 2 acted upon 1 per cent. starch solution containing 700 mg. sodium chloride and 1.5 cc. of 0.01 *N* sodium hydroxide per 100 cc.

The results of the four series expressed in mg. of cuprous oxide were as follows:

Time. Min	Curve A.	Time Min.	Curve. B.	Curve. C	Time. Min.	Series. D.
20	47	10	25	25	5	81
40	83	20	48	50	10	140
60	117	30	72	74	15	172
80	142	40	94	100	20	184
100	160	50	118	125	25	194
120	174	60	138	147	30	198
140	179	70	160	170	40	204
160	187	80	185	192	55	212
180	189	90	204	215	70	214
200	193	100	224	237	100	221
220	197	110	243	259	130	225
240	199	120	263	280	190	230

The results of series A, B, and C are also shown graphically in the accompanying curves:



It will be seen from the data and curves (1) that the *initial* speed of conversion for a constant amount of enzyme was the same for the three different concentrations of starch; (2) that the speed of the reaction diminished more rapidly the smaller the initial concentration of the starch.

By a mathematical consideration of the relation between the original concentration of the starch and the amount of reducing sugar estimated as maltose formed, the following differential and integral equations were deduced:

$$\frac{dx}{dt} = K\left(\frac{C - x}{C + x} - \frac{x}{PC}\right)$$

and

$$\frac{PC(1-P+\sqrt{R})}{2\sqrt{R}M}\left(\log_{10}\frac{\sqrt{RC}+PC+C}{\sqrt{RC}+PC+C+2x} + \frac{\sqrt{R}+P-1}{\sqrt{R}-P+1}\log_{10}\frac{\sqrt{RC}-PC-C}{\sqrt{RC}-PC-C-2x}\right) = Kt.$$

In these equations:

C = original concentration of starch;

x = varying concentration of reducing sugar;

P = a constant;

R = $(P^2 + 6P + 1)$;

M = the logarithm of e to the base 10.

The value for P is determined by substituting the experimental results of series B and C in the equation and finding a number which gives constant values to K for the entire series of observations. The value thus found for P was 12. When the numerical data of our experiments were substituted for these letters the equation reduced to the form

$$\left(\log_{10}\frac{13.865\,C}{13.865\,C + x} + 6.9\log_{10}\frac{0.865\,C}{0.865\,C - x}\right) = Kt.$$

It is by means of this equation that the values of K given in the preceding paper were established.

Influence of Temperature.—Vernon[1] pointed out the fact that Roberts found an optimum temperature at 30°. The activity remained at its maximum until 45°, when it rapidly diminished to 70°, where it ceased. Vernon himself gives figures (with tap water) indicating 35° as the optimum temperature and the activity still existing at 65°. When he used 0.2 per cent. salt the results were widely different. The maximum activity was then at 50° instead of 35° C., but the action ceased between 65° and 70°.

Our results on the effect of temperature are as follows:

When no added electrolyte is present the effect of increasing the temperature from 21° to 40° is to depress the activity. The following Lintner figures were obtained with 4 samples of pancreatin:

Lintner figure		Per cent.
at 21° C.	at 40° C.	40°/21°.
6.98	5.78	83
1.27	1.16	91
13.79	12.22	88
1.38	0.83	60

---

[1] *J. Physiol.*, 27, 174 (1901).

If, however, the proper amounts of salt and alkali are present the activity at 40° is nearly four times as great as at 21°.

The following figures were obtained with pancreatin No. 6, by the regular gravimetric method followed throughout the work. There were 10 cc. of 0.02 molar disodium phosphate and 700 mg. of salt present in every 100 cc. of solution. One-half mg. of enzyme was allowed to act for 1 hour in each case.

Temperature.	Cuprous oxide Mg.
21°	65
30°	122
40°	238
45°	298
50°	345
55°	378
60°	256
65°	66

Between 20° and 40° the speed is about doubled every 10°, in accordance with van't Hoff's rule for normal chemical reactions; between 40° and 55° the acceleration is less, but temperature still has a great effect. Beyond 55°, where the maximum activity was obtained, the rate of change decreases very rapidly.

The depressing effect of increasing the temperature on amylase in solutions without added salt and alkali may be due to the fact that the water itself has a greater paralyzing effect at the higher temperature. We know that pure water, acting on pancreatic amylase free from neutral electrolyte, gradually destroys it, but if a trace of salt and alkali are present it will remain active for a long time.

Influence of Asparagine.—Marked differences of opinion exist as to whether asparagine really increases the diastatic power of amylases or only helps to give them favorable conditions for activity by regulating the reaction of the solution.

We have experimented upon the effect of asparagine in two ways:

First, by determining the time curve for solutions containing alkali with and without the addition of asparagine. The results of these showed no increase of activity in the presence of the asparagine.

The results are as follows:

	Cuprous oxide, mg.			
Minutes.	A.	B.	C.	D.
5	48	46	49	47
10	85	81	88	86
15	119	118	124	122
20	145	142	151	149
25	164	162	170	168
30	174	175	180	179

Solution A contained 2 cc. 0.01 *N* sodium hydroxide per 100 cc.
Solution B contained 2 cc. 0.01 *N* sodium hydroxide + 50 mg. asparagine.
Solution C contained 2 cc. 0.02 molar disodium phosphate.
Solution D contained 2 cc. 0.02 molar disodium phosphate + 50 mg. asparagine.

In a second series we added asparagine to solutions containing increasing amounts of alkali as phosphate.

So long as the amount of phosphate was below the optimum the addition of asparagine depressed the activity of the amylase. When so much phosphate was added that its alkalinity depressed the action, the addition of asparagine helped to counteract the effect of the excess of alkali and to allow the enzyme to act normally. The results follow:

Alkalinity of solution. cc 0.02 molar Na_2HPO_4 per 100 cc	Mg. cuprous oxide	
	without asparagine.	with asparagine.
2	260	227
3	(290)	281
4	301	291
5	(304)	309
6	307	312
7	(308)	327
10	313	329
16	296	329
20	273	324
30	264	316
40	236	307

In the presence of 10 cc. of 0.02 molar disodium phosphate increasing the amount of asparagine had no effect.

Asparagine. Mg.	Cuprous oxide. Mg.
10	321
100	329
150	328
200	330
300	324

Summary.

1. Pancreatic amylase when tested in the form of high grade commercial preparations upon soluble starch prepared by the Lintner method and purified by dialysis, was inactive, but was activated by the addition of a small amount of neutral electrolyte and was still further activated by the addition of both salt and alkali.

2. Until the enzyme was fully activated the optimum concentrations of salt and alkali appeared to depend upon each other; beyond this point the optimum concentration of alkali appeared to depend primarily upon the concentration of the starch.

3. With a given amount of enzyme, properly activated, the initial rate of hydrolysis was not dependent upon the amount of starch; as the re-

action proceeded its rate diminished but less rapidly the greater the amount of starch present.

4. Working with 1 per cent. starch, however favorable the conditions of salt and alkalinity and however large the amount of enzyme, the hydrolysis tended to come to equilibrium when the weight of maltose reached about 85 per cent. of the initial weight of starch.

5. In the presence of more than the optimum amount of alkali the point of equilibrium was approximately the same if sufficient time was allowed and fresh enzyme added during the reaction.

6. The data obtained have been applied in a method of determining and expressing diastatic power based upon the optimum conditions of salt and alkalinity as found for pancreatin and the quantitative relation between the amount of amylase and the reducing sugar it produces as shown by the velocity curve. The description of this method has been given in the preceding paper.

7. Between 20° and 40° the action of pancreatic amylase (properly activated by sodium chloride and sodium phosphate) showed a temperature coefficient approximating van't Hoff's rule for normal chemical reactions, since it nearly doubles for a rise of 10°.

8. Tested in solutions of varying alkalinity containing sodium chloride and sodium hydroxide or sodium phosphate, asparagine showed little, if any, effect not explainable by its influence upon the alkalinity of the solution.

NOTE.

Note: Preparation of ortho- and para-Nitrophenols.—The preparation of the nitrophenols as ordinarily carried out is accompanied by the production of much tar and is a somewhat unpleasant operation. The yield of the para compound is small, 50 grams of phenol giving according to Gattermann only from 5 to 10 grams of para-nitrophenol. Inexperienced operators often get no more than one or two grams of the compound, if any at all. This justifies the publication of the improvement recommended in the present note.

The production of tar is completely avoided and a yield of 18 per cent. of para-nitrophenol (13 grams from 50 grams of phenol) is obtained uniformly, *if the nitric acid is vigorously stirred during the addition to it of the phenol.* The results given below were obtained by carrying out the operation as follows: A solution of 80 grams sodium nitrate and 100 grams of strong sulphuric acid in 200 cc. of water was energetically stirred with the aid of a small water motor and kept at about 25°. To this was added drop by drop, at the rate of about 30 or 35 drops a minute, out of a separatory funnel, a solution of 50 grams crystallized phenol in 5 grams alcohol. The stirring was continued for about one-half hour after the addition of the phenol was completed, the mixture was allowed to stand for an hour and one-half longer, and then treated, as usual, with double its volume of water. The heavy oil that separated out was reddish-brown in color, but invariably transparent and free from sticky or tarry ingredients. The oil was washed two or three times with water and subjected to distillation with steam. The distillate yielded slightly less than 30 grams of a beautiful ortho-nitrophenol (the quantity obtained by Gattermann). The residue was evaporated to less than half its volume, boiled with 20 grams of bone-black, filtered hot, and allowed to crystallize in the cold. Two consecutive operations yielded, respectively, 13.2 and 12.9 grams of pure para-nitrophenol, which is about 18 per cent. of the theoretical yield from 50 grams of phenol. A nitration similarly carried out, but with the temperature kept, not at 25° but at 4°, resulted in 12.8 grams of para-nitrophenol. Below 4° the nitration refused to take place, altogether. Further, a nitration carefuly carried out at 50° yielded 12.5 grams of para-nitrophenol and slighty less of the ortho compound than is usually obtained at lower temperatures.

The temperature thus seems to have but little influence on the yield of both ortho- and para-nitrophenol, and the ordinary temperature of the laboratory is but slightly more propitious than either higher or lower temperatures. Far more important are the vigorous stirring of the solution during nitration and the very gradual addition of the phenol.

NEW BOOKS.

Radiochemistry. By A. T. CAMERON, M A., B.Sc., Lecturer in Physiological Chemistry, University of Manitoba. London: J. M Dent & Sons, Limited 1910. viii + 174 pp. Price 2 s. 6d. net.

The book, the contents of which are based largely on three articles dealing with the "Transformation of Elements" which appeared in *Science Progress* in 1908, treats selected topics of the subject of radioactivity from the chemical point of view. The physical side is sketched only in sufficient outline to enable the reader who has some knowledge of physics and chemistry to appreciate the chemical results.

Those chapters which recount the properties and chemical behavior of radium emanation are of greatest interest; part of the results represent the author's own work with Sir William Ramsay. Radium emanation is now known in the solid and liquid as well as in the gaseous state. In the latter form it is produced to the extent of 0.1 cm. per day per gram of radium. The liquid emanation has a density of about 5; it boils at

—62°; it is practically colorless, with a marked greenish phosphorescence; the solid glows with great brilliancy like a small steel-blue arc light. It is now fully established that the emanation can bring about numerous purely chemical reactions; "each atom of the emanation, as it disintegrates, produces a certain definite chemical effect." It is also certain that helium is a product of the spontaneous disintegration of the emanation; but the possibility of the transmutation or atomic degradation of common elements under the influence of the emanation is still an open question. In addition to the familiar case of copper and lithium, these supposed transmutations now include the production of neon from the emanation and pure water, argon from a copper solution, and carbon dioxide from each of the elements thorium, zirconium, lead, titanium and silicon. However, the author shows that it is possible that the lithium came from the glass, in which it previously existed and that the neon and argon came from the air, while the carbon dioxide may have been formed by purely chemical changes of traces of carbonates present as impurities. (Although thorium oxalate is by far the least soluble of all oxalates, the reviewer has observed that it is appreciably soluble in a concentrated solution of thorium nitrate. Since thorium is always separated as oxalate in the process of manufacture, it is possible that some oxalate may remain in the otherwise pure nitrate and by subsequent decomposition give carbon dioxide.) The last two chapters are devoted to applications of radioactivity to geology and to medicine; a bibliography of nearly one hundred titles completes the book.

For a greater part of the matter of the second chapter, which treats of radioactive methods as illustrated by the thorium series, acknowledgement is made to Rutherford's *Radioactivity*, second edition. But apparently the author has not read this classic very carefully, if we may judge by pp. 16–18. In explanation of the rise to a maximum of the activity of the Th X separated from Th, it is said that this maximum represents the time when in any given interval as much of the products of Th X is formed as decays in that time. "These products are then said to be in radioactive equilibrium and no longer affect the nature of the curve." Now, as a matter of fact, the maximum *amounts* of the products are not reached until about 40 hours after the start, whereas the maximum *activity* is attained in about 18 hours. Furthermore the decay curve, as measured by the activity, is appreciably affected for three days after the maximum activity is passed and at no time does a state of radioactive equilibrium result. In giving the fundamental equation for the decay of any radioactive substance, p. 17, the author has blindly followed the misprint in Rutherford, p. 222, writing $I_0/I_t = e^{-\lambda t}$, instead of $I_t/I_0 = e^{-\lambda t}$. This leads him to the erroneous equation $2 = e^{-\lambda t}$, where t is now the period. On p. 90 the same incorrect fundamental equation occurs twice. A number of other errors occur; as p. 26, that the δ rays obey the light laws; p. 39, that U X dissolves in the *ether* layer, in the separation by Crookes' method and p. 55 that thorium occurs chiefly in Ceylon. However, the story of radioactivity is inherently so interesting that, in spite of these errors, the book will not disappoint the reader who wishes to learn the present state of our knowledge of radioactive transformations and suspected transmutations.

HERBERT N. MCCOY.

Outlines of Organic Chemistry. By F. J. MOORE, PH.D., Associate Professor of Organic Chemistry in the Massachusetts Institute of Technology. New York City: John Wiley & Sons. 1910. pp. ix + 315. Cloth, $1.50.

The book is the outgrowth of a series of lectures given to students whose principal work is in Physics, Biology and Sanitary Engineering. It differs from most elementary texts in that a few of the customary subjects are omitted and in those subjects considered only a few compounds are taken up, but these are discussed fully and clearly. Its aim seems to be "to teach not much but well." The almost complete absence of empirical formulas is noticeable.

Typographical errors incident to a first edition are found in formulas on pages 47, 94, 159 and 184. Most teachers of chemistry will object to oxidation or reduction reactions being written with the symbols O_2 or H_4 where ordinary oxidations or reductions are being described, pages 112, 251, 254, 261, 264, 266, 272, 281, 284 and 293. The formula for an isocyanide, page 74, and the spelling of the plural of formula, page 84, should be changed to agree with modern chemical usage.

Organic chemistry is being recognized as a subject of general interest and for the needs of the average students in the short courses, which are being given in increasing numbers by the American colleges and universities, this text will be found to serve excellently.

RALPH H. MCKEE.

Handbuch der landwirtschaftlichen Bakteriologie. By DR. F. LÖHNIS. Berlin; Gebrüder Borntraeger. 8vo. viii + 907 pp.

The development of agricultural science, like that of any other science, is marked by the appearance, from time to time, of books that summarize and interpret the data scattered in current publications. The present volume may be deservedly included in this list of important books, both for the unusual richness of the reference material contained in it and for the scholarly interpretation of the almost endless array of facts dealing with some of the agricultural relations of bacteria.

The five divisions of the book are arranged as follows: (1) Occurence and Activities of Microörganisms in Foodstuffs, 97 pp.; (2) Occurrence and Activities of Microörganisms in the Retting of Flax and Hemp and in the Fermentation of Tobacco, 16 pp.; (3) Occurrence and Activities of Microörganisms in Milk and Milk Products, 310 pp.; (4) Occurrence and Activities of Microörganisms in Barnyard Manure, 73 pp.; (5) Occurrence and Activities of Microörganisms in the Soil, 280 pp; Index, 115 pp.

No attempt is made by the author to discuss the bacteriology of water, sewage and sewage disposal. Evidently these topics appeared to him as belonging properly to the domain of sanitation, rather than that of agriculture. Similarly the rather extensive body of facts relating to bacteria pathogenic to higher plants is not considered by the author. While this may appear unfortunate to some of us, it must be admitted that he had good reason for this omission, since any discussion of plant-pathology from the bacterial standpoint alone must of necessity remain incomplete and one-sided. To secure completeness, one would have to consider the more or less distinct field of mycology, a task that would be hardly pertinent and far from simple.

To the American student this volume will prove of especial interest, because of the very satisfactory review of American data. The author deserves much credit for the thoroughness of this part of his work, particularly since he had to depend for his material almost entirely on the Experiment Station Record. Incidentally this achievement may be regarded as a splendid compliment to the editor and staff of the Experiment Station Record. For instance, the reference material on ensilage; on the numbers and kinds of bacteria in milk as influenced by handling and treatment; and on the ripening of hard and soft cheeses is reasonably complete. The same may be said of much of the soil-bacteriological work of the Delaware, North Carolina and New Jersey Experiment Stations.

Everything considered, the Handbook should prove serviceable to every student, teacher and investigator in the domain of agricultural bacteriology. All of these will feel indebted to the author for the many hours of tedious searching in books and journals that he will have saved them. They will, no doubt, appreciate also the helpful discussion of methods and culture media that represents one of the valuable features of the book. JACOB G. LIPMAN.

Laboratory Exercises in General Chemistry. WILLIAM MARTIN BLANCHARD, Professor of Chemistry, Depauw University. The Chemical Publishing Company: Easton, Pa. pp. 88. Price, $1.00.

This is a laboratory manual in general chemistry "arranged to meet the needs of college students who have had no previous training in chemistry." While there is little original material in the book, the experiments are well chosen and carefully written and include a number of quantitative experiments. To perform those given will require about six hours a week during the college year. C. W. BALKE.

VOL. XXXII. OCTOBER, 1910. No. 10.

THE JOURNAL

OF THE

American Chemical Society

ANNUAL REPORT OF THE INTERNATIONAL COMMITTEE ON ATOMIC WEIGHTS, 1911.

Received August 25, 1910.

In the autumn of 1909 the Council of the Chemical Society of London voted unanimously in favor of issuing the annual report of the International Committee on Atomic Weights in September or October instead of in January, as heretofore. In that proposition the Chemical Society of France has concurred, and American sentiment has also been favorable to the suggested change. Therefore the change is now made.

The reasons offered for the new policy are very simple: First, the school year, at least in most educational institutions, begins in the autumn. It is desirable that teachers should then have the latest table of atomic weights at their command, in order to avoid changes after school work has begun. Secondly, publishers of text-books are accustomed to issue their new works in the autumn, and often request early information as to changes which are likely to be made. The proposed change in the time of issuing the table is therefore an aid to teachers, students and publishers, and no disadvantage to any one else. The immediate usefulness of the table is increased, and to attain that end should be a main purpose of the committee.

Since the preparation of the report for 1910, a number of important memoirs upon atomic weights have appeared. The results obtained are, in brief, as follows:

Chlorine.—The density, composition by volume, and compressibility of hydrochloric acid have been measured by Gray and Burt[1] with great care. From the density and volumetric composition, when H = 1.00762, Cl = 35.459. From the density and compressibility, Cl = 35.461.

---

[1] *J. Chem. Soc.*, **95**, 1633.

The mean, 35.460, is the value given in the annual table of atomic weights for the past two or three years.

The density of hydrochloric acid has also been determined by Scheuer,[1] who gives measurements made under varying conditions. His final conclusion, based upon his own work after comparison with that of Gray and Burt, is that Cl = 35 466.

Lithium.—Richards and Willard,[2] in their important research upon the atomic weight of lithium, measured three distinct ratios; namely, silver to lithium chloride, silver chloride to lithium chloride, and lithium perchlorate to lithium chloride. From these ratios, without the intervention of any others, the following independent values for three atomic weights are obtained:

Li = 6.939
Cl = 35.454
Ag = 107.871

The value for silver varies from the accepted value, 107.88, by about one part in 12000, which is probably less than the actual uncertainty. That for chlorine diverges more widely, namely, by about one part in 6000. The new figures are undoubtedly entitled to great weight, but in view of the excellent work done by others it would be unwise to make any hasty change in the table. For lithium, however, the value 6 94 may be taken, replacing the old 7.00.

Strontium.—Thorpe and Francis,[3] in their determinations of the atomic weight of strontium, measured six ratios, and obtained the following results:

Ratio 2Ag to $SrBr_2$,	Sr = 87.645
Ratio 2AgBr to $SrBr_2$,	Sr = 87.653
Ratio 2Ag to $SrCl_2$,	Sr = 87.642
Ratio 2AgCl to $SrCl_2$,	Sr = 87.645
Ratio $SrBr_2$ to $SrSO_4$,	Sr = 87.629
Ratio $SrCl_2$ to $SrSO_4$,	Sr = 87.661
Mean of all,	Sr = 87.646

The value adopted by the authors is 87.65. Richards' figure is 87.62. An intermediate value, 87.63, is adopted in the new table.

Phosphorus.—Atomic weight redetermined by Baxter and Jones.[4] From the ratio between silver and silver triphosphate the authors find P = 31.043, when Ag = 107.88. The rounded-off figure 31.04 is to be adopted.

Vanadium.—From the ratio between silver chloride and vanadyl trichloride, Prandtl and Bleyer[1] find V = 50.963 and 51.133 in two series of experiments.

---

[1] *Z. physik. Chem.*, **68**, 575.

[2] THIS JOURNAL, **32**, 4.

[3] *Proc. Roy. Soc., London A*, **83**, 277.

[4] THIS JOURNAL, **32**, 298.

In a later paper, Prandtl and Bleyer,[2] also from analyses of vanadyl trichloride, find V = 51.061. From reductions of V_2O_5 to V_2O_3 they found V = 51.374. The latter method, however, they regard as uncertain. The value V = 51.06 may be provisionally adopted.

Tellurium.—Marckwald and Foizik,[3] by a somewhat complex volumetric process, based on the oxidation of TeO_2 by $KMnO_4$, conclude that Te = 127.61. This agrees with many of the other recent determinations of the constant, but is not sufficiently exact to supplant the value given in the table.

Rhodium.—Two inaugural dissertations upon the atomic weight of rhodium have been issued from Gutbier's laboratory at Erlangen. Renz reduced rhodium pentammine bromide in hydrogen and found Rh = 102.92. H. Dittmar,[4] by similar reductions of the corresponding chloride, found Rh = 102.93.

Platinum.—The very elaborate investigation of Archibald[5] upon the atomic weight of platinum was based upon analyses of the chloroplatinates and bromoplatinates of potassium and ammonium. In all, 28 ratios were measured, giving values for Pt ranging between 195.19 and 195.25. Their arithmetical mean gives Pt = 195.22. Archibald, however, in his final discussion, uses only 12 ratios, giving, in mean, Pt = 195.23. The figure 195.2 is given in the table.

The Inert Gases.—The densities and molecular weights of helium and neon have been redetermined by Watson.[6] For the atomic weights he finds He = 3.994 and Ne = 20.200. In another paper[7] he applies the critical constants of krypton and xenon to their densities as determined by Moore, and finds Kr = 82.92 and Xe = 130.22. There are also new determinations of the density of argon, by Fischer and Hahnel.[8] Their mean value, referred to O = 16, is 19.945, a figure rather higher than that given by Ramsay and Travers. It corresponds to an atomic weight of A = 39.89.

It is also to be noted that a third, revised, edition of Clarke's "Recalculation of the Atomic Weights" has recently been published by the Smithsonian Institution.

THE ATOMIC WEIGHT OF MERCURY.

(SECOND PAPER.)

BY C. W. EASLEY.

Received July 30, 1910.

In a series of experiments on the atomic weight of mercury, described in a previous communication,[1] mercuric chloride of very great purity was prepared and its analysis tended to show that the accepted value of this constant was too low. This conclusion was reached as a result of work having to do with the ratio $HgCl_2 : 2AgCl$. Since the results differ from the accepted value by three-tenths of one per cent., it seemed best to establish their correctness in a general way before publication. This was done by determining the percentage of mercury in mercuric chloride but it was explicitly stated that the method of verification was involved and did not approach in accuracy the one by which the ratio $HgCl_2 : 2AgCl$ was determined and that the former was employed merely to indicate the general neighborhood in which the true value lay. The value obtained by this, less accurate, method differed from the first by less than one-tenth of one per cent. but the process was so questionable from the standpoint of the complete collection[2] of the mercury that the same ratio has been determined in another way by work in this laboratory. The results corroborate and agree very closely with the higher value previously published. To determine this ratio, the metal was deposited electrolytically from mercuric chloride of the same degree of purity as that employed in the previous work, the methods of preparation being identical. The value obtained, 200.63, is in almost exact agreement with the finding of the previous investigation, 200.62, calculated from the ratio $HgCl_2 : 2AgCl$, which was believed to give a result with very small error.

Historical and Critical Survey.

In order to find a possible source of error in the work of previous investigators, it may be best to append the work already published.

The table brings to light the fact that mercury itself constitutes one term of every ratio. The metal has been liberated from the several compounds by two methods: (1) by heating with calcium oxide or copper in a stream of an inert gas by means of which the mercury was swept out of the tube containing the reacting mixture, the vapor being condensed in a portion of the apparatus used subsequently for weighing the deposit; (2) by depositing the metal on a platinum dish with the aid of the electric current. It is not unlikely that the first method is subject to loss of mercury through imperfect condensation, as it will be shown later that the vapor pressure of mercury at rather low temperatures, although small, is sufficient to be of considerable importance. This would seem to be the main point of weakness in all the previous work, as the preparation of the compounds in a fairly pure condition, with the exception of the oxide, appears to be a comparatively simple matter.[2] Whether any of the compounds escaped contact with the lime or copper, however, might be questioned. The process was certainly complete in the electrolytic method of Hardin but the details concerning such an important matter as the drying of the deposit are so meager that the results do not carry the weight that their agreement would otherwise warrant.

---

[1] THIS JOURNAL, 31, 1207.

[2] That a small portion of the finely divided metal passed by the filter in the process of its separation from the filtrate containing the chlorine was known from the solvent action of the mercury salt on the silver chloride. This was described in the previous paper. In fact, only a few of the attempts to collect and determine the mercury were successful, owing to its tendency, under the conditions of the experiments, to be precipitated in such a finely divided state.

Turner[1] (*Phil. Trans.*, 1833, 531)	$HgCl_2 : 2AgCl$	.....

The loss of mercury at low temperatures due to its vapor pressure, however slight, is not to be overlooked. At a given temperature, the loss would obviously depend upon the rate at which the vapor was swept through the condensing tube, or, in the case of drying deposits on platinum dishes, on the amount of convection currents in the immediate neighborhood. In the first case, it is entirely possible that the condensation of the mercury, its partial pressure in the mixture being small, from the stream of hot gas was not complete in spite of the fact that gold leaf was employed to collect the portions which might escape. The question involved in the later electrolytic work is the same but here we have to do with the metal spread over the surface of a dish which "was washed several times with boiling water and carefully dried." The temperature and method of drying are not stated.

---

[1] In this determination, no account whatsoever was taken of the solvent action of mercury salts on silver chloride so that the values have been excluded from the table as being subject to known error. The results were abnormally high.

[2] It was shown in the previous paper that the sublimation of the chloride from material containing water, such as recrystallized salt, is attended with the production of a slight amount of basic salt.

It is well-nigh impossible to reproduce the exact conditions under which various observers have worked but some experiments were undertaken to show the effect of evaporation at moderately low temperatures on the weight of mercury. However, no attempts at exaggerating the ordinary drying methods were made. Instead of exposing a considerable surface of the metal such as a deposit on a dish, a globule of dry mercury having a surface of 1.5 sq. cm. was placed in a weighing bottle 3 sq. cm. in cross section and 5 cm. in height. The bottle was placed in an air oven and maintained for such periods of time and at such temperatures as are shown in the accompanying table. Under such conditions there are no air currents to any extent and no other liquid whose vaporization would tend to carry away the mercurial vapor with it.

Hours in oven.	Temperature of oven	Total loss in grams.	Loss in grams per hour.
3	50°	0.0016	0.00053
4½	50	0.0024	0.00053
10	50	0.0033	0.00033
6	50	0.0027	0.00048
3½	50	0.0010	0.00029
19	50	0.0057	0.00030
8	60	0.0050	0.00063

The results are as concordant as one might expect and even under these conditions, where the evaporation is reduced to a minimum, the loss is considerable. Especially in the case of a mercury deposit on a platinum dish,[1] the effect is not to be neglected because of the relatively large error[2] due to the small amount of mercury which may be satisfactorily dealt with in this manner.

In the following work, in view of the errors which might arise from the volatility of the metal, it was decided to dry the mercury at ordinary temperatures, using acetone to remove the water as was done in the previous work. The error committed by this procedure is exceedingly small although under favorable conditions the evaporation of mercury may be measured at quite low temperatures. Thus, in a room, subject to draughts, at a temperature of 25°, a slight though decided loss was noticed on several occasions when a considerable surface of mercury was exposed for 24 hours.

---

[1] The manuals on electro-analysis do not agree on the temperature at which mercury should be free from water. One commonly used, however, recommends the drying on a moderately warm plate.

[2] Thus, with one gram of mercuric chloride, the average amount used by Hardin, each change of a tenth of a milligram of the metal in the neighborbood of the actual amount present affects the atomic weight in the first decimal place.

General Method.

In order to secure recognition of the higher value of the atomic weight of mercury by any method, the latter must be free from the objections urged against the process used in determining the same ratio as described in the preliminary paper.[1] The electrodeposition of mercury from the chloride under proper conditions realizes this condition to a marked degree. That the metal is completely freed from the chlorine by this process is well known and its complete collection is assured from the form of the apparatus. Again, electrolytic methods in general possess simplicity. In the work here described even greater simplicity, and therefore greater accuracy, has been attained from the manner in which the deposit is handled. A special vessel was devised in which the metal was deposited in globular form by means of a mercury cathode and without being removed was washed by decantation, freed from water by means of acetone and finally weighed. A test of the method is whether a globule of mercury can be subjected to the above-mentioned treatment without change of weight. Many experiments bearing on this point show that the changes in weight, a similar vessel receiving similar treatment, of course, serving as a counterpoise, are small, never being greater than a tenth of a milligram and generally no more than a few hundredths. Such changes may therefore be attributed to errors incident to weighing glass vessels of the size employed. By the electrolysis of known weights of mercuric chloride with precautions to be mentioned later, one has a method at once simple and accurate and possessing the very great advantage, other things being equal, that relatively large amounts of mercury may be deposited without increasing the error of measurement. Over twenty grams of mercuric chloride were electrolyzed in the tube with the same ease and accuracy as were the smaller amounts.

The Material.—For the sake of comparison with the work previously published, three samples of mercuric chloride were prepared with the same care and in precisely the same manner as in that work. For the details reference should be made to that paper. The corresponding samples are designated by the same numbers in both communications. The analyses of these samples are considered in a series by themselves for the reason that no suspicion whatever is attached to the purity of either the salt or the mercury obtained from it.

Not so much can be claimed for sample o which was originally intended for the preliminary work in order that some uniformity of results might be attained while the method was being tested out. To this end, the choicest appearing crystals from Kahlbaum's highest grade of mercuric chloride were sublimed in a current of dry air in the special tube described in the previous paper. A large fraction coming over first was discarded, but most of the remainder was collected. During the sublimation, the temperature was maintained in the neighborhood of, 300°. An exceedingly small residue, for commercial material, remained, which had every appearance of being carbon. The salt was entirely soluble in water.

---

[1] This Journal, 31, 1207.

The results of the analyses of this sample were quite concordant, and a search was begun to discover the nature of the traces of impurities for it was evident that very pure salt was being dealt with. Slight amounts of arsenic only could be found in the original Kahlbaum salt and none whatever in the sublimed portion, so that it was decided to use the results of the analyses of this sample as evidence in this investigation. Naturally, less weight must be attached to the results from this sample, subjected to physical treatment only in its purification, than to the values from samples 1, 2, and 3, especially as the latter samples were the last to be analyzed and thus greater manipulative skill was possible at this stage of the work. That some impurity was present, however, was evidenced from the fact that the globule after drying had a peculiarly striated appearance here and there, although the surface was lustrous. Any metal deposited simultaneously must have been present in very small amounts and would probably have dissolved in the mercury. The deposition of platinum was not the cause for the same phenomenon did not occur with any of the other samples. Judging from the high results, if a foreign metal is present, it must have an atomic weight higher that that of mercury, which is quite improbable. The sample gives a result so little above that of the final series, however, that the difference might be accounted for by the retention of a minute quantity of water or even acetone by the peculiar surface which, in turn, might have been caused by the slightest amount of an impurity.[1]

Weighing.—A Sartorius balance was used and the consecutive weighings could be relied upon to one-fortieth of a milligram. In determining the weight of the salt, substitution was the method employed while, in the case of the mercury, the tube containing the metal was counterpoised with a similar tube and was subjected to the process of double weighing in order to correct for the inequalities in the length of the balance arms.

---

[1] That the presence of very small amounts of certain impurities interferes with the tendency of the separate particles to unite is well known. In washing the mercury obtained from this sample, the particles sometimes became detached and considerable more difficulty was experienced in reuniting them than in the case of the other samples. It is not impossible that a small amount of packing material, often found in chemicals, was destroyed during the sublimation and that some of the products distilled over so that the appearance of the mercury might be due to very small detached particles of the metal itself covered with a film of organic matter.

The gold-plated brass weights were calibrated and the proper corrections applied. The following vacuum corrections were made:

+0.000080 gram per gram of mercuric chloride.
—0.000055 gram per gram of mercury.

The Cathode.—In view of the difficulties attending washing and drying deposits on platinum dishes. it was decided very early in the course of the work to make use of a mercury cathode, an idea due to Wolcott Gibbs[1] in 1883 and used by him and others in depositing various metals in the form of amalgams. The main drawback to the more general adoption of such a method has been the difficulty of handling the deposit, an objection which has been overcome in this work. In the present case, such a cathode seems ideal in that it avoids an interface of any considerable area with another conducting surface, with the consequent questionable procedure of washing and drying under such circumstances. Again, one is not limited to the deposition of very small amounts of metal, which amounts cannot be exceeded in using platinum dishes, owing to the tendency of the mercury to collect in drops at the bottom of the dish; nor does the question of current density arise to change the nature of the deposit.

To discover whether or not hydrogen was retained by the mercury, a dilute solution of hydrochloric acid in one case and of sulphuric acid in another was electrolyzed and the effect on the weight of the cathode was determined. In one of the experiments only was there an increase in weight, so that the change in this exceptional case was considered accidental. Had this effect been caused by hydrogen, the atomic weight of mercury would have been changed only one unit in the second decimal place.

For the electrode, five to ten grams of mercury, prepared by the reduction of pure mercuric chloride, was placed in the electrolyzing tube in contact with the platinum wire. The mercury was first washed with water, treated with acetone and dried with air, as will be described later. At the conclusion of some of the experiments, a portion of the deposited metal was retained to serve as a cathode, thereby effecting a saving in the preparation of pure mercury. The globule constituting the cathode always possessed a clean, lustrous surface.

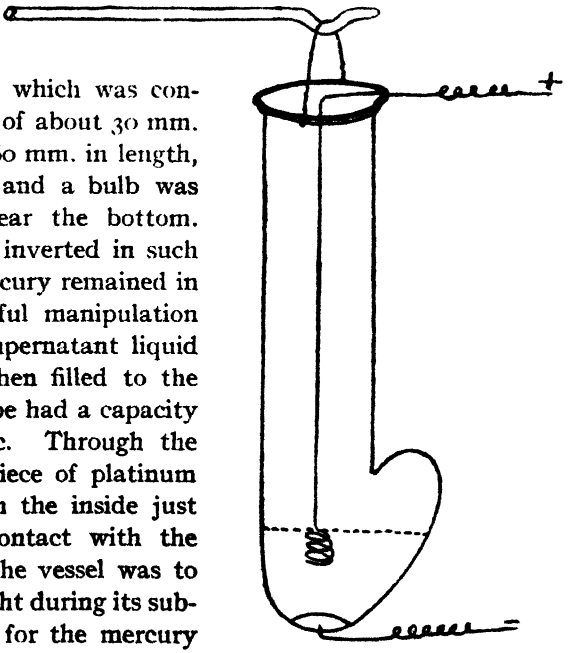
The Anode.—As concentrated solutions of mercuric chloride were to be electrolyzed with the consequent production of strong chlorine solutions, considerable time was spent in search for suitable anode material, for it was expected that platinum would be strongly attacked. Carbon in several of its forms was tried but it was not to be relied upon, either because of its absorptive properties or because of the tendency of portions to become detached. Again, such electrodes are difficult to treat in such a manner that constant weight is maintained and thus one has no check on this important point. In describing a method of overcoming the solvent effect of chlorine on a rotating platinum anode, Smith[1] recommends the use of a layer of toluene or xylene on the solution just above the anode. This was tested, although in this work the anode was stationary, with the result, as afterward found, that more of the platinum was dissolved by this treatment than without the absorptive layer. It was therefore decided to use the platinum, as is ordinarily done, find its loss of weight, determine the amount in the solution after the electrolysis and thus calculate by difference the amount deposited with the mercury. Contrary to expectations, the loss of platinum by solution was exceedingly small and practically all of the dissolved portion was deposited with the mercury, none being found in solution at the conclusion of an experiment. The anode at the beginning of the experiments described later weighed 1.54895 grams and at their conclusion 1.54880; or, during the course of eleven experiments in which over 125 grams of mercuric chloride had been electrolyzed, the anode lost 0.00015 gram.

---

[1] *Am. Chem. J.*, 13, 571.

The platinum wire, weighing 1.5 grams and having a length of 35 cm., was wound at one end into a spiral, the latter being maintained at approximately 2 cm. from the cathode. The other end of the wire was connected with the battery terminal by means of a clip.

The Electrolyzing Tube.—The figure illustrates the essential features of this vessel, which was constructed of glass tubing of about 30 mm. diameter. The tube, 160 mm. in length, was closed at one end and a bulb was blown into its side near the bottom. The tube could thus be inverted in such a manner that the mercury remained in the bulb and by careful manipulation practically all of the supernatant liquid could be removed. When filled to the top of the bulb, the tube had a capacity of approximately 50 cc. Through the bottom was sealed a piece of platinum wire which projected on the inside just far enough to make contact with the mercury cathode. As the vessel was to remain unaltered in weight during its subsequent treatment, save for the mercury



---

[1] *Electroanalysis.*

deposited, all portions of the surface were carefully smoothed in the flame. To this same end, the platinum wire was connected with the battery terminal by means of a clip which precluded any abrasion of the surface of the platinum. For convenience during the processes of electrolysis and weighing, a platinum wire was wound about the neck of the tube to serve as a loop for suspension. During the former process, the tube hung on a glass rod; in weighing, the hooks on the balance arms were utilized as supports. It has already been stated that a counterpoise, similar in every respect to the electrolyzing tube, was used throughout the work. Consecutive weighings proved the adequacy of this procedure.

The Procedure.—A known amount of mercuric chloride[1] was placed on the cathode in the electrolyzing tube with sufficient water to make a total volume of 25 or 30 cc., the sides of the tube having been carefully washed down. A few drops of a dilute solution of redistilled hydrochloric acid were added to make the solution approximately one-fortieth normal. This was necessary to increase the conductivity of the solution at the outset and this particular compound was chosen in order not to introduce ions other than those which would be present later. The water added was not sufficient to entirely dissolve the salt so that the latter was dissolved, except in so far as its solubility was affected by the presence of substances formed during the course of the process, only as the solution became depleted by the electrolysis. With the strength of current used, the action had ordinarily proceeded for 8 or 10 hours before the disappearance of the solid phase. At the end of a similar period, the action was complete, as shown by the preliminary work, but traces of mercury compounds were probably adhering to the sides of the tube and to the funnel placed in the mouth of the tube to prevent loss in the form of spray. An addition of approximately 20 cc. of water was made in washing the funnel and walls of the tube and the current was allowed to pass several hours longer, after which no trace of mercury could be detected in the solution. Sometimes the whole process consumed 48 hours, varying altogether with the amount of salt to be electrolyzed and whether or not it was convenient to perform the subsequent operations. Copious fumes of chlorine escaped during the action and as is usual in the electrolysis of mercuric chloride, insoluble particles said to be the mercurous compound gradually accumulated at the anode only to fall off and finally disappear. To prevent any of these particles from becoming permanently lodged between the glass surface and the cathode, the globule was agitated by a gentle whirling motion of the tube. This was not attempted, however, until the electrolysis was practically complete for fear of entangling solution and from that time on the process was repeated at intervals to insure completeness. At no time was the agitation violent enough to sever the connection between the mercury and platinum Sometimes the mercury exhibited a tendency to assume a form perhaps "deadened" and the separate particles had no tendency to unite with the main globule. Gentle tapping, however, generally sufficed to cause the formation of one globule.[1] It is not unlikely that the disengagement of hydrogen from the cathode was the cause of the separation of these small particles.

---

[1] The non-hygroscopic character of the salt was proven in the previous work.

To free the tube of conducting material at the end of the electrolysis, a funnel, with its stem almost reaching to the surface of the mercury, was placed in the tube and without breaking the electric connections at least 500 cc. of pure water were poured into the tube, the overflow being caught in a large porcelain dish where any particles of escaping mercury could be detected. During the washing process, the tube was rotated as previously described so that no chlorine would be retained between the cathode and glass and thus remain in contact with the mercury after the breaking of the circuit. After removing the funnel, the water in the tube was decanted, the mercury with perhaps a drop or so of water remaining in the tube, owing to the bulb arrangement. Five washings were made with redistilled acetone, each being decanted in turn. The tube was next immersed to its neck in a bath of acetone to free the outer surface of water and was finally hung on a glass rod to dry. The counterpoise was subjected to exactly the same treatment. The two tubes hung side by side and were gently agitated from time to time to prevent the possibility of the retention of any acetone between the globule and glass. Meanwhile, a current of air of the same intensity was passed over each globule so that in a short time the vapor of acetone was effectually removed and the tubes were full of air ready for their transfer to the bal-

THE RESULTS.

PRELIMINARY EXPERIMENTS

			Mean,	200.63

---

[1] In the preliminary experiments where less pure mercuric chloride was being dealt with, more difficulty was encountered.

[2] Calculated on the assumption that chlorine has the value, 35.46, THIS JOURNAL, 32, 4.

[3] In expt. 3, a portion of the mercury became detached and during the washing was poured into the catch dish. It is possible that the low value obtained in this case may be explained by the incomplete recovery of the separated particles.

ance arms. As soon as constant temperature was attained, the weighing was made by the method described before. Repetition of the drying process insured its completeness.

The current was supplied by three storage cells and was reduced by means of a suitable resistance to one- or two-tenths of an ampere. The action proceeded quietly, no spray being noticeable and no rise of temperature above 30° took place.

FINAL EXPERIMENTS.

No. of expt.	Sample of $HgCl_2$.	Weight of $HgCl_2$ in vacuum.	Weight of Hg in vacuum	Per cent Hg in $HgCl_2$.	Atomic weight[1] of mercury.
1.........	2	8.14695	6.01909	73.882	200.61
2.........	1	11.03881	8.15592	73.884	200.64
3	1	13.48192	9.96129	73.886	200.66
4..	3	11.08026	8.18610	73.880	200.60
5.........	3	11.31231	8.35819	73.886	200.66
6.........	3	21.44026	15.84060	73.882	200.62
				73.883	200.63

It now remains to consider the results in this and in the previous paper:

Series		Atomic weight.
1.	The ratio $HgCl_2$: Hg (from the previous paper)....	200.48
2.	" " $HgCl_2$: 2AgCl (from the previous paper).	200.62
3.	" " $HgCl_2$: Hg (prelim. expts, this paper)..	200.63
4.	" " $HgCl_2$: Hg (final " " ")...............	200.63

Giving each series equal weight, the mean value of the atomic weight of mercury becomes 200.59. It is reasonable, however, in seeking an optimum result to reject any series known to be faulty either on account of the nature of the material dealt with or in method. For the last reason, Series 1 is dropped and for the first, Series 3 is thrown out. Considerable weight is attached to the mean value, 200.63, of the two remaining series for (1) the mercuric chloride analyzed was the same in each, and, from the manner of preparation, it must have been practically free from foreign material and (2) the complete analysis, by methods which seem above question and which are radically different, shows that the sum of the mercury and chlorine contents gives essentially the real value. Thus,

Per cent. Mercury:

From the fact that 56.52119 g. of mercury resulted from 76.50051 g. of mercuric chloride (Series 4)........................ 73.883

Per cent. Chlorine:

On the basis that 86.21813 g. of silver were obtained from 81.66510 g. of mercuric chloride (Series 2)........................ 26.118

The sum...... .... 100.001

THE UNIVERSITY OF MAINE.

THE ATOMIC WEIGHT OF TANTALUM.[1]

BY CLARENCE W. BALKE.

Received July 1, 1910.

Introduction.

Of the previous determinations of the atomic weight of this element, those by Berzelius,[2] Rose,[3] Hermann[4] and Blomstrand[5] need not be considered, as their material was too impure to give results of value. The determinations of Marignac,[6] which appeared in 1866, were far more satisfactory. He analyzed potassium fluotantalate, K_2TaF_7, and the corresponding ammonium salt, $(NH_4)_2TaT_7$. In the case of the potassium salt he obtained the following percentages:

Ta_2O_5, 56.50, 56.75, 56.55, 56.56; K_2SO_4, 44.37, 44.35, 44.22, 44.24.

The ammonium salt gave the following percentages of tantalum oxide: 63.08, 63.24, 63.27, 63.42. These numbers were corrected for a small amount of potassium sulphate which was present in the oxide, due to the fact that he was unable to prepare the ammonium fluotantalate free from traces of the potassium salt.

If in the calculations the atomic weights of the elements involved are taken as given in the 1910 International Table the following values for the atomic weight of tantalum are obtained:

From the ratio, $K_2TaF_7 : Ta_2O_5$	182.4 to 184.6
From the ratio, $K_2TaF_7 : K_2SO_4$	181.6 to 182.9
From the ratio, $K_2SO_4 : Ta_2O_5$	181.9 to 183.0
From the ratio, $(NH_4)_2TaF_7 : Ta_2O_5$	180.5 to 183.8

It will be observed that there is a variation of several whole units between the individual determinations, yet for about forty years the accepted value of this constant was based on these results.

In 1906 Hinrichsen and Sahlborn[7] published a series of determinations in which metallic tantalum was burned to the oxide. The method has great simplicity, but it appears very doubtful to the writer if this metal can be prepared sufficiently pure for the purposes of atomic weight work. Their results follow on page 1128.

Here again there is a variation of over one unit between the individual determinations. Clarke,[8] after reviewing these various determinations of the value of this constant, remarks that its uncertainty probably amounts to as much as a unit.

			Mean, 181.03

While carrying out an investigation on columbium[1] it was found possible to make a satisfactory determination of the atomic weight of that element through the conversion of its pentachloride into the corresponding oxide. Consequently the writer decided to carry out a similar investigation with tantalum chloride, and, in general, the methods used were very similar to those employed in the former work.

Preparation of Materials.

In the preparation of all materials used during the investigation great care was exercised in the cleaning of all containing vessels and especial care was taken to exclude dust. Whenever possible the apparatus used was made continuous by fusing the various parts together, and this was always the case where chlorine was being used. In the case of chemicals not especially purified, those of the highest purity obtainable were employed.

Chlorine.—The chlorine used, including that used in the preparation of the sulphur monochloride, was made by allowing hydrochloric acid to drip upon potassium permanganate contained in a large flask. The acid used was prepared by distilling the constant boiling mixture from large Jena retorts. During the first part of the distillation small quantities of potassium permanganate were added from time to time and the first portions of the distillate were rejected. The chlorine was passed through a wash bottle containing water, two containing sulphuric acid and finally through a tower one meter long containing glass pearls and so arranged that the latter could be moistened from time to time with concentrated sulphuric acid.

Sulphur Monochloride.—This compound was prepared by passing a stream of chlorine over molten sulphur which had been crystallized previously from carbon disulphide. The apparatus was so constructed that the liquid could be redistilled from the receiver without transferring the material. The first portions of the distillate were rejected and the final product was collected directly in sealing flasks through which a stream of dry, filtered air had been allowed to flow.

Nitric Acid.—The nitric acid used in the determinations was distilled twice from a platinum retort, the middle third of the distillate being retained in each case. The acid was preserved in quartz flasks.

---

[1] Balke and Smith, THIS JOURNAL, 30, 1637 (1908).

Water.—The water used, including that employed in the final recrystallizations of the potassium fluotantalate, was prepared by redistilling the ordinary distilled water of the laboratory, after the addition of alkaline permanganate, from a still ordinarily used in the preparation of conductivity water.

Tantalum Chloride.—This compound was prepared by the ignition of tantalum oxide in a current of chlorine and the vapors of sulphur monochloride. The oxide used for preparations I and II was prepared from some of the potassium fluotantalate which had been obtained by Hall and Smith[1] from the columbite of South Dakota, and which was very kindly furnished me by Professor Edgar F. Smith.[2] This salt was recrystallized four times from water containing appreciable amounts of redistilled hydrofluoric acid, and only the first crops of crystals were used in the next crystallization. These operations were carried out in platinum and hard rubber dishes and hard rubber funnels were used in the filtration of the solutions. The final crop of crystals was heated in platinum dishes with concentrated sulphuric acid, which had been distilled from platinum, until most of the acid had been expelled. The residue was washed by decantation with large amounts of pure water. After this washing was complete, the mass was strongly ignited in platinum or quartz crucibles. Tantalum oxide prepared in this way has been shown to be pure.[3]

The oxide used for the third preparation of the chloride was obtained from the columbite of South Dakota as follows: The finely ground mineral was fused with potassium hydroxide in large iron crucibles; the mass was dissolved in water and the solution, after filtration, was treated with sulphuric acid, which precipitated the metallic acids. These were washed with water by decantation and then dissolved in an excess of hydrofluoric acid. The addition of potassium hydroxide to this solution gave a precipitate of potassium fluotantalate.[4] The final purifications were carried out as previously outlined.

The apparatus used for the preparation of the chloride is shown in Fig. I. The tantalum oxide (50–100 grams) was introduced into the hard Jena glass tube H, the ends of which were connected with the bulbs E and I by means of carefully ground joints which were lubricated with a trace of graphite. These joints were wrapped with several thicknesses of asbestos paper and the bulb of a thermometer was inserted in the latter at G and the temperature regulated so as to prevent a deposition of the chloride at this point. A stream of chlorine was passed through the apparatus by means of the tube B for 3–4 hours, the entire apparatus being heated with a free flame in order to remove any traces of moisture which might be present. At this time the tube H containing the oxide was heated to a low red heat for the same purpose. Sulphur monochloride was then run into the bulb E through C and heated to boiling. The oxide was slowly converted directly into the chloride which together with the excess of sulphur monochloride collected in bulb I. When all of the oxide had been converted into chloride, leaving practically no residue in the tube H, the sulphur monochloride was driven on through the entire apparatus and collected in O. The tantalum chloride was then distilled over into the bulb J and the apparatus sealed off at L. The two-way stopcock was then turned so as to deliver chlorine through D. The tantalum chloride was heated to boiling and the entire apparatus heated, so that the residue of sulphur monochloride and some of the tantalum chloride was driven over into O. The entire amount of chloride was then distilled over into K and finally into the small bulbs N. The chloride in all the bulbs was then brought to the boiling point and a small amount distilled over into the receiver O to insure the re-

[2] The author wishes to take this opportunity to express his appreciation for this and many other kindnesses shown him by Professor Smith.

[3] Balke, This Journal, 27, 1140.

[4] My thanks are due to one of my students, Mr. Lloyd Almy, who carried out this preliminary work.

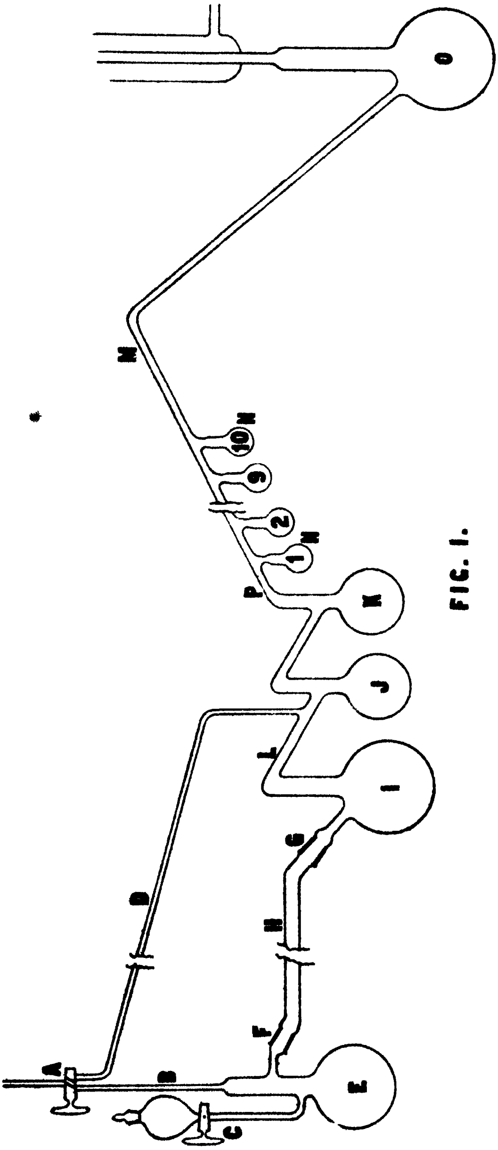

FIG. 1.

moval of the last traces of sulphur monochloride. When cold the apparatus was sealed off at P and M and finally the individual bulbs were sealed off. These contained from 5–20 grams of chloride.

The tantalum chloride so prepared was absolutely white in color, having none of the pale yellow tint which this compound is usually said to possess. When fused the chloride had a pale straw-yellow color. Five grams of this chloride were thrown into a flask containing bromine water, and the contents heated for several hours. The tantalum hydroxide was filtered out and the filtrate was evaporated to a very small bulk. This remained perfectly clear after the addition of a solution of barium chloride, which was taken to indicate that no sulphur remained in the preparation.

Density of Tantalum Chloride.—The density of this chloride was determined in carbon tetrachloride and the number 3.62 obtained. Tantalum chloride is somewhat soluble in carbon tetrachloride, and consequently a more satisfactory determination was obtained when heptane was used. This liquid did not react with the chloride nor did any of the latter dissolve. The following results were obtained:

Wt. of Pycnometer	10 2313
Wt. of Pycnometer + $TaCl_5$	23.6545
Wt. of Pycnometer + H_2O	35.2073
Wt. of Pycnometer + heptane	28 4050
Wt of Pycnometer + heptane + $TaCl_5$	39.1710

t = 27° Density of $TaCl_5$ = 3.68

Density of Tantalum Oxide.—As was found in the case of columbium oxide, the density of the tantalum oxide obtained from the present determinations varied quite appreciably, the numbers 8.62, 7.91, and 8.06 having been obtained. The density of this substance is not far from that of the weights used which were taken as having a density of 8.4 and it was found unnecessary to make a vacuum correction in the case of this substance.

Analyses of Tantalum Chloride.

The ratio studied was that of tantalum chloride to tantalum oxide, the transformation being made in quartz bulbs provided with tightly ground stoppers of quartz or glass. One of Ruprecht's best balances was used in the work and the weights were carefully standardized. All weighings were made by substitution, using a tare of the same material and very nearly the same weight as the object being weighed. The excess weight of the quartz bulb and its stopper over the tare was determined. By carefully tapping one of the small bulbs containing the tantalum chloride the latter was broken up into small pieces and by means of a file and a hot rod a crack was drawn about two-thirds of the way around the neck of the bulb. This bulb, together with the weighed quartz bulb, into the neck of which had been slipped a wide-neck funnel tube, were introduced into a gas-tight box supplied with a removable plate-glass top. Two holes had been cut in the sides of the box and rubber gloves were attached on the inside. This box contained a large amount of calcium chloride, and a stream of air, which had been passed through large amounts of sulphuric acid and then filtered through glass wool, was passed through the apparatus for several hours. By slipping the hands into the gloves it was possible to remove the top of the bulb containing the chloride and introduce the latter into the quartz bulb without soiling the neck of the bulb. In this way it was possible to effect the only transfer of material involved in the determinations in an atmosphere of dry air. After replacing the stopper in the quartz bulb the latter was removed from the box and the excess of weight over the tare again determined. The bulb was next placed in a vacuum desiccator containing water and the air pumped out. In one or two days the chloride had completely hydrolyzed and the greater part of the hydrochloric acid produced had dissolved in the water outside of the bulb. A small amount of water and a few cc. of concentrated nitric acid were introduced into the bulb and the mass evaporated to dryness with the aid of the apparatus shown in Fig. II. The hood B was fastened to the neck of the bulb by means of the split rubber stopper E, which was prevented from actual contact with the neck of the bulb by means of a strip of filter paper. F was a double-walled steam bath. D contained cotton to filter the air which was drawn slowly through the apparatus by means of a water pump attached at C. The mass was evaporated to dryness three times, a little water and a small amount of nitric acid being added each time. This insured the removal of the hydrochloric acid before the final ignition, which was made with a good blast lamp arranged so that both the air and gas were filtered through cotton in order to mini-

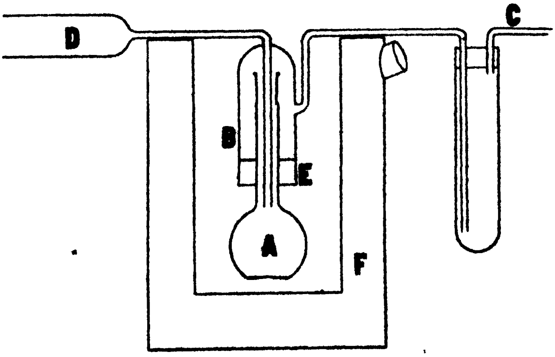

FIG. II.

mize the amount of dust which might be blown against and adhere to the sides of the bulb. These ignitions were continued until no further loss of weight was observed. In making the calculations the atomic weight of chlorine was assumed to be 35.46. The temperature of the balance and the barometric reading were recorded in the case of the individual weights and these numbers were used in applying the vacuum corrections. In the calculation the density of tantalum chloride was taken as 3.68 and that of the weights as 8.4. As mentioned previously, no vacuum correction was applied in the case of the tantalum oxide, since this correction, which was smaller than the error in weighing, affected the fifth decimal only. The following table includes the results of all determinations made which were carried to completion without accident.

Series	Bulb.	Wt of $TaCl_5$ (vac.).	Wt. of Ta_2O_5 (vac).	100 parts of $TaCl_5$ — parts of Ta_2O_5	At wt. of Ta
II	3	12.99680	8.02326	61 733	181.49
II	5	9.24957	5.71104	61 744	181.60
II	4	10.17456	6.28133	61.736	181.52
II	1	17.99542	11.11014	61.739	181.55
II	2	11.70558	7.22693	61.739	181.55
III	4	6 24767	3.85658	61.728	181.46
III	3	7.26375	4.48398	61.731	181.48
I	2	15.88270	9.80465	61 732	181 49
					Mean, 181.52

Summary.

In eight experiments 91.51605 grams of tantalum chloride gave 56.49791 grams of tantalum oxide, corresponding in round numbers to 181.5 as the atomic weight of tantalum, a number one-half a unit higher than that now given in the international table. In conclusion, it may be as well to state that further work upon the value of this constant is in progress.

SUMMARY.

INTRODUCTION.—OUTLINE OF THE INVESTIGATION AND REVIEW OF PREVIOUS WORK.

It is commonly assumed that sulphuric acid in aqueous solution ionizes in two stages according to the reactions

$$H_2SO_4 = H^+ + HSO_4^- \quad \text{and} \quad HSO_4^- = H^+ + SO_4^{=},$$

but no investigation, except that of Noyes and Eastman,[1] which was begun after this one, has furnished valuable evidence as to the proportion of the intermediate hydrosulphate ion (HSO_4^-) present, or indeed as to its existence in the solution. This research was therefore undertaken with the hope of furnishing more definite knowledge in regard to the ionization relations of this important acid.

The separate determination of the ionization constants for the two hydrogens is attended with much greater difficulty in the case of this acid than in the case of almost any of the organic dibasic acids or of such inorganic acids as sulphurous or phosphoric acid. This is true for the reasons, first, that the first hydrogen, and probably also the second hydrogen, of sulphuric acid is so largely ionized that the mass-action law cannot be employed in the study of its equilibrium relations; and second, that the difference between the degrees of ionization of the two hydrogens of sulphuric acid is much smaller than in the case of the other acids referred to, thus causing both stages of its ionization to be superposed, and preventing, among other things, a direct determination of the conductance of the intermediate hydrosulphate ion, a knowledge of which is of great importance in interpreting the conductance and transference data. In consequence of these difficulties many of the commonly applied methods fail to give, in this case, reliable results.

Thus it might be thought that the transference experiments which have previously been made by several investigators would throw much light upon the question of the intermediate ion; but the following simple calculation shows that the transference number would not be greatly different whether the acid be completely ionized in the one way or the other, provided a certain probable value be assumed for the conductance of the hydrosulphate ion. The number of chemical equivalents of sulphate ion transferred for each faraday of electricity passed would evidently be given in the two cases by the expressions:

---

[1] *Carnegie Institution Publications*, 63, 239–81 (1907).

$$\frac{\Lambda_{SO_4}}{\Lambda_H + \Lambda_{SO_4}} \text{ and } \frac{2\Lambda_{HSO_4}}{\Lambda_H + \Lambda_{HSO_4}}$$

respectively, where the Λ's represent the equivalent conductances of the ions indicated by the subscripts. At 18° the value of the first expression is $68/(68 + 315) = 0.178$; and, assuming that hydrosulphate ion has the same conductance as acetate ion,[1] the value of the second expression would be $70/(315 + 35) = 0.200$, provided in both cases it be assumed that Λ_H has the value (315) which it has at zero concentration. The matter is, however, complicated by the uncertainty as to the value of Λ_H that should be used in calculating the transference number at higher concentrations. Thus, if we put $\Lambda_H = 330$ in accordance with the transference results of Noyes and Sammet and of Noyes and Kato[2] with 0.006–0.018 normal acids, the transference number for complete ionization into hydrogen ion and sulphate ion becomes 0.171, and for that into hydrogen ion and hydrosulphate ion becomes 0.192. Experimentally the transference number for sulphuric acid at 18° in 0.01 to 0.05 formal[3] solution has been found by Tower and by Jahn and Hugbrechts to be 0.176, within a limit of error that can hardly exceed 0.002. These considerations indicate that a not very large proportion of hydrosulphate ion is present; but they also show that, on account of the errors involved in the measurement and interpretation of the transference number, it does not furnish a satisfactory means of calculating the concentration of that ion. It will be shown below, however, that the transference data do furnish valuable evidence as to the equivalent conductance of the hydrosulphate ion, and that, assuming that ion is really present in considerable proportion, they confirm the approximate validity of Noyes and Eastman's assumption in regard to it.

The existing freezing-point determinations, made by a great number of different investigators,[4] show that hydrosulphate ion is at 0° largely dissociated. Thus, in 0.05 formal solution, the value of the mol number i (representing the mols from one formula weight) has been found to be about 2.22, while in 0.01 formal solution values between 2.42 and 2.56 have been obtained. Complete ionization into H^+ and HSO_4^- would, of course, require the value 2.00, and into $2H^+$ and $SO_4^{=}$ the value 3.00. Moreover, it will be shown below that the quantity $(i - 1)$ is equal to the number of equivalents of hydrogen ion resulting from one formula weight of sulphuric acid (that is, $i - 1 = C_H/C$, where C is the formal concentration of the sulphuric acid), and that therefore freezing-point values furnish a quantitative measure of the concentration of this constituent.

---

[1] This assumption was made in all their computations by Noyes and Eastman, but without other basis than the apparently similar molecular complexity of the two ions.

[2] See *Carnegie Institution Publications*, 63, 326 (1907).

[3] In accordance with the practice now followed in this laboratory, the term "formal" is here used to express a solution containing one formula weight (in this case of H_2SO_4) per liter of solution.

[4] For references see the following section.

The experiments on the relative catalytic influences of sulphuric acid and of hydrochloric acid upon the rate of hydrolysis of cane sugar and of ethyl acetate also furnish a means of determining the proportion of hydrogen ion in sulphuric acid solutions. The results will be considered more fully below. It may be mentioned here, however, that those of Ostwald on the sugar inversion indicate that at 25° in 0.05 formal solution 1.20 equivalents of hydrogen ion result from one formula weight of sulphuric acid; and that those of Kay on the ethyl acetate catalysis indicate that at 35° at the same concentration 1.16 equivalents result.

Noyes and Eastman,[1] upon the basis of certain probable assumptions, have derived from their conductance measurements with sulphuric acid and potassium hydrogen sulphate through a wide range of temperature definite estimates of the concentrations of sulphate ion and of hydrosulphate ion in solutions of both of these substances. Thus they estimate that in a 0.05 formal solution of sulphuric acid at 18° there are 6 per cent. H_2SO_4, 61 per cent. of HSO_4^-, and 33 per cent. of $SO_4^{=}$. This corresponds to 127 per cent. of hydrogen ion, which is in rough agreement with the results of the hydrolysis experiments just referred to. In view of the assumptions involved in their estimates, independent determinations of the concentrations of these constituents seem very desirable.

From the existing thermochemical data on the heat of neutralization of sulphuric acid, Noyes and Eastman have also calculated the heat of ionization of the hydrosulphate ion, and have found that it corresponds roughly with the heat value derived from the change of dissociation of that ion with the temperature.

The purpose of this article is to discuss critically the existing data relating to sulphuric acid and the conclusions to be drawn from them, and to present the results of some new work, which includes measurements of the conductance of sulphuric acid and sodium hydrogen sulphate, transference experiments with solutions of this salt, experiments upon the relative effect of sulphuric and hydrochloric acids upon the ionization of picric acid, and determinations of the distribution of sulphuric acid between water and amyl alcohol.

PART I.—SOLUTIONS OF SULPHURIC ACID.

1. The Hydrogen-Ion Concentration Derived from Freezing-Point Measurements.

The equivalents of hydrogen ion resulting from one formula weight of the acid can be calculated from the value of the mol number i, as determined from the freezing-point lowering, by merely subtracting unity from it; that is, $C_H/C = i - 1$. For evidently:

$$iC = C_H + C_{H_2SO_4} + C_{HSO_4} + C_{SO_4}, \text{ and } C = C_{H_2SO_4} + C_{HSO_4} + C_{SO_4},$$

where C represents the formal concentration of the acid and the C's with subscripts the formal concentration of the constituents represented by those subscripts.

The freezing points of dilute sulphuric acid solutions have been determined by Pickering,[1] Loomis,[2] Jones,[3] Wildermann,[4] Ponsot,[5] Barnes,[6] Hausrath[7] and Bedford.[8] In order to determine the best values at a series of round concentrations and to form an estimate of their probable accuracy, the results of all these investigators (except the early ones of Pickering) have been correlated and combined by a method described by Noyes and Falk.[9] Only the values of $i - 1$ or C_H/C corresponding to the final values of i derived by them need therefore be reproduced here. It seems scarcely possible that any of these values at the concentrations 0.02 to 0.1 formal inclusive are in error by as much as 2 per cent., but those at 0.01 and 0.005 may well be in error by two or three times this amount.

TABLE I.—VALUES OF THE HYDROGEN-ION CONCENTRATION (C_H/C) AT 0° DERIVED FROM FREEZING-POINT MEASUREMENTS.

Formal concentration	0.005	0.010	0.020	0.025	0.050	0.100
C_H/C	1.59	1.47	1.35	1.32	1.22	1.13

2. The Hydrogen-Ion Concentration Derived from Conductance and Transference Measurements.

Noyes and Eastman, as stated in the introduction to this article, derived from their conductance measurements alone, with the aid of certain assumptions, an estimate of the hydrogen-ion concentration in sulphuric acid solutions at various concentrations and temperatures. Making the assumption that the HSO_4^- ion has the same equivalent conductance as the acetate ion, they first showed that the hydrogen-ion concentration must lie between certain comparatively narrow limits. Then making the further assumption, based on the conductivity results at high temperatures, that sulphuric acid has with respect to its first hydrogen the same ionization tendency as hydrochloric acid, definite values of the concentrations of all the constituents in the solution were derived.

[9] THIS JOURNAL, 32, 1027 (1910).

It may readily be shown that the first and most arbitrary of these two assumptions can be dispensed with by combining with the conductance values the results of transference experiments. Thus for the specific conductance L we have

$$1000\ L = C_H\Lambda_H + 2C_{SO_4}\Lambda_{SO_4} + C_{HSO_4}\Lambda_{HSO_4}, \qquad (1)$$

where the C's represent the formal concentrations and the Λ's the equivalent conductances of the various ions. And for the number of equivalents (N_{SO_4}) of SO_4 transferred per faraday of electricity, we have

$$N_{SO_4} = \frac{2C_{SO_4}A_{SO_4}}{1000\ L} + \frac{2C_{HSO_4}A_{HSO_4}}{1000\ L}. \qquad (2)$$

This follows from the principle that the quantity in equivalents of each ion transferred per faraday is equal to the ratio of its conductance to the whole conductance and from the fact that one electrical equivalent of HSO_4 ion yields two chemical or analytical equivalents of SO_4. Writing this equation in the form

$$\tfrac{1}{2} \times 1000\ L\ N_{SO_4} = C_{SO_4}A_{SO_4} + C_{HSO_4}A_{HSO_4}, \qquad (3)$$

subtracting it from equation (1), dividing both members by C, the formal concentration of the sulphuric acid, and putting $1000L/2C = A$, the equivalent conductance of the acid, we get

$$2A\,(1 - \tfrac{1}{2}N_{SO_4}) = \frac{C_HA_H}{C} + \frac{C_{SO_4}A_{SO_4}}{C}. \qquad (4)$$

The last term of this expression is relatively small and can vary only between the limits zero and $\frac{1}{2}(C_H/C)A_{SO_4}$, corresponding to the two limiting cases where HSO_4^-, and where $SO_4^{=}$, is the only anion present. Within corresponding limits the value of C_H/C can therefore be determined, and evidently without involving any assumption as to the value of A_{HSO_4}.

Let us now consider the transference and conductance data available for this calculation.

The transference number for sulphuric acid has been determined by many different investigators,[1] but only the determinations by Bein, by

---

[1] Wiedmann, *Pogg. Ann.*, 99, 162 (1856); Hittorf, *Ibid.*, 106, 401 (1859); Bein, *Z. physik. Chem.*, 27, 52 (1898); Starck, *Ibid.*, 29, 394 (1899); Tower, THIS JOURNAL, 26,

Tower, and by Jahn and Hugbrechts, seem to have been made with precautions sufficient to warrant the consideration of the results. The following table contains the final values obtained by them for the transference number of the anion (N_{SO_4}) reduced to uniform temperatures by means of the temperature coefficient 0.0011[1], and in the case of Jahn and Hugbrecht's results interpolated for round concentrations.

TABLE II.—TRANSFERENCE NUMBER FOR THE SULPHATE ION.

Formal concen	At 8°		At 20°		At 32°.		At 97°.
	Bein	Tower.	Tower.	J & H.	Tower	J. & H.	Bein.
0.5000	..	...	0.188	...	...	...	...
0.250		.	0.187	..	..	...	...
0.125			...	0.170	...	...	...
0.100		.	0.181	...	...	...	...
0.050	.	0.164	0.176	0.177	0.192	..	..
0.025	0.172	0.164	0.179	0.177	0.192	0.194	0.304
0.010		0.168	0.181	0.178	0.191	0.189	..
0.004		..	.	0.158		0.164	..

From these results one is justified in concluding that the transference number is substantially constant between 0.01 and 0.05 formal, and that within this concentration interval it has the following values:

0°.	8°.	18°	20°	25°.	32°.
0.157[2]	0.165	0.176	0.178	0.184	0.192

At the higher concentrations 0.1 to 0.5 formal Tower's data are to be regarded as the best values, in view of the concordance of his results with the cathode and anode portions, and of the constancy in content of the middle portions.

Two entirely independent series of measurements of the conductance of sulphuric acid at 25° have recently been made in this laboratory, by Mr. G. W. Eastman[3] and by Mr. F. L. Hunt,[4] respectively, and a series at 0° with the same solutions has been made by the latter.[5] The

[1] This is the value found by Tower for the temperature-coefficient ($\Delta N_{SO_4}/\Delta T$) between 8 and 32° for 0.01 to 0.05 formal solutions. The reduction was in no case for a greater interval than 3°.

[2] This value is extrapolated, but can in consequence hardly be in error by more than 0.001.

[3] *Carnegie Institution Publications*, **63**, 262 (1907).

[4] In connection with a research which is soon to be published in detail.

[5] Measurements with dilute sulphuric acid have been previously published at 18° by Kohlrausch (L.-B.-M. Tabellen, p. 746); at 0 and 18° by Barnes (*Proc. Royal Soc. Canada*, [2] **6**, III, 46 (1900)); at 0, 15, 25 and 35° by Jones and Douglas (*Am. Chem. J.*, **26**, 436 (1901)); see also Tower's "Conductivity of Liquids," p. 164); at 0 and 18° by Whetham (*Z. physik. Chem.*, **33**, 351 (1900); **55**, 205 (1906)); and at 18° to 306° by Noyes and Eastman (*Loc. cit.*).

results of these determinations are presented in the following table. The concentrations are expressed in formula weights per liter at the temperature of the measurement, and the equivalent conductance in reciprocal ohms:

TABLE III.—EQUIVALENT CONDUCTANCE OF SULPHURIC ACID AT 25° AND 0°.

Formal concn.	25°. N. & E.	25° F. L. H.	25°. Mean.	0°. F. L. H.
0.1000	...	234.7	234.7	165.4
0.0500	251.2	251.2	251.2	177.2
0.0250	273.0	273.1	273.0	191.5
0.0125	...	299.3	299.2	206.9
0.00625	327.5	...	327.5	...
0.00500	(337.0)	336.8	336.8	226.4
0.00100	390.8	...	390.8	...
0.00025	413.7	...	413.7	..
0.00010	418.5	. .	418.5	..

Besides the transference and conductance data for the acid, the values of the equivalent conductances of hydrogen ion (Λ_H) and sulphate ion (Λ_{SO_4}) are needed for the computation of C_H/C. For Λ_H at zero concentration, Goodwin and Haskell[1] and also Kohlrausch[2] have derived the value 315 at 18°, which corresponds to 348 at 25° if the temperature coefficient ($d\Lambda/\Lambda_{18}dT = 0.0153$) given by Kohlrausch be employed. For Λ_{SO_4} the value given by Kohlrausch[2] at 18° is 68, which, using his temperature coefficient (0.0227), becomes 79 at 25°.

The values of Λ_H and Λ_{SO_4} at 0° at zero concentration we have found to be 224 and 43, respectively, by the following method of derivation. Noyes and Coolidge,[3] from their measurements at 0° of the conductance of potassium chloride (which are perfectly concordant with those of Whetham), obtained the value 81.4 for Λ_0 for that salt. Multiplying this by the transference number 0.496 (assumed to be the same as at 18°) we get $\Lambda_K = 40.3$ and $\Lambda_{Cl} = 41.1$. Furthermore, Λ_0 for HCl at 0° was found to be 265.4 by multiplying Λ_0 for HCl at 18° = 379.5 by the ratio of the Λ values for 0.01 normal HCl at 0° and 18°, which ratio has been found to be 0.700 by Barnes[4] and 0.6994 by Déguisne.[5] Subtracting $\Lambda_{Cl} = 41.1$, we then obtain $\Lambda_H = 224$.[6] Similarly, Λ_0 for K_2SO_4 at 0° was found to be 83.1 by multiplying Λ_0 for K_2SO_4 at 18° = 132.6 by the ratio of the Λ values for 0.001 normal K_2SO_4 at 0° and at 18°, which ratio has the value 0.627 (0.628 according to Archibald[1] and 0.625 according to Déguisne). Subtracting $\Lambda_K = 40.3$, we get $\Lambda_{SO_4} = 42.8$.

[5] See *Landolt-Bornstein-Meyerhoffer Tabellen*, p. 755.

[6] Attention may here be called to the fact that Johnston's rough estimate of Λ_H at 0° as 240 (THIS JOURNAL, 31, 1015 (1909)) is much too high.

It should be mentioned, however, that the transference experiments of Noyes and Sammet[2] and of Noyes and Kato[3] with hydrochloric and nitric acids have indicated that the equivalent conductance of hydrogen ion is about 5 per cent. greater in 0.005 to 0.02 normal solutions of these acids than it is at zero concentration. It seems reasonable to assume that this may be also the case in sulphuric acid solutions; and it seems therefore worth while to show in the subsequent calculations the effect of this assumption, according to which Λ_H would have the value 365 at 25° and 235 at 0°. At the same time it should be recognized that the employment of these particular values at higher concentrations than 0.02 normal has at present no experimental basis.

The values of C_H/C at 25° and at 0°, calculated from the foregoing data by means of equation (4) under the two limiting assumptions that C_{SO_4} is equal to zero and to $\frac{1}{2}C_H$, respectively, and for the two values of Λ_H just referred to, are given in the following table The first values given in each column are those corresponding to the assumption that SO_4 is the only anion present:

TABLE IV VALUES OF C_H/C AT 25° AND 0° DERIVED FROM CONDUCTANCE AND TRANSFERENCE MEASUREMENTS.

Formal concen	C_H/C at 25° (for $\Lambda_H = 348$)	C_H/C at 25° (for $\Lambda_H = 365$)	C_H/C at 0° (for $\Lambda_H = 235$)	C_H/C at 0° (for $\Lambda_H = 224$).
0.100	1.10–1.22	1.05–1.16	1.19–1.29	1.24–1.36
0.050	1.18–1.31	1.13–1.24	1.27–1.39	1.33–1.46

0.00625	1.53–1.71	1.46–1.62	....	......
0.00500	1.58–1.76	1.51–1.67	1.63–1.77	1.70–1.86

3. The Equivalent Conductance of Hydrosulphate Ion Derived from Conductance and Transference Measurements.

The value of the equivalent conductance of the hydrosulphate ion is of so much importance in the interpretation of transference and conductance results that it is worth while to consider just what conclusion in regard to it can be drawn from the existing data. For this purpose we may make use of equation (3), written in the form:

$$\Lambda N_{SO_4} = \Lambda_{SO_4}(C_{SO_4}/C) + \Lambda_{HSO_4}(C_{HSO_4}/C). \qquad (5)$$

In this equation N_{SO_4}, Λ, and Λ_{SO_4} are known; and between C_{SO_4}, C_{HSO_4}, and C_H (which last is known within comparatively narrow limits) there exists the following relation expressing the equality of the equivalent concentrations of the positive and negative ions:

---

[1] *Trans. N. S. Inst. of Science*, 10, 38 (1898).

[2] THIS JOURNAL, 24, 958 (1902).

[3] *Ibid.*, 30, 333 (1908).

$$C_H = 2C_{SO_4} + C_{HSO_4}. \qquad (6)$$

In order that Λ_{HSO_4} might be definitely determined by these equations, either C_{SO_4} or C_{HSO_4} would have to be known; but it is found by computation that the value involved is such that it can be determined within narrow limits, provided only the assumption is justified that the concentration C_{HSO_4} forms a reasonably large part (say as much as one-fourth) of the total ion concentration $(C_{HSO_4} + 2C_{SO_4})$. Thus the values of Λ_{HSO_4} calculated by (5) from the data given in Tables II, III and IV under the limiting assumption that $C_{HSO_4} = C$ and under the assumption that $C_{HSO_4} = \frac{1}{4}C_A$, and with the values of C_H/C corresponding to the smaller and larger values of Λ_H are given in Table V.

TABLE V.—CALCULATED VALUES OF THE EQUIVALENT CONDUCTANCE OF HYDROSULPHATE ION AT 25° AND 0°

Concentration.	At 25°.				At 0°.			
	For $C_{HSO_4} = C$		For $C_{HSO_4} = \frac{1}{4}C_H$.		For $C_{HSO_4} = C$.		For $C_{HSO_4} = C$	
	$\Lambda_H = 348$	$\Lambda_H = 365$.	$\Lambda_H = 348$.	$\Lambda_H = 365$	$\Lambda_H = 224$	$\Lambda_H = 235$	$\Lambda_H = 224$	$\Lambda_H = 235$
0.100	36.0	38.4	37.0	44.0	18.9	20.2	13.8	17.6
0.050	35.1	37.5	34.0	41.0	18.8	20.1	14.1	17.6
0.025	35.3	37.7	34.5	41.0	18.8	20.2	14.5	18.3
0.0125	35.3	37.7	34.5	42.0	18.8	20.5	15.1	19.1
Mean,	35.4	37.8	35.0	42.0	18.8	20.2	14.4	18.1

It is evident from these calculations that at 25° the value of Λ_{HSO_4} is 35 ± 1 if $\Lambda_H = 348$, or 40 ± 2 if $\Lambda_H = 365$, and that at 0° the value is 16 ± 2 if $\Lambda_H = 224$, or 19 ± 1 if $\Lambda_H = 235$, it being always assumed that the HSO_4^- ion is present in sufficient proportion to make the calculated values significant. It will be noted that the value 40 at 25° or 19 at 0° for Λ_{HSO_4} is not far from one-half of that for Λ_{SO_4} (79 or 43), which would be the case if the frictional resistance to the motions of the two ions were nearly equal, since the electric force acting on the latter, owing to its double charge, is twice as great.

4. The Hydrogen-Ion Concentration Derived from Catalysis Experiments.

Since the catalytic influence of acids upon reactions of hydrolysis is nearly proportional to their hydrogen-ion concentration and is little influenced by other factors, the concentration of that ion in sulphuric acid solutions may be determined by comparing the effect of that acid on the reaction rate with that of an acid of known ionization, such as hydrochloric acid, at nearly the same ion concentration. The data that seem best adapted to this purpose are those of Ostwald[1] upon the sugar inversion and of Kay[2] on the ethyl acetate hydrolysis. Table VI contains the specific reaction rates as determined by these two investigators.

---

[1] Ostwald, *J. prakt. Chem.*, [2] 31, 313–4 (1885).

[2] Kay, *Proc. Royal Soc. Edinburgh*, 22, 493–496 (1898–9).

TABLE VI.—RELATIVE CATALYTIC EFFECTS OF SULPHURIC AND HYDROCHLORIC ACIDS.

Acid.	Formal concen	Sugar inversion at 25°.	Ethyl acetate hydrolysis at 35°.
HCl	0.5	20.5	...
	0.2	....	146.9
	0.1	3.34	71.8
	0.01	0.313	...
H_2SO_4	0.25	10.7	201.5
	0.05	2.08	44.1
	0.005	0.265	6.06

The best method of computation clearly seems to be to determine by interpolation the concentration (C_A) of a hydrochloric acid solution which has the same catalytic effect as each of the measured sulphuric acid solutions. This we have done (for the two most dilute solutions of the latter acid) by calculating first for the former acid the values of the ratio (k_A/C_A) of the specific reaction rate to the concentration, which values do not vary greatly with the dilution, interpolating for a concentration which is estimated to be nearly isohydric with the sulphuric acid solution in question, and then dividing the reaction rate for the latter acid by this ratio, the interpolation and division being once more repeated, if necessary. The concentration C_A of hydrochloric acid so obtained, when multiplied by the corresponding ionization (γ_A) as given by the conductance ratio (Λ/Λ_0), yields the hydrogen-ion concentration C_H in the solution of either acid, and this, when divided by the concentration of the sulphuric acid C_B, gives the mols of hydrogen ion resulting from one formula weight.

Two sets of values of the ionization γ_A were employed, these being obtained by dividing the values of Λ for hydrochloric acid at 18° found by Kohlrausch, Goodwin and Haskell, and Noyes and Cooper[1] in one case by $\Lambda_0 = 380$, and in the other case by $\Lambda_0 = 396$, corresponding respectively to the values of Λ_H at zero concentration (315), and at higher concentrations (331), as found by Noyes, Sammet, and Kato.

The data and results are given in Table VII:

5. The Hydrogen-Ion Concentration Derived from the Relative Effects of Sulphuric and Hydrochloric Acids upon the Ionization of Picric Acid.

Experiments by M. A. STEWART.

A method which naturally suggests itself for the determination of the hydrogen-ion concentration is that based on the principle of isohydric solutions, which consists in finding the concentration which a solution of sulphuric acid must have in order that it may be mixed with a definite solution of hydrochloric acid with the production of a mixture whose specific conductance is the mean of that of the separate solutions. Theoretically this result occurs only when the hydrogen-ion concentrations of the two acids are equal. Both calculation and experiment clearly showed, however, that the sensitiveness of the method was so slight as to make it of no value.

---

[1] *Carnegie Institution Publications*, 63, 138 (1907).

A new method was therefore employed. This consists in principle in determining the relative concentrations of hydrochloric acid and of sulphuric acid which drive back the ionization of a third acid to the same extent. Picric acid was chosen as the third acid, and the condition of equal concentration of its un-ionized part in the solution was determined by shaking it with benzene, between which and water it distributes itself, as shown by the investigation of Rothmund and Drucker.[1]

The experiments were carried out in detail as follows: In one of two bottles of two-liter capacity were placed about 1300 cc. of the sulphuric acid solution to be investigated, and in the other the same volume of a hydrochloric acid solution (of a concentration estimated to be about isohydric); then to both were added an equal volume (about 70 cc.) of a nearly saturated solution of picric acid in benzene. These were rotated for four to five hours in a thermostat at 25°. The same volume (about 50 cc.) of the benzene phase was then removed from each, and, after the addition of a little water, each portion was titrated with about 0.3 normal barium hydroxide, using phenolphthalein as indicator. Then the experiment was repeated with a second solution of hydrochloric acid of somewhat different concentration from that first used, and the rate of change was computed of the concentration of the acid with the quantity of picric acid contained in the benzene phase,

$$\left(\frac{\Delta C_{HCl}}{C_{HCl}} \Big/ \frac{\Delta C_{HP}}{C_{HP}}\right);$$

and therefrom, under the assumption of proportionality, the concentration of hydrochloric acid which would have an effect just identical with that of the sulphuric acid was calculated.

The picric acid used was purified by crystallization from dilute hydrochloric acid, from benzene, from alcohol, and from water. The benzene used was the thiophene-free commercial product.

Preliminary experiments showed that no appreciable amount of either sulphuric acid or hydrochloric acid would go into the benzene. Normal sulphuric acid was shaken with 50 cc. of benzene; the benzene layer was separated, and to it were added a little water and phenolphthalein and then 0.1 normal alkali. One drop of the alkali gave as strong a coloration as in the case of pure water to which phenolphthalein was added, showing that no appreciable amount of sulphuric acid could have gone into the benzene. A similar experiment with normal hydrochloric acid gave the same result.

---

[1] *Z. physik. Chem.*, 46, 827–53 (1903).

The error due to the effect of the picric acid on the ionization of the sulphuric and hydrochloric acids is very small: first, because the amount of picric acid is relatively small, so that the hydrogen ion from it forms only a small part of the total hydrogen ion, and second, because the sulphuric and hydrochloric acids would be affected to nearly the same extent and in the same direction. Moreover, since the ion concentrations in the two acid solutions are nearly the same, an appreciable error can hardly arise through a variation in the distribution ratio for the picric acid between the two phases.

The experimental results, all of which are at 25°, are given in the following table. The fourth column shows the percentage difference in the concentrations of the picric acid in the two benzene solutions which had been shaken with the hydrochloric acid and with the sulphuric acid solutions. The values in heavy type in the rows below each group of experiments, show in the second and third columns the calculated concentrations of the two acids at which they have the same hydrogen-ion concen-

[1] Or 1.10, assuming $\Lambda_0 = 396$ and $100\gamma = 90.3$.

[2] Or 1.20, assuming $\Lambda_0 = 396$ and $100\gamma = 92.0$.

tration, and in the last three columns the corresponding values of the percentage ionization of the hydrochloric acid (as derived from its conductance ratio Λ/Λ_0, using Kohlrausch's data[1] at 18° and taking $\Lambda_0 = 380$), of the hydrogen-ion concentration C_H in either solution, and of the ratio C_H/C of that concentration to the formal concentration of the sulphuric acid. The calculated values of C_H and C_H/C would be 4 per cent. smaller than those gven in the table if in calculating the ionization Λ_0 be taken equal to 396. This may be justifiable for the two most dilute solutions, but any value assumed for the more concentrated solutions would be entirely arbitrary.

6. Comparison of the Hydrogen Ion Concentrations Derived by Various Methods.

The values of the hydrogen-ion concentration (C_H/C) derived by the methods already considered are brought together in Table IX. Excepting those derived from the freezing point, the values given are those calculated under the assumption that the equivalent conductance of hydrogen ion Λ_H is that derived from the conductance of acids at zero concentration. If it be assumed, in correspondence with the transference results of Noyes, Sammet, and Kato, that in acid solutions of medium concentrations Λ_H is 5 per cent. greater than at zero concentration, then all the values of C_H/C (except those derived from the freezing point) should be increased by 4 to 5 per cent.

TABLE IX.—VALUES OF THE HYDROGEN ION CONCENTRATION DERIVED BY VARIOUS METHODS.

Formal concentration.	Freezing point. 0°.	Conductance and transference.		Sugar catalysis. 25°.	Picric acid expts. 25	Ester catalysis 35°.
		0°.	25°.			
0.050	1.22	1.33–1.46	1.18–1.31	1.20	1.15	1.16
0.025	1.32	1.44–1.57	1.28–1.42	....	1.25	....
0.005	1.59	1.64–1.79	1.58–1.76	1.65	....	1.68

It will be seen that at 0° the values derived from the freezing points are much less than even the lower limiting values derived from the conductivity and transference experiments, which values were obtained under the assumption that only H^+ and $SO_4^=$ ions exist in the solution. This discordance may well be due in part to error in the value of (Λ_H) employed, but it can not be wholly accounted for in this way.

It will also be noted that the conductance and transference data show that there is a large decrease in the hydrogen-ion concentration between 0° and 25°. It will also be observed that the values derived from the conductance are in accordance with those derived from the sugar catalysis; but that they are considerably higher at 0.05 and 0.025 formal than those derived by the picric acid method. It may be recalled that a change in the assumed value of Λ_H will not account for this divergence, since it would affect the latter values to nearly the same extent as those from the conductance.

---

[1] As given in *Landolt-Börnstein-Meyerhoffer's Tabellen*, p. 746.

7. Concentration of the Other Constituents.

Since the values of the hydrogen-ion concentration calculated from the conductance and transference data differ by about 10 per cent. in the two limiting cases, in one of which no hydrosulphate ion and the other of which no sulphate ion is assumed to be present, it might seem that the proportion of these two ions in the solution might be obtained by considering in connection with these limiting values that of the hydrogen-ion concentration derived by some of the other methods. The degree of inaccuracy of all the values is, however, great enough to make such a calculation of little, if any, value. Indeed, the values obtained by the picric acid distribution methods (like those at 0° obtained from the freezing point) are below the lower limit of those derived from the conductance, so that upon solving the appropriate equations mathematically a negative value of the hydrosulphate ion concentration results.

In order to determine the concentration of the other constituents (SO_4^{--}, HSO_4^-, and H_2SO_4), further information in regard to at least one of them is therefore essential. The others would then become determined in virtue of the condition equations,

$$C_H + C_{HSO_4} + 2C_{H_2SO_4} = 2C, \tag{7}$$

and

$$C_{SO_4} + C_{HSO_4} + C_{H_2SO_4} = C. \tag{8}$$

To find a method which will give such information in a conclusive way is difficult. The most promising line of attack would seem to be to determine the concentration of the sulphate ion through the measurement of some property closely related to it; and in the hope of doing this we have studied the effects of sodium sulphate, sodium hydrogen sulphate, and sulphuric acid on the solubility of thallous sulphate. But the results of these experiments, which will be described in another article, show, even in the case of sodium sulphate, such a wide divergence from the law of the solubility product that it seems impracticable to employ them for the purpose in question. Another method, simpler in principle, of determining the sulphate-ion concentration in sulphuric acid solutions is to measure the electromotive force of a concentration cell, such as is represented by the combination Hg, Hg_2SO_4, K_2SO_4Aq, H_2SO_4Aq, Hg_2SO_4, Hg. Experiments of this kind are to be undertaken in this laboratory.

In the absence of information as to the sulphate ion the conclusion of Noyes and Eastman that the ionization tendency of sulphuric acid with reference to its first hydrogen is the same as that of hydrochloric acid is the only principle that seems to be sufficiently well substantiated to warrant being made the basis of a provisional computation of the constitution of sulphuric acid solutions.

That conclusion, it may be recalled, was based: (1) on the fact that at the temperature of 156° the formal conductance of potassium hydrogen sulphate (435) in 0.1 formal solution has become even less than that of potassium chloride (490), showing that the former salt can dissociate to an important extent only into K^+ and HSO_4^-, that therefore the ion HSO_4^- is only very slightly dissociated; (2) on the conclusion that this ion must *a fortiori* be very slightly dissociated in fairly concentrated solutions of sulphuric acid itself at 156° and above; (3) on the fact that the conductance of such solutions when interpreted under this assumption shows that the ionization of the acid is substantially equal to that of hydrochloric acid of the same concentration at 156, 218, and 306°; and (4) on the assumption that this equality of ionization holds true also at lower temperatures, such as 18°, inasmuch as differences in ionization of largely ionized substances are as a rule less pronounced at lower than at higher temperatures.

Upon the basis of this conclusion in regard to the un-ionized H_2SO_4, the concentration of the constituents may be calculated by equations (7) and (8) by using separately each of the values of C_H/C, given in Table IX. It has seemed worth while, however, to make such calculations only with the values at 0° derived from the freezing point and with the mean of the values at 25° derived from the sugar catalysis experiments and the picric acid experiments. We have, in addition, calculated the concentrations of the various constituents by the method described by Noyes and Eastman[1] from the conductance and transference data at 0° and 25°, so that the results may be compared on the one hand with those at 0° obtained from the freezing-point data, and on the other hand with those at 25° obtained by the catalysis and picric acid experiments. The results are given in Table X.

8. Relative Concentrations of Un-ionized Sulphuric Acid Derived from Distribution Experiments.

Experiments by M. A. STEWART.

In the hope of furnishing further evidence as to the proportion of unionized H_2SO_4 in the sulphuric acid solutions, an attempt was made to find an organic solvent between which and water the acid would distribute itself to an appreciable extent. In this way at least the relative concentrations of H_2SO_4 in different solutions might be determined. Though the experiments made in this direction do not lead to very definite conclusions, yet they seem worthy of record.

Amyl alcohol was the only solvent that was found to take up from water a considerable quantity of sulphuric acid, and the commercial product did this in much less degree after it had been thoroughly washed with cold dilute sulphuric acid (one volume of the concentrated acid and two of water), with alkali, and with water, and distilled. It was, however, the so purified alcohol that was used for the following experiments.

The methods of measurement and of computation were as follows: The sulphuric acid solutions and amyl alcohol were shaken from four to six hours at 25°, in bottles which had previously been well steamed out in an inverted position and then quickly dried by a current of air. After settling clear, a certain volume of the alcohol phase was removed and shaken in a dry bottle with a certain volume of water which had been saturated with amyl alcohol at 25°. This second water phase was then separated and its specific conductance measured. The specific conductances of the first water phase (*i. e.*, the sulphuric acid solutions after they were shaken with the amyl alcohol) were also measured. The concentration of sulphuric acid in the first water phase and also its concentration in the amyl alcohol phase (derived from its concentration in the water with which that phase was shaken) were obtained from a plot of the cube root of the specific conductance against the ratio of the specific conductance to the concentration (L/C).

This method of determining the concentration of the sulphuric acid in the amyl alcohol was used because the concentrations were so small that by ordinary chemical methods of determination large errors would be likely to be introduced. The concentration of sulphuric acid in the first water phase had to be determined after the shaking because some of the water went into the amyl alcohol and some amyl alcohol went into it, thereby changing its concentration. The specific conductance of ordinary solutions of the acid in water could not be used in this case, for it was found that the amyl alcohol which went into the water phase decreased its specific conductance. Three experiments, made to determine the magnitude of the necessary correction, showed that the decrease of specific conductance due to saturation with amyl alcohol was

5 per cent. at 0.1897 formal, 7.2 per cent. at 0.0471 formal, and 7.6 per cent. at 0.0059 formal.

The specific conductance of a 0.0016 normal solution of sulphuric acid in amyl alcohol (obtained by shaking amyl alcohol with 0.094 normal aqueous sulphuric acid) was found to be less than 9×10^{-6}, which showed that the ionization of the sulphuric acid in the amyl alcohol was negligible.

The following tables contain the results. Under C_W is given the formal concentration of the sulphuric acid present after shaking in the aqueous phase, and under C_A/C_W the ratio to this concentration of that (C_A) in the amyl alcohol phase. An *s* attached to the experiment number shows the equilibrium was approached from the side of supersaturation, namely, by first shaking the amyl alcohol with a stronger sulphuric acid solution than that with which it was finally brought into equilibrium. All the experiments were made at 25°.

TABLE XI.—DATA RELATING TO THE DISTRIBUTION BETWEEN WATER AND AMYL ALCOHOL.

Expt. No.	C_W.	$10^3C_A/C_W$.
1	0.1752	8 996
2	0.1749	8.825
3*s*	0.1844	9.183
4*s*	0 1849	9.207
5	0.08340	7.142
6	0.08131	7.183
7*s*	0.09034	7.271
8*s*	0.09154	7.384
9	0.04484	6.093
10	0.04447	6.138
11*s*	0.04695	6.140
12*s*	0.04695	6.257
13	0.02216	5.347
14	0.02234	5.294
15*s*	0.02160	5.355
16*s*	0.02162	5.232

TABLE XII.—MEAN VALUES OF THE DISTRIBUTION RATIO.

C_W.	C_A/C_W.
0.0220	0.00531
0.0460	0.00617
0.0870	0.00725
0.1800	0.00906

It will be seen that the concentration (C_A) of the acid in the alcohol increases more rapidly than its concentration (C_W) in the water, corresponding to the increase in the proportion of un-ionized acid in the more concentrated aqueous solutions. The fact that the rate of that increase is so small—smaller even than in the case of hydrochloric acid at corresponding concentrations—is apparently significant, for it indicates that the un-ionized H_2SO_4 is formed out of two ions (H^+ and HSO_4^-) in analogy with diionic substances, instead of directly out of three ions (H^+, H^+, and $SO_4^{=}$), in analogy with triionic substances.[1]

PART II.—SOLUTIONS OF SODIUM HYDROGEN SULPHATE.

9. Transference Measurements.

By M. A. Stewart.

Transference experiments with sodium hydrogen sulphate should throw much light on the extent to which hydrosulphate ion ionizes into hydrogen ion and sulphate ion. Such experiments were therefore made with an approximately 0.1 formal solution of this salt at 25°.

a. Preparation and Analysis of the Solutions.—A solution of sulphuric acid approximately 1-formal was made up and titrated against ignited sodium carbonate. About 500 cc. of this acid solution were weighed out, and enough sodium carbonate was added to it to neutralize it to within 0.5 per cent. This solution was boiled to expel the carbon dioxide and the neutralization completed with sodium hydroxide, with methyl orange as indicator. (Sodium hydroxide was not used for the entire neutralization for the reason that it is not readily obtained so pure as the carbonate.) To this solution was then added a second portion of the original sulphuric acid solution, of the same weight as the first portion, and the mixture made up to ten liters. A second solution (No. 2) was afterwards prepared in the same way.

The solutions were analyzed: (1) by determining the sodium by evaporating, igniting, and weighing as Na_2SO_4; (2) by determining the sulphate as barium sulphate; and (3) by determining the hydrogen by titrating (by weight) with a standardized, approximately 0.2 formal, sodium hydroxide solution.

The mean results of the analyses of the sodium hydrogen sulphate solutions are as follows, the content being referred to 1000 grams of the solution:

	Mols. SO_4.	Mols. H.	Mols. Na.	Density at 25°/4°.
Solution No. 1..........	0.09889	0.09905	0.09886	1.0063
Solution No. 2..........	0.10090	0.10096	0.10083	1.0065

---

[1] The results of a distribution experiment made by shaking a 0.1015 formal solution of sodium hydrogen sulphate with amyl alcohol are also worth recording. It was found in this case that the value of C_A was 0.000299. Correcting the $NaHSO_4$ concentration to just 0.1000 formal, we get for C_A the value 0.000294; and interpolation of the data obtained for the acid itself shows that the sulphuric acid solution which would be in equilibrium with this same amyl-alcohol phase, and which would therefore contain un-ionized sulphuric acid at the same concentration as the 0.1000 formal sodium hydrosulphate is 0.0474 formal.

b. Description of the Apparatus and Method.—The apparatus used in these experiments was of the same form as that used earlier by Noyes.[1] It consisted of two glass U-tubes, each with one arm bent at right angles, joined together by a double band of rubber tubing. The inside diameter of the tubes used at first was about 3.5 cm. and the height about 37 cm. Smaller tubes, 2.5 cm. in diameter, with the other dimensions the same as before, were used later. The positive electrode was a polished platinum disk which would just fit loosely in the tube, and the negative electrode was a platinum spiral. A disk was used as anode, in order to give a large surface, so as to reduce the current density and prevent as far as possible the formation of decomposition products of sulphuric acid. The surface of the liquid at the cathode was kept at about two-thirds of the height of the tube, and the surface at the anode about 5 cm. above the top of the lower bend, with the anode about 1 cm. below the surface. The surface of the liquid in the anode limb was kept at this low position because the liquid around the anode tends to become heavier (due to the migration of sulphuric acid into it), so that to fill up that limb much above the bend would unnecessarily increase the quantity of solution. This position was maintained by connecting the anode arm with a small tube dipping beneath a column of water. All the openings were closed with rubber stoppers, but the liquid in the cathode arm was open to the outside air through a glass tube passing through the stopper. The middle portions of the solutions were removed through the small upright tubes on the middle arms. In order to make the joint between the U-tubes as tight as possible, a coating of vaseline was put over the rubber band and each side wound around with wire. The apparatus was immersed in a thermostat at 25° ± 0.02°, so that the horizontal middle part was covered by at least 3 cm. of water. Two silver coulometers were used, one on each side of the transference apparatus, in order to make sure that there was no leakage of the electric current.

After the electrolysis the solution was divided into an anode, a cathode, and a middle portion (represented by A, C, and M in the tables below), except that in the first experiment the middle portion was divided into three parts (M_A, M, and M_C).

The middle portion was titrated with a solution of sodium hydroxide containing 0.19816 equivalent NaOH per 1000 grams of solution, the content having been determined by titration against a standard sulphuric acid solution. The cathode and anode portions were also titrated with this sodium hydroxide solution; and, in addition, their contents in sulphate and in sodium were determined in the same way as was done with the original solution, the former by precipitating and weighing as barium sulphate and the latter by evaporating, igniting, and weighing as sodium sulphate. The determination of the sulphate was made in the portion of the solution that had already been titrated with sodium hydroxide.

---

[1] THIS JOURNAL, 23, 42 (1901).

c. Data of the Experiments.—Ten transference experiments were made, but in four of them the change in the middle portion was so large that the experiments were not completed. The results of the other six experiments are given in the following tables.

The headings of the columns are for the most part self-explanatory. The figures in columns II, IV, and V represent grams; those in VI, VII, VIII, and IX, milli-equivalents. In the case of Experiment No. 1, column VIII*a* contains the sum of the changes in the anode (A) and anode middle (M_A) portions or in the cathode (C) and cathode middle (M_C) portions.

10. Summary of the Transference Results.

The results of the preceding experiments are summarized in the following table. The figures show the increase in the number of milliequivalents of the three constituents named in the heading in the anode and cathode portions when one faraday of electricity is passed at 25° through a solution containing approximately 0.1 formula weight of sodium hydrogen sulphate per liter. The "weighted mean" is derived from the means of the anode and cathode values by assigning to each a weight inversely proportional to the square of its average deviation ("A. D."). The "final values" are derived from the three weighted means upon the basis of the principle[1] that the increment of the equivalents of hydrogen must equal the difference of the increments of the equivalents of sulphate and of sodium ($\Delta H = \Delta(\frac{1}{2}SO_4) - \Delta Na$), by distributing the deviation from this principle upon the three separate values in inverse proportion to the square of their average deviations.

---

[1] This principle can be shown to be a consequence of the facts that one equivalent of hydrogen is produced at the anode by the electrolysis; that the only ions in

11. Conductance Measurements.

Before discussing further the transference values, the results of some conductance measurements with sodium hydrogen sulphate will be presented. These measurements were made in a U-shaped conductance vessel with electrodes which were mechanically roughened, but not platinized.

The results are given in the following table, in which the "dilution" signifies the liters of solution in which one formula weight of $NaHSO_4$ was contained.

Table XV.—Formal Conductance of Sodium Hydrogen Sulphate at 25°.

Dilution.	Series 1.	Series 2.	Mean.	Barth.
10	261.60	261.73	261.67	...
20	297.00	....	297.00	...
40	337.78	337.68	337.73	336.8
80	381.42	....	381.42	380.7
160	424.94	424.58	424.76	423.0
320	463.48	463.10	463.30	463.0
640	494.40	494.60	494.50	497.0
1280	516.60	516.89	516.75	519.0
2560	530.74	531.20	530.97	...

the solution are H^+, Na^+, HSO_4^-, and $SO_4^{=}$; that the transference of each constituent is determined by that of these separate ions, as expressed by these equations:

$$\Delta H = 1 + HSO_4^- - H^+, \ \Delta Na = -Na^+, \text{ and } \Delta SO_4 = HSO_4^- + SO_4^{=};$$

and that the sum of all the equivalents of all the ions transferred must be unity:

$$H^+ + Na^+ + HSO_4^- + 2SO_4^{=} = 1.$$

From these equations there results by combination:

$$\Delta H = 2\,\Delta SO_4 - \Delta Na = \Delta(\tfrac{1}{2}SO_4) - \Delta Na.$$

[1] Omitted in the calculation, since their deviations are greater than 3 A. D.

Measurements of the conductance of this salt at 25° had previously been made by Barth.[1] His values, reduced from Siemens' units to reciprocal ohms and interpolated graphically (from a plot of Λ against log v) for the dilutions at which our measurements were made, are given in the last column of the table.

12. Concentrations of the Sodium Ion and Hydrogen Ion Derived from the Transference and Conductance Data.

A simple interpretation of the transference results is obtained through the following considerations. Let C_H, C_{Na}, C_{SO_4}, and C_{HSO_4} represent the formal concentrations in the sodium hydrogen sulphate solution of the ions denoted by the subscripts; let Λ_H, Λ_{Na}, Λ_{SO_4}, and Λ_{HSO_4} represent the equivalent conductances of those ions, and N_H, N_{Na}, and N_{SO_4} the equivalents of hydrogen, sodium, and sulphate transferred for each faraday of electricity passed; and let L represent the specific conductance of the solution. Then, since the number of equivalents of any ion transferred is equal to the ratio of the actual conductance of that ion to that of the solution, and since hydrogen is transferred in the two forms, H^+ and HSO_4^-, and sulphate in the two forms HSO_4 and SO_4 , we have the relations

$$N_{Na} = \frac{C_{Na}\Lambda_{Na}}{10^3\,L} \quad (9); \quad N_H = \frac{C_H\Lambda_H - C_{HSO_4}\Lambda_{HSO_4}}{10^3\,L} \qquad (10);$$

and

$$N_{SO_4} = \frac{2C_{SO_4}\Lambda_{SO_4} + 2C_{HSO_4}\Lambda_{HSO_4}}{10^3\,L}. \qquad (11)$$

In these equations we may substitute $C\Lambda$ for 10^3L, introduce the values $N_{Na} = 0.133$, $N_H = 0.521$, $N_{SO_4} = 0.346$, $\Lambda = 261.7$, $\Lambda_{Na} = 51$, $\Lambda_{SO_4} = 79$, $\Lambda_H = 365$ or 348 (see Section 2), and $\Lambda_{HSO_4} = 39.5$,[2] and solve for the ratios C_{Na}/C, C_H/C, etc. We thus obtain from equations (9) and (11),

$$\frac{C_{Na}}{C} = 0.68, \text{ and } \frac{2C_{SO_4}}{C} + \frac{C_{HSO_4}}{C} = 1.15.$$

Since the sums of the equivalent concentrations of all the positive and negative ions must be equal, we have $C_{Na} + C_H = 2C_{SO_4} + C_{HSO_4}$, and therefore also

$$\frac{C_{Na}}{C} + \frac{C_H}{C} = 1.15, \text{ and } \frac{C_H}{C} = 0.47.$$

A value of C_H/C lying between certain not very wide limits can be obtained from equation (10) also, since the second term in its last member is a much smaller quantity than the first term which contains C_H/C. Placing C_{HSO_4}/C equal to zero as one limit and equal to 0.5 as the other (which last is the largest value, consistent with that of C_H/C, which it can have), one obtains

---

[1] *Z. physik. Chem.*, 9, 182 (1892).

[2] In Section 3 Λ_{HSO_4} was found to be about 40 when Λ_H was taken as 365, and about 35 when Λ_H was taken as 348. We have assumed in these calculations $\Lambda_{HSO_4} = \frac{1}{2}\Lambda_{SO_4} = 39.5$, since equation (11) can then be solved directly for $2C_{SO_4} + C_{HSO_4}$. The error arising from this uncertainty is almost surely less than that arising from the errors in the transference data.

$$\frac{C_H}{C} = \begin{cases} 0.37 \text{ for } \Lambda_H = 365 \text{ and } C_{HSO_4}/C = 0.0 \\ 0.43 \text{ for } \Lambda_H = 365 \text{ and } C_{HSO_4}/C = 0.5 \end{cases}$$

$$\text{or} \quad \frac{C_H}{C} = \begin{cases} 0.39 \text{ for } \Lambda_H = 348 \text{ and } C_{HSO_4}/C = 0.0 \\ 0.45 \text{ for } \Lambda_H = 348 \text{ and } C_{HSO_4}/C = 0.5 \end{cases}.$$

Taking the mean (0.41) of these four values and combining it with the value (0.47) obtained from equation (11), we get as the final value

$$C_H/C = 0.44.$$

Although C_{HSO_4}/C can be definitely calculated by equation (10), by substituting in it the value of C_H/C derived from equation (11), yet the result (0.85 for $\Lambda_H = 365$ or 0.65 for $\Lambda_H = 348$) has no significance, since it is seriously affected by the accumulated error resulting from the two successive subtractions of terms much larger than that containing C_{HSO_4}/C.

It is therefore only the values of C_H/C and C_{Na}/C that can be derived with a fair degree of accuracy from the transference and conductance data, unless some additional assumption be made. It is of some interest to compare the values of these quantities obtained above with the results of Noyes and Eastman[1] for 0.1 formal potassium hydrogen sulphate at 18°, which were derived from conductance data alone with the help of estimates as to the concentrations of the un-ionized substances (K_2SO_4, H_2SO_4, and $KHSO_4$) in the solution, based upon analogies with other substances of these same types. Their values are $C_H/C = 0.51$ and $C_{Na}/C = 0.63$, while ours are $C_H/C = 0.44$ and $C_{Na}/C = 0.68$.

13. The Hydrogen-Ion Concentration Derived from Catalysis Experiments.

A value of the hydrogen-ion concentration may also be derived from the catalysis experiments made at 35° by Kay.[2] He found that the specific reaction rate of the hydrolysis of ethyl acetate under the influence of 0.1 formal sodium hydrogen sulphate is 32.4. This becomes 31.0 when corrected in accordance with his experiments for the influence of the neutral-salt ions (the Na^+ and $SO_4^=$) upon the rate. Dividing this value by the specific reaction rate per equivalent of hydrochloric acid (708) at the corresponding concentration, as determined by him, we get 0.0448 as the concentration of the hydrochloric acid solution which has the same catalytic effect as the 0.1 formal sodium hydrogen sulphate.[3]

---

[1] *Carnegie Institution Publications*, 63, 276 (1907).

[2] *Proc. Royal Soc. Edinburgh*, 22, 491 (1898).

[3] Kay found the effect of $LiHSO_4$ to be nearly identical with that of $NaHSO_4$, and that of $KHSO_4$ to be about 2 per cent. smaller.

Taking the ionization of the acid as 95 per cent., we find *0.416* to be the value of C_H/C in the sulphate solution at 35°. The value derived from the transference and conductance measurements was 0.44 at 25°. The agreement is seen to be fairly close, especially in view of the fact that C_H/C decreases rapidly with rising temperature.

Noyes and Eastman have already pointed out that their value of C_H/C at 100° (0.31 at 0 01 formal) agrees well with that (0.315) derived by Trevor[1] from sugar inversion experiments at 100°.

14. Concentrations of the Other Constituents.

Although unfortunately, on account of lack of accuracy, it was not possible to calculate the relative concentrations of sulphate ion and hydrosulphate ion from the transference and conductance data alone, yet we are in a better position to estimate these concentrations than were Noyes and Eastman, for there is now available not only a more directly determined value of C_H/C, but also, in addition, a fairly reliable value of C_{Na}/C. From the latter (0 68) one can at once conclude that the sum of the concentrations of the un-ionized salts ($2C_{Na_2SO_4} + C_{NaHSO_4}$) is 0.32, and no considerable error can result if we distribute this value between the two salts in the proportion $C_{Na_2SO_4} : 2C_{SO_4} = C_{NaHSO_4} : C_{HSO_4}$, in accordance with the principle that in a mixture with a common ion the un-ionized fraction of a unibivalent salt is approximately twice as large as that of a uni-univalent salt. (In making this distribution any probable value may be assigned provisionally to C_{SO_4}/C and C_{HSO_4}/C, such as 0.44 and 0.22, and the operation can then be repeated with the more accurate values of the latter quantities subsequently obtained.) If further we make the assumption, substantiated by Noyes and Eastman (see Section 7), that sulphuric acid with respect to its first hydrogen and hydrochloric acid are equally ionized under corresponding conditions, we can estimate the un-ionized H_2SO_4 present in the solution and finally obtain by subtraction the concentrations of the HSO_4^- and SO_4^{--} ions. The results of such a calculation are given in the following table:

TABLE XVI.—CONCENTRATIONS OF THE CONSTITUENTS IN 0.1 FORMAL SODIUM HYDROGEN SULPHATE SOLUTION AT 25°.

C_{Na}/C	0.68	C_{NaHSO_4}/C	0.08
C_H/C	0.44	$C_{Na_2SO_4}/C$	0.12
C_{HSO_4}/C	0.44	$C_{H_2SO_4}/C$	0.02
C_{SO_4}/C	0.34		

It is of interest to calculate from these data and also from the corresponding data given in Table X for sulphuric acid the values of the product $C_H C_{SO_4}/C_{HSO_4}$, which, if the mass-action law held, would be the ionization constant for the second hydrogen of sulphuric acid. The values of this product at 25° are found to be 0.034, 0.031, and 0.022, using the data for 0.1 formal $NaHSO_4$, 0.05 formal H_2SO_4, and 0.025 formal H_2SO_4, respectively.[1] The "ionization constant" at these concentrations (0.025 — 0.1 formal) may therefore be taken in round numbers at 3×10^{-2}. The rough agreement of the values derived from the independent and widely different data for sulphuric acid and its acid salt is welcome evidence of the approximate correctness of the computed concentrations of the sulphate ion and hydrosulphate ion in the solutions, the computation of which was based in both cases, it must be remembered, upon the only indirectly substantiated principle that the hydrogen of hydrochloric acid and the first hydrogen of sulphuric acid are equally ionized under corresponding conditions.

---

[1] *Z. physik. Chem.*, 10, 342 (1892).

SUMMARY.

It has been shown in Section 1 of this article that in the case of a dibasic acid like sulphuric acid the hydrogen-ion concentration (C_H) can be derived from the freezing-point lowering, or from any other property which gives the value of the mol number i, by the relation $C_H/C = i - 1$, where C represents the formal concentration of the acid (that is, the number of formula weights of H_2SO_4 per liter of solution). The values of C_H/C at 0° so derived from the existing freezing-point data have been presented.

Noyes and Eastman have previously shown that there can be derived from conductance data alone not very widely divergent maximum and minimum values of the hydrogen-ion concentration in sulphuric acid, corresponding to the two limiting cases where the only negative ion present is $SO_4^{=}$ and where it is HSO_4^-. In their calculations it was, however, necessary to assume a value for Λ_{HSO_4}, the equivalent conductance of hydrosulphate ion, the assumption made being that its conductance is equal to that of acetate ion, which has a similar molecular complexity. It has been shown that any such assumption can be dispensed with, if with the conductance data there be combined the transference data for the acid. In this way, using the existing transference data and the conductance data at 25° and 0° determined in this laboratory and presented in Section 2, limiting values of C_H/C at these temperatures have been calculated.

Incidentally, there have been derived through a consideration of the existing conductance data at 0° the best values to adopt for the equivalent conductance at 0° of certain ions. These values are $\Lambda_K = 40.3$, $\Lambda_{Cl} = 41.1$, $\Lambda_{SO_4} = 42.8$, and $\Lambda_H = 224$. The last value is much lower than that (240) estimated by Johnston.[2]

It has been shown in Section 3 that the transference and conductance data enable the value of Λ_{HSO_4} at 25° and 0° to be approximately calculated, provided it be true that the hydrosulphate-ion is present in the sulphuric acid solution in considerable quantity, so that its conductance may enter as a factor. The values obtained (35 to 40 at 25°) are not far from one-half of that of Λ_{SO_4} (79 at 25°).

---

[1] The values at 0° are 0.061 for 0.05 formal H_2SO_4 and 0.042 for 0.025 formal H_2SO_4.

[2] This Journal, 31, 1015 (1909).

From a consideration of the relative catalytic effects of sulphuric and hydrochloric acids on the hydrolysis of cane sugar at 25°, as determined by Ostwald, and on that of ethyl acetate at 35° as determined by Kay, values of the hydrogen-ion concentration (C_H/C) have also been calculated (see Section 4).

A new isohydric method of determining the hydrogen-ion concentration has been described in Section 5. It consists in determining by experiment the relative concentrations of hydrochloric acid and of sulphuric acid which drive back the ionization of picric acid to the same extent, the condition of equal ionization of the picric acid being ascertained by shaking the aqueous solution with benzene, into which the un-ionized picric acid distributes itself.

The values of C_H/C at various concentrations at 0° and 25°, obtained by these various methods, will be found in Table IX on page 1146.

To derive the concentrations of the other constituents from these values of the hydrogen-ion concentration, the latter must be combined with some further knowledge or data relating to those constituents. Noyes and Eastman, through a study of the conductance of sulphuric acid and potassium hydrogen sulphate through a wide range of temperature, have made it highly probable that under corresponding conditions the first hydrogen of sulphuric acid is equally dissociated with that of hydrochloric acid. Upon the basis of this principle the concentration of the un-ionized H_2SO_4 was estimated by Noyes and Eastman, and, from this concentration and that of the hydrogen ion the concentrations of the other two constituents, the sulphate ion and hydrosulphate ion, were obtained by them by subtraction. We have made similar calculations, using the values of the hydrogen-ion concentration derived in this paper. The results, which will be found in Table X on page 1148, show that sulphate ion and hydrosulphate ion are both present in large proportions at medium concentrations, that the latter is present in much larger quantity at 0.05 formal and the former at 0.005 formal, and that at 0.05 formal the ratio C_{HSO_4}/C_{SO_4} increases greatly between 0° and 25°. It will also be seen that the hydrogen-ion concentration decreases markedly within the same temperature interval.

Experiments have been described in Section 8 upon the distribution of sulphuric acid between water and amyl alcohol. The ratio C_A/C_W of the concentration of the acid in the alcohol to that in the water was found to increase from 0.0053 for $C_W = 0.022$ to 0.0091 for $C_W = 0.180$, corresponding to an increase in the proportion of un-ionized sulphuric acid in the aqueous solution. The rate of this increase is somewhat smaller even than in the case of hydrochloric acid, indicating that the un-ionized H_2SO_4 is formed out of two ions (H^+ and HSO_4^-), in analogy with di-ionic substances, instead of directly out of three ions (H^+, H^+, and $SO_4^{=}$) in analogy with tri-ionic salts.

Determinations were also made of the transference of sodium, of hydrogen, and of sulphate occurring during the electrolysis of a 0.1 formal solution of sodium hydrogen sulphate at 25°. The results are summarized in Table XIV, on page 1156. Measurements were also made upon the conductance of this salt at various concentrations at 25°. By combining the transference and conductance data the concentrations of the sodium ion and hydrogen ion in the 0.1 formal solution were calculated (in Section 12). The values so obtained are $C_{Na}/C = 0\ 68$, and $C_H/C = 0.44$.

It has also been shown (in Section 13) that the experiments of Kay on the catalysis of ethyl acetate by 0.1 formal sodium hydrogen sulphate at 35° furnish an independent means of determining the hydrogen-ion concentration, and that the value of C_H/C derived therefrom is 0 416, which agrees well with that (0.44) derived from the transference experiments.

From the values of C_H/C and C_H/C_{Na} derived from the transference and conductance data the concentrations of the other constituents in the 0.1 formal $NaHSO_4$ were computed (in Section 14) with the help of the principle above referred to in regard to the ionization of the first hydrogen of sulphuric acid. In this way C_{HSO_4}/C was found to be 0.44 and C_{SO_4}/C to be 0.34 (see Table XVI).

From these data and also from the corresponding ones for 0.05 formal H_2SO_4 the values of the product $C_HC_{SO_4}/C_{HSO_4}$, the ionization constant of the second hydrogen of sulphuric acid, were calculated to be 0.034 and 0.031, respectively, or in round numbers 3×10^{-2} at concentrations 0.025 to 0.1 formal.

BOSTON, July, 1910.

ON SURFACE ENERGY AND SURFACE TENSION.

BY J. E. MILLS AND DUNCAN MACRAE.

Received July 25, 1910.

In an article by Whittaker[1] "On the Theory of Capillarity," it was shown that the following empirical relation was apparently true: "*The surface energy of a liquid in contact with its own vapor at any temperature is proportional to the product of the internal latent heat and the* (*absolute*) *temperature.*"

The proposed relation and further related applications and inferences have since been discussed by Kleeman in a number of papers.[2]

---

[1] *Proc. Roy. Soc.*, **81**, 21 (1908).

[2] *Phil. Mag.*, **18**, 39, 491, 901 (1909); **19**, 783 (1910)

Some explanation of the relation proposed is perhaps necessary. Particles in the interior of a liquid are attracted by the surrounding molecules equally in every direction; but particles on, or near, the surface are attracted only, or as a resultant, inward, in a direction perpendicular to the surface. When the area of the surface of a liquid is increased, work is therefore done against the molecular forces in bringing additional molecules within the surface layer. If the surface of a liquid is actually increased—as in blowing a soap bubble—it will be found that as the surface increases in size under the action of the externally supplied force (the pressure of the air blown within the bubble), the surface layer of the liquid becomes at the same time colder. Heat is absorbed from the surrounding bodies in order to raise the temperature of the surface film to the initial temperature. Therefore the total energy necessary to increase the surface area is supplied partly as mechanical (external) work and partly as heat energy. If E represents the total energy per square centimeter of surface layer, γ, the necessary mechanical work performed in making this surface, and T the absolute temperature, we have from Helmholtz's free energy equation the relation first stated by Lord Kelvin,

$$1. \qquad E = \gamma - T\frac{d\gamma}{dT},$$

where $-T\,d\gamma/dT$ represents the amount of heat energy absorbed from the surrounding bodies. The mechanically supplied surface energy, γ, in ergs per square centimeter, is numerically equal to the surface tension per linear centimeter in dynes.

The heat of vaporization necessary to change a liquid into a vapor is expended in two ways: *first*, in pushing back the external pressure as the liquid expands, and *second*, in doing certain internal work within the liquid. The first amount of energy is easily calculated and when subtracted from the total leaves the so-called "internal heat of vaporization." This internal heat of vaporization, λ, can be calculated from the thermodynamical relation discovered by Clausius and Clapeyron,

$$2. \qquad \lambda = \left(T\frac{dP}{dT} - P\right)(V - v);$$

here P denotes the vapor pressure, and v and V denote the volume of liquid and its saturated vapor, respectively.

The proposed relation of Whittaker states that

$$3. \qquad \frac{E}{T\lambda} = \text{constant},$$

where E is obtained from equation 1 and λ from equation 2.

Whittaker himself stated that the above empirical relation, being yet without theoretical basis, and being based only on the behavior of five substances over a limited range of temperature, must be received with caution until further comparison with experimental results was possible.

It seemed to the authors desirable, for the reasons mentioned below, to re-examine the experimental basis for the proposed relation.

First.—The values of the internal heat of vaporization used by Whittaker were taken from a paper by one of us[1] and these values have been lately revised. The revision was made necessary by the changes made by Dr. Sydney Young in the original data used for the calculation of these values. These changes were usually small, but extensive, and affected principally the volumes of the saturated vapor at the lower temperatures and the vapor pressure.[2]

Second.—Whittaker, due to the increasing uncertainty in the values for the internal heat of vaporization, and in $d\gamma/dT$ as the critical temperature was approached, did not extend his study of the relation given in equation 3 nearer the critical temperature than 40 or 50°. While it is true that the data become increasingly uncertain, it is also true that λ, E, γ, and $d\gamma/dT$, when plotted against the temperature, give early straight lines over the range of temperature investigated by Whittaker. It becomes of very greatly increased importance therefore to carry the study of equation 3 nearer the critical temperature.

Third.—Whittaker obtained his values of $d\gamma/dT$ from the values for γ as given by Ramsay and Shields.[3] Now they concluded from an apparently sufficient experimental basis that the surface tension, γ, could be expressed for non-associated liquids, as were those investigated by Whittaker, by the equation

$$4. \qquad \gamma(Mv)^{2/3} = k(\tau - d),$$

where τ represents degrees counted from the critical temperature, and k and d are constants, k being approximately 2.12, and d varying with the different substances investigated from 5.9 to 8.5. Mv is the molecular volume of the liquid. Equation 4 is true nearly to the critical temperature, and it is clear that the function $-d\gamma/dT$ must therefore decrease continuously and consistently with increase of temperature; that is, for non-associated liquids $-d\gamma/dT$, when plotted against the temperature, must neither increase nor give a line of double curvature. An examination of the values of $d\gamma/dT$ given by Whittaker for carbon tetrachloride, benzene, and chlorobenzene show that his values do not strictly obey the above statement and seem too greatly influenced by the individual errors of observation. We have changed, therefore, in the tables below, usually only very slightly, some of the values of $d\gamma/dT$ as given by Whittaker for the above-mentioned substances.

Whittaker states on page 23 of the article cited that "A point is at length reached, about 180° below the critical point, at which E is stationary, and thenceforward E diminishes as the temperature decreases—a somewhat surprising result. These changes in E are identical with the changes of the function $T\lambda$, which has its stationary point at the same temperature as E." We consider this statement to be in error as regards the behavior of the surface energy so far as non-associated liquids are concerned. The remark seems true for associated liquids. For confirmation of our point of view it is sufficient to cite the form of the surface tension curves as shown in the paper by Ramsay and Shields, and the values of the internal heat of vaporization as given in the papers by Mills already cited.

Fifth.—We found data available for a study also of ethyl acetate, and for the supposedly associated liquids, water, acetic acid, and methyl and ethyl alcohols.

The data and the results obtained are given in the tables below. The surface tension, γ, was obtained from the measurements of Ramsay and Shields.[1] The values of $d\gamma/dT$ were derived from the measurements of γ given, and were smoothed in accordance with the observations above made. The values of $d\gamma/dT$ given by Whittaker were used for ethyl ether and methyl formate at the lower temperatures, and his values were not greatly changed for carbon tetrachloride and benzene. The values for E were obtained from the data given by the use of equation 1. The

values given for λ were calculated by Mills and have been partially published.[1] Details and references will be found in that paper. The complete data will be published later.

We have, except for the alcohols, averaged the values of the constant $10^4E/T\lambda$ for each substance down to the values marked with an asterisk, and have marked with an asterisk all values differing from the mean values so obtained by more than 3 per cent. The mean values are given in Table XI.

Considering first the non-associated substances, it will be seen that the "constant" decreases to the extent of 3 per cent. or more from its value at the lowest temperature to a minimum value, and then rises in value until the critical temperature is reached. This consistent behavior of the constant tends strongly to show that it is not a true constant. A closer examination of the data tends to confirm this belief.

For the divergence of the "constant" from constancy cannot be due to the values used for the internal heats of vaporization. One of us has made an extended and close study[2] of the internal heat of vaporization both of the substances at present under investigation and of other substances. From the discussion and data given in the papers cited we feel certain

that the heats of vaporization given are correct to within 2 per cent. except as the critical temperature is approached. Nearly always they are correct to within 1 per cent. Now as the critical temperature is approached, it is true, as shown in the papers cited, that the internal heat of vaporization as usually calculated by the use of equation 2, and as given in this paper, is too small. But the error thus caused is not nearly great enough to account for the great increase in the value of the constant.

For it was further shown that the true heat of vaporization, even in the immediate neighborhood of the critical temperature, can be very closely obtained by means of two equations, one proposed by Mills and the other by Dieterici. Values thus obtained, designated Mills and Dieterici, respectively, are given in the tables for comparison, and the constant shown as calculated from them. But one conclusion is possible when the papers cited and the results shown have been studied: *The increase in the value of the constant near the critical temperature is not largely due to errors in the values of the heats of vaporization used.*

Are then the surface tension measurements in error? The surface tensions used were calculated by Ramsay and Shields from the rise of the liquid in a capillary tube by means of the formula

$$5. \qquad \gamma = \tfrac{1}{2}\, r.\, h.\, g.\, (d - D),$$

where r is the radius of the tube, h is the height to which the liquid is raised, g is the gravitation constant, and d and D are the densities of the liquid and its saturated vapor at the temperature of the experiment. Since errors in r and g could not thus affect the result, we have only to consider the probable size of the errors in h and in $d - D$. There seems no good reason to suppose that large and regular errors were made in the determinations of the height of the rise of the liquid in the capillary tube. Regarding the possibility of errors in $d - D$, it is clear that, since d approaches D in value as the critical temperature is approached, errors of measurement of the densities will be greatly multiplied near the critical temperature in their effect upon γ. But the well-known form of the density curves and the law of "rectilinear diameters" aids greatly in smoothing out individual errors of observation. The papers of Ramsay and Shields do not state from what source the densities were obtained, but comparison makes it fairly certain that the measurements for ethyl oxide and water (except the densities for these two substances of the liquid to 100°), methyl and ethyl alcohols, and acetic acid were by Ramsay and Young, for methyl formate and ethyl acetate by Young and Thomas, for benzene, chlorobenzene, and carbon tetrachloride by Young. The measurements of these investigators, as is well known, are exceedingly accurate and would introduce only comparatively small errors in γ. (We would note a misprint in the density of methyl formate, liquid at 140°, 0.7368 for 0.7638, also in accordance with Young's data, carbon tetrachloride vapor at 230° should be 0.1232; benzene at 280° should be 0.1660; and ethyl alcohol at 200° should be 0.5568 for the liquid. The values for acetic acid have been revised by Young, the only changes of significance for our purpose being at 280° where the density of the liquid should be 0.6629 and of the vapor 0.0883; and at 320° for the vapor, which should be 0.2421. These changes will not affect the character of the results shown in the tables.) We conclude therefore *that the sur-*

face tension measurements are fairly accurate and cannot directly cause the variation shown in the constant.

A relatively very large error is introduced in the determination of $d\gamma/dT$. For near the critical temperature $-T\,d\gamma/dT$ becomes very large compared to γ and errors in $d\gamma/dT$ affect the constant almost proportionately. In determining $d\gamma/dT$ we deal with the difference of measurements of γ in themselves nearly equal and subject to some individual error. We would be inclined to think that with any one substance the error introduced into the constant through the uncertainty of the factor $d\gamma/dT$ might be quite sufficient to explain the rise in the value of the constant at the critical temperature. But there seems no reason to suppose that the error thus introduced would always be large and in the same direction, unless there is some undiscovered defect in the determination of the surface tension. Nor is it reasonable to suppose that the consistently recurring decrease, even though it be small, in the value of the constant at low temperatures, is to be attributed to chance errors in the measurements.

The authors therefore conclude *that the variation of the constant in the relation, $E/T\lambda$ = constant, proposed by Whittaker, is not due to the measurements used in testing the relation, but to the fact that the relation is only approximately true.*

With regard to the associated liquids, as was to be expected, the constant makes no pretense of constancy for the alcohols. But contrary to expectation, the constant remains as near a constant for water and acetic acid as it does for the non-associated liquids. We have no idea of the reason for this behavior.

It is seldom that any physical relation holds exactly true throughout a wide range of temperature. It is therefore quite reasonable to study further the relation stated by Whittaker and to seek a possible cause for the same. One of the authors in a paper already cited has discussed theoretically, and carefully tested by means of the extensive series of exact measurements available, the three following equations for the internal heat of vaporization:

$$2.\quad \lambda = \left(T\frac{dP}{dT} - P\right)(V - v) = 0.0_43183\left(T\frac{dP}{dT} - P\right)(V - v) \text{ calories.}$$

$$6.\quad \lambda = \mu'(\sqrt[3]{d} - \sqrt[3]{D}) \text{ calories.}$$

$$7.\quad \lambda = CRT\,ln\,\frac{d}{D} = 4.77\,C\,\frac{T}{m}\log\frac{d}{D} \text{ calories.}$$

Equation 2 is the thermodynamical equation already mentioned. In obtaining the constant the pressure is expressed in millimeters of mercury, and v and V are the volumes occupied by a gram of the liquid and of its saturated vapor.

In equation 6 μ' is a constant for any particular non-associated liquid,

d is the density of the liquid, and D is the density of the saturated vapor. The values of μ' for the substances studied in this paper are given in Table XI. The equation was deduced theoretically by Mills from assumptions regarding the molecular attraction and has been extensively studied[1] and would seem to be exactly true for normal non-associated liquids.

In equation 7 C is a constant for any particular substance, having approximately the same value, 1.755, for all normal non-associated liquids, R is the usual gas constant, and d and D represent densities as before. The values for C are given in Table XI. The equation was first proposed as an empirical equation by Dieterici[2] and has been further studied by Richter[3] and by Mills.[4]

Inserting the values of E and λ from equations 1 and 2 in equation 3, we get,

$$8. \qquad \frac{\gamma - T\dfrac{d\gamma}{dT}}{T\left(T\dfrac{dP}{dT} - P\right)(V - v)} = \text{constant},$$

as the form of the relation already studied. Now if it were possible to get the limit of this equation at the critical temperature a further test of its truth could be applied. This does not seem possible with our present knowledge. γ probably falls out and T cancels, leaving

$$\frac{d\gamma}{dT}\Big/\left(T\frac{dP}{dT} - P\right)(V - v)$$

as the indigestible form of the equation. The combination of the equations 1, 2 and 3 under approximate conditions has been studied by Kleeman in the papers cited.

Next combining the relation given in equation 6 with that of Whittaker we obtain, calling the constant of Whittaker's relation k,

$$9. \qquad E = k\mu'T(\sqrt[3]{d} - \sqrt[3]{D}).$$

The values of $k\mu'$ are given in Table XI, though we have as yet been able to draw no conclusion from their product. That the surface energy of a liquid should be proportional to the product of the absolute temperature and the difference of the cube roots of the densities of the liquid and vapor is very suggestive. For it has been shown in the papers by Mills already cited that equation 6 expresses a relation between the molecular attractive forces, and that this relation leads to the conclusion that $\mu'\sqrt[3]{d}$ is the energy necessary to overcome the molecular attraction in pulling the molecules of a liquid apart to an infinite distance. Similarly $\mu' \sqrt[3]{D}$ would represent the energy necessary to pull apart the molecules of a vapor to an infinite distance, the temperature of the vapor remaining constant. Now the so-called liquid surface is really the resultant of two surface layers, the one of the liquid and the other of its vapor, in contact, with oppositely directed forces. Hence it would seem that the total surface energy of a liquid, as usually so-called, can be divided into two parts, one part due to the liquid E_L and the other part due to the vapor over the liquid E_V, the resultant forces being oppositely directed and the surface energy of opposite sign from the standpoint of a surface molecule. We can then write the equations:

---

[4] THIS JOURNAL, **31,** 1099 (1909).

10. $$E_L = K'T\sqrt[3]{d}.$$

11. $$E_V = K'T\sqrt[3]{D}.$$

12. $$E_L - E_V = E = K'T(\sqrt[3]{d} - \sqrt[3]{D}).$$

Perhaps equations 10, 11, and 12 do not express a point of view entirely new so much as they serve merely to add emphasis and give a quantitative expression to a fact already well known,[1] namely, that the nature of the surrounding gas influences the surface tension. It would seem from the suggested equations that perhaps the amount of such influence has been greatly underestimated.

It would seem probable that if equations 10, 11 and 12 are true, the surface tension as usually measured should similarly be capable of division into two parts, one part due to the liquid surface, the other part due to the gaseous surface over the liquid. Such a process of division might result in finding simpler and more accurate relations between the surface tension and other quantities. Search by one of us for the proper modification to be applied to the liquid surface tension as usually measured in order to eliminate the effect of the vapor has apparently met with success, and if a full investigation confirms the results already derived the investigation will shortly be published.

[1] See paper by Ramsay and Shields already cited, page 666, and similar determinations by others.

* Not constant.

If the value of λ from equation 7 be used in the equation 3 proposed by Whittaker we have

$$E = kCRT^2 \ln \frac{d}{D}. \tag{13}$$

The value of the product 10^4Ck is given in Table XI, but we can draw no conclusion of interest from the result. Equation 7, as has been shown in the papers cited, is not exactly true at very low vapor pressures for the liquid, but the error is probably not so great as one calorie for any of the non-associated substances over the entire range of temperature covered by the present investigation. The errors introduced by equation 7 are therefore far less than the errors of equation 2 with which it was combined.

Equation 13 is similar to equation 9 in its suggestion of a division of the total surface energy into two parts, one due to the liquid and the other due to the vapor. The resulting equations can be written,

$$E_L = K''RT^2 \ln d, \tag{14}$$

$$E_V = K''RT^2 \ln D, \tag{15}$$

$$E_L - E_V = E = K''RT^2 \ln \frac{d}{D}, \tag{16}$$

where $K'' = Ck$. These relations will also be further studied.

In conclusion, we differ from the arguments and conclusions advanced in the papers by Kleeman already cited at many points, but we would call particular attention to but two things: *First.*—In the investigation of the *inverse fifth power* law of the molecular attraction[1] he uses data from the papers already cited on molecular attraction by Mills. He ignores the fact that in those papers it has been shown that the assumption of the *inverse square* law of the distance gives a consistent agreement with the data over the entire range of temperature, not only for the substances that he investigates but for numerous others. Also when the results within 20° of the critical temperature are left out of consideration Kleeman obtains a consistent decrease of about 25 per cent. in his results at different temperatures. If the attractive force did not vary with the temperature, the greatest allowable variation from the mean to be attributed to the usual errors in the data should be 2 per cent., and we have shown that the *inverse square law* gives results within this limit—and usually far within this limit—for eight substances investigated gave no divergence from the mean greater than 1 per cent.

Second.—To explain the variation he obtains, Kleeman thinks that the force of attraction may diminish with rise of temperature. The papers by Mills as cited find that as regards the molecular attraction all of the evidence disproves this position, and as regards the chemical attraction, the possibility of a change of attraction with temperature was further especially considered in a paper on chemical energy,[1] and no evidence whatever for such a belief was found in the case investigated.

---

[1] *Phil. Mag.*, 19, 795 (1910)

Summary.

1. The relation proposed by Whittaker that "The surface energy of a liquid in contact with its own vapor at any temperature is proportional to the product of the internal latent heat and the (absolute) temperature" has been investigated and the conclusion drawn that the relation is only approximately true.

2. The relation is shown to suggest a division of the so-called surface energy of a liquid into two parts, one part due to the liquid surface and the other to the surface of the vapor over the liquid. Further investigation of this suggestion is promised.

THE ADIABATIC DETERMINATION OF HEATS OF SOLUTION OF METALS IN ACIDS.

PART II. THE HEAT OF DILUTION OF THE ACID SOLUTIONS.

BY THEODORE W. RICHARDS, ALLEN W. ROWE AND L. L. BURGESS.

Received July 8, 1910.

Introduction.

An account of a new series of determinations of the heat of solution of five metals in fairly concentrated acids was published in a recent number of THIS JOURNAL.[2] There it was shown that the heats of dilution, both of the acids and of the residual solutions after the reactions had been completed, affect the result much more than has usually been supposed. It was made clear that the actual results of the heats of solution of the metals in fairly concentrated acids must receive large corrections in order that they may all be reduced to the common standard of the heat of solution of the metal in the theoretical amount of acid of the standard dilution $HCl.200H_2O$. The actual attainment in a single experiment of this theoretical result is not possible because the completion of the reaction of the theoretical quantities would require an exceedingly long time, and therefore could not be measured with precision in the calorimeter.

As an example of the correction of the results, the case of zinc may be cited. In a single experiment 7 496 grams of pure zinc were dissolved in 941.4 grams of acid of the concentration $HCl.20H_2O$, and in the process 3461.0 calories of heat were evolved. This amount of zinc is 0.11467 gram atom, and the solution actually in the calorimeter contained 2.372

---

[1] *Trans. Am. Electrochem. Soc.*, 14, 35 (1908).

[2] Richards and Burgess, THIS JOURNAL, 32, 431 (1910).

gram molecules of hydrogen chloride. Accordingly the actual reaction in the calorimeter was as follows:

$$0.11467\ Zn + 2.372\ (HCl.20H_2O) = 0.11467\ H_2 + (0.11467\ ZnCl_2 + 2.143\ HCl + 47.44\ H_2O) + 3461 \text{ calories.}$$

On multiplying this equation by 8.721 in order to find the amount of heat evolved by the solution of 1 gram atom of the metal, the following equation is obtained:

$$Zn + (20.69\ HCl + 414\ H_2O) = H_2 + (ZnCl_2 + 18.69\ HCl + 414\ H_2O)$$
$$(x = 30183 \text{ calories or } 126.8 \text{ kilojoules}).$$

Thus a very large excess of acid was used. The following additional equations (analogous to those already given on page 134 of the article just mentioned) are necessary in order to reduce the result to the more generally useful equation:

$$Zn + 2(HCl.200H_2O) = ZnCl_2\ 400H_2O + H_2 + Q \text{ kilojoules.}$$

In the first place the heat evolved by the dilution of all the hydrochloric acid is needed, in the next place the heat of dilution of all the residual solution, and finally the heat of mixture of dilute solutions of zinc chloride and hydrochloric acid. These are given in order below:

$$20\ 69(HCl + 200H_2O) + 3724H_2O = 20.69(HCl + 200H_2O) + y \text{ kj.} \quad (2)$$

$$(ZnCl_2 + 18.69\ HCl + 414H_2O) + 3724H_2O = (ZnCl_2 + 18.69HCl + 4138H_2O) + z \text{ kj.} \quad (3)$$

$$(ZnCl_2 + 400H_2O) + 18\ 691(HCl + 200H_2O) = (ZnCl_2 + 18.69HCl + 4138H_2O) + q \text{ kj.} \quad (4)$$

From these equations, by simple elimination or cancellation, the desired result is easily found to be as follows:

$$Zn + 2(HCl.200H_2O) = H_2 + ZnCl_2.400H_2O + 126.8 - y + z - q \text{ kj.}$$

Therefore the quantity sought, $Q = 126.8\text{kj.} + (z - y) - q$. It will be shown that the quantity q is zero in all the cases under consideration, hence it is clear that the ideal value for the heat of solution of the metal in dilute acid is to be obtained by adding to the heat of solution in concentrated acid the difference between the heat of dilution of the mixture remaining after the reaction and heat of dilution of all the acid originally taken. The fact that the quantity $(z - y)$ is a difference of similar quantities obtained in precisely the same way greatly increases the ease of determining it accurately, for any systematic errors in y would appear also in z, and hence be eliminated from the result $(z - y)$.

Similar sets of equations with the appropriate concentrations of acid must be used in the cases of aluminium, cadmium, and iron. In the case of magnesium, in which the proper concentration ($HCl.200H_2O$) of hydrochloric acid had been used in the first place, only one of these equations, that corresponding to (1) above, is necessary. Thus, in order to reduce the results given in the preceding paper to the same standard, eleven series of experiments on heat of dilution must be made, in order to determine the quantity y for two strengths of acid, the quantities z and q in four of the cases, and the quantity q in the fifth.

Before beginning the experimental work, two theoretical questions of great importance face the experimenter, namely, first, the question as to the temperature at which these dilutions should be conducted, and, secondly, the further question as to the heat capacity (whether that of the factors or that of the products) which should be used in the calculation of the several heats of dilution. These questions are connected with one another, and may be answered together.

At first it might be supposed that the heat of dilution of the hydrochloric acid should be measured at the initial temperature of the main reaction (namely, about 16°) because this is the only temperature in the process at which the acid solution exists unchanged. This interpretation is nevertheless illusory and erroneous. Although the main reaction of acid on metal takes place over the range from 16 to 20°, the result as calculated from the heat capacity of the factors corresponds to the heat given out by the reaction *conducted isothermally at the final temperature of 20°.*[1]

In thermochemical work precision in reasoning is only attained when all the data are reduced to an isothermal basis. Hence it is clear that all the dilutions must be conducted in such a way as to correspond to this same isothermal standard of 20°. This end may be effected in either of two ways: the dilution may be started at 20°, and the heat capacity of the product used in the calculation, or the dilution may be arranged so as to finish at 20° and the heat capacity of the *factors* used in the calculation. The latter method was used, because it was somewhat more convenient. Attention should perhaps be called to the fact that for the sake of ideal consistency, the specific heats used in these calculations should correspond to the small range of a few tenths of a degree just below 20°, and not to the whole range from 16 to 20°. This subtlety, however, may be safely overlooked in the present case, as the slight error which thereby arises in the individual data will appear in all, and will hence be cancelled in the final calculation of the quantity $(z - y)$. Moreover, because in the results to be tabulated, nine-tenths or more of the heat capacity was due to pure water (obviously, the chief factor in the dilution experiments) a large error in the specific heat of the concentrated solution produces very little effect on the result. Accordingly, the specific heats already given for the two acids, $HCl.8.808H_2O$ and HCl $20.00\ H_2O$—namely, 0.7312 and 0.8486—were used in the calculation.

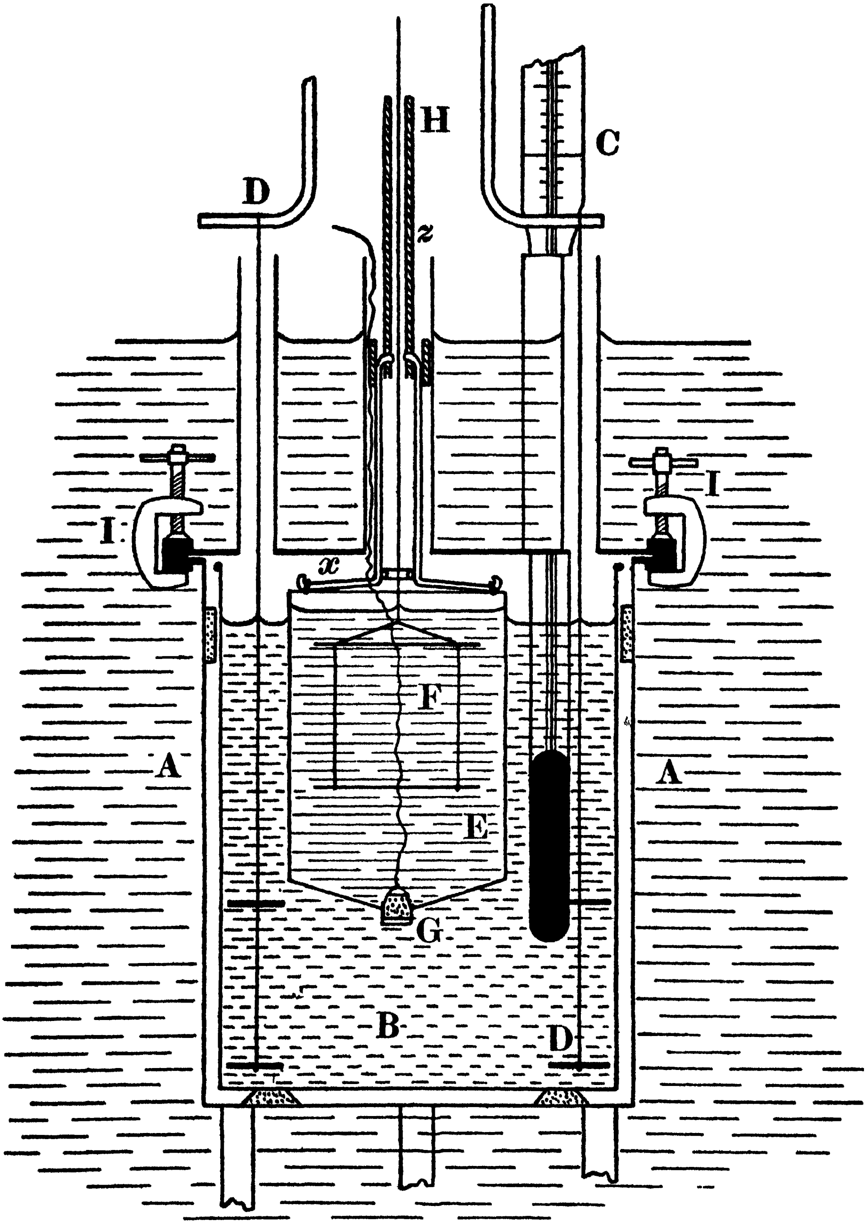
[1] Richards, THIS JOURNAL, 25, 209 (1903).

Calorimeter for Dilution Experiments.

For determining the heats of dilution of the acid liquids, that is to say, the parallel quantities y and z, special apparatus was needed. We employed for this purpose a device essentially similar to that used by Rich-



ards, Henderson, and Forbes in a previous investigation.[1] In this apparatus the concentrated solution was enclosed in a receptacle partly immersed beneath the water in the calorimeter; when both liquids had attained exactly the same temperature, the inner vessel was put into connection with the outer, and by suitable stirring the fluids were mixed.

The special form of apparatus used in this case was slightly different from that employed in the previous investigation. It is shown in the accompanying diagram. The inner vessel consisted of a platinum cylinder wholly open at the top, and having a small opening in the bottom. It was suspended on stout platinum wires, connected with thin hard-rubber rods above. The hole in the bottom was stopped by means of a small rubber stopper, the handle of which projected through the cover of the calorimeter. The inner vessel was filled with the solution to be diluted, and a small hand-driven propeller (made by sealing pieces of platinum foil to the sides of a thin-walled glass tube) served to stir it. The calculated amount of water was placed in the outer calorimeter, and the apparatus was adjusted to the position shown in the diagram. The thermometer was a new, very carefully calibrated instrument with degrees 10 centimeters long. When it had attained constancy after a prolonged stirring of both liquids, the plug was pulled out, and the inner platinum vessel lowered until it was entirely immersed in the water, the acid being free to escape both above and below. The liquid in the innner platinum vessel was then easily mixed with the water outside, because the outer stirrer, consisting of two rings of stout platinum foil with a vertical stroke, forced the liquid backwards and forwards through the inner cylinder after the fashion of a pump. The whole calorimeter vessel was enclosed in a larger copper vessel, nickel-plated inside and provided with tubes above for the stirrer, thermometer, and actuating mechanism. This "submarine" apparatus was surrounded by a concentric jacketing vessel, containing dilute alkali to which was added sulphuric acid at such a rate that the outer temperature exactly kept pace with the inner. The heat capacity of all the platinum parts, the rubber stopper, and the thermometer were equivalent to a sum total of 15.37 grams of water. The heat evolved by the stirring apparatus in the inner calorimeter was determined as a part of each experiment. The rate of the motor was such that it was usually sufficient to raise the temperature of the calorimeter at a rate of 0.004° in 10 minutes, the maximum time of the experiment. The correction is duly applied in each case for this extra heat.

There follow the experimental results for the heats of dilution of the two more concentrated solutions of hydrochloric acid. This table explains itself and presents no obscure features. Incidentally it may be remarked that the heat of dilution of $HCl.20H_2O$ at 16°, four degrees lower than that mentioned in the table below, was also determined and found to be not far from seven per cent. less than the values given below. These results, however, do not concern the present investigation, and will be published in another connection.

HEAT OF DILUTION OF HYDROCHLORIC ACID AT 25°.

Expt No.	Reaction measured	Temp of experiment	Corrected rise of temperature.	Heat capacity in Cal./t° units.	Average energy change, Cal.	Energy change for 1 mol. HCl in large Calories.
1	130 0 grams HCl	19.88	0.152			
2	20.H_2O + 1062 5	19 93	0 153	1188.1	181.5	0.556
3	grams H_2O	19.93	0 153			
4		19 93	0 153			
5	60.0 grams HCl	19 8	0.365			
6	8.8H_2O + 1059	19.8	0.366	1118 3	408.2	1 330
7	grams H_2O	19.8	0.366			
8		19.8	0.366			

The numbers given in the last column of the foregoing table indicate that when to $HCl.20H_2O$ is added $180H_2O$, 0.556 Calories of heat are evolved at 20°, and that when $HCl.8\ 81H_2O$ is diluted with $191.2H_2O$, 1.330 Calories are evolved. For use in calculating the value y in several equations, these numbers must of course be multiplied by the number of moles of hydrochloric acid concerned in the actual reaction. For instance, in the case of zinc one gram atom of the metal was dissolved in a solution containing 20 69 moles of $HCl.20H_2O$. Therefore y in this case equals 0.556 × 20 69 or 11.5 Calories. Other factors are obviously necessary in the other cases; these factors will be named later.

The preliminary experiments with the solutions left in the calorimeter after the metals had been dissolved in the acid showed that considerable change in the heat of dilution is caused by the presence of the metal instead of hydrogen, which it had displaced. Thus the heat of dilution of the solution containing zinc was found to be over 0 08° more than the hydrochloric acid and the aluminium a few thousandths of a degree. On the other hand, the heat of dilution of the solution containing cadmium was less than that of the hydrochloric acid from which it was made by about 0.02° and the ferrous chloride solution remaining from the experiment with iron showed a very slight difference indeed, when compared to the pure acid. These results show that the heats of dilution may be a very serious factor in the result, and that they must therefore be determined with the greatest possible care. The next table records these very careful experiments, giving the heats of dilution of the mixed solutions remaining after the reaction, solutions which still contained a large excess of hydrochloric acid, but also a small amount of the dissolved chloride of the metal. These determinations were made in precisely the same way, as nearly as possible, as the experiments with pure hydrochloric acid. The same part of the thermometer was used, so that undetected errors in calibration, if present, would be automatically cancelled from the final result.

The dilution of the ferrous chloride solution presented some difficulty, owing to its tendency to oxidize. Obviously, results obtained with a solution which had oxidized either before or during the dilution experiment would be worthless. To prevent the solution from oxidizing before use, it was prepared in a flask connected with a hydrogen generator and fitted with a siphon and a delivery tube. In this way an atmosphere of hydrogen was maintained above the solution, and no oxidation could occur. The end of the siphon was kept under toluene, and the first portion discharged always rejected. During the experiment the surface of the liquids, both in the platinum container and in the calorimeter can, were covered with a layer of toluene, which sufficiently prevented access of air during the brief time of the experiment. The water used was, of course, boiled to free it from dissolved air. The toluene was first weighed into the inner platinum vessel and then the end of the siphon, which was drawn out to a long capillary, was inserted below the surface of the toluene and the ferrous solution allowed to run. When carried out in this fashion, the solution contained only the merest trace of ferric salt previous to the mixing, and after the mixing had been accomplished there was no appreciable increase, as estimated by colorimetric comparison, with sulphocyanate.

In order to calculate the heat of dilution the heat capacity of the two liquids being mixed must be known. One of these is pure water, the other a solution of hydrochloric acid containing a small amount of metal. From the results of Marignac it seemed probable that the substitution of the small amount of metal for some of the hydrogen in the acid would not have a very great effect upon the heat capacity of a given quantity of the acid. From his results it is apparent, for example, that the conversion of $2(HCl.25H_2O)$ into $SrCl_2.50H_2O$ causes a change in heat capacity of only about 1 per cent. Data in other cases are lacking, but this case may be taken as typical.[1] In order to make assurance doubly sure, however, the case of zinc (which gave the most divergent results) was tested with great care. 636 grams of $HCl.20H_2O$ were treated with about 5 grams of zinc. When the solution was complete, the specific heat of the resulting mixture was found by two very concordant results to be 0.8575. Hence the heat capacity of the total amount taken was $641 \times 0.8575 = 549$ "calorie units." The acid from which the solution was made had a heat capacity of 540. Thus there is a gain of heat capacity, owing to the substitution of zinc for hydrogen, of less than 2 per cent. Clearly this is a change too small to have any serious effect upon the results of the heat of dilution; for the greater part of the heat capacity in dilution experiments is due to the water and not to the much smaller bulk of acid solution. An error of 2 per cent. in the heat capacity of the zinc solution would cause only 0.2 per cent. in the total heat capacity—a range of accuracy beyond one's ability to read the thermometers concerned in determining the heat of dilution. Because the most divergent case was that of zinc, it seems clear that no important error would be introduced by assuming that the heat capacity of the solution in all the other cases is equal to that of the hydrochloric acid from which the solutions were made. In yet more accurate work this point would demand consideration.

---

[1] *Ann. chim. phys.*, [5] 8, 410 (1876).

A table containing four series of experiments wth these residual liquids is given below:

HEAT OF DILUTION OF FINAL SOLUTIONS.

Expt No	Reaction measured.	Initial temperature of experiment.	Corrected rise of temperature	Heat capacity in Cal./t° units.	Energy change, Calories	Energy change for 1 gram atom of chlorine in large Calories.
11	125.0 grams of zinc soln + 1013.7 grams of water	19.95	0.238°	1136	0.2715	0.868
12		19.94	0.238			
13		19.99	0.240			
14		19.94	0.239			
15		19.96	0.240			
16	125 grams aluminium soln. + 1020.9 grams water	19.94	0.156	1142	0.1784	0.567
17		19.92	0.156			
18		19.95	0.156			
19		19.94	0.156			
20		19.96	0.157			
21	60 grams cadmium soln. + 1043.4 grams water	19.90	0.346	1102	0.3824	1.262
22		11.94	0.348			
23		19.93	0.348			
24		19.93	0.347			
25		19.94	0.348			
26	60 grams ferrous soln. + 1049.7 grams water	19.94	0.368	1109	0.4081	1.339
27		19.93	0.369			
28		19.94	0.368			
29		19.94	0.367			
30		19.94	0.367			

The data given in the last column of this table are used for the calculation of the quantity z, by multiplication with the appropriate factor. In the case of zinc, this factor is, as before, 20.69, because 20.69 molecules of hydrochloric acid were present for each atom of zinc. The other factors are given below in the next table.

The marked differences between the heats of dilution of the solutions containing small amounts of zinc and aluminium, but otherwise alike, is very interesting. The correspondence with the preliminary results is very close.

It is not necessary to give the full details of the careful experiments indicating the complete absence of heat of mixture of $(^1/_n\mathrm{MCl}_n)$ $200\mathrm{H_2O}$ with an excess of $\mathrm{HCl.200H_2O}$. Ten experiments of this kind were made, two with each of the chlorides of zinc, aluminium, magnesium, cadmium, and iron in place of MCl_n. Exact weighing was not necessary in these cases because a slight excess of one or the other reagent would have a vanishingly small effect, since the total change to be measured was found to be imperceptible. In no case was a perceptible evolution of heat observed in these reactions. Hence the quantity q in the previous equations became 0 in each case, as has been already stated.

Calculation of Final Results.

The various data concerning dilution may now be applied to the heats of solution of the metals in concentrated acids, thus computing the theoretical value of the heat which the reactions would evolve in each case, provided that the metal were dissolved in just enough $\mathrm{HCl} + 200\mathrm{H_2O}$ to effect its complete solution, giving a product free from excess of acid. In order to accomplish this, there must be in each case subtracted from the value of the heat of solution actually observed for a gram atom of metal, the heat of dilution of the hydrochloric acid employed under the experimental conditions to act upon a gram atom of metal; and there must be added to the result the heat of dilution of the corresponding quantity of residual solution. The following table indicates the number of moles of acid corresponding to a gram atom of metal, the data being taken from the record of the experiments already given in the previous paper:

MOLECULAR PROPORTIONS OF ACID AND METAL.

	Weight of metal.	Atomic weight.	Fraction of gram atom present.	Gram mols. of acid present.	Gram mols. of acid for each gram atom of metal
Zinc	7.496	65.37	0.11467	2.372	20.69
Aluminium	0.747	27.1	0.02756	2.372	86.06
Magnesium	0.849	24.32	0.03492	...	...
Cadmium	14.983	112.32	0.13328	5.038	37.80
Iron	9.000	55.85	0.16114	5.037	31.26

The values given in the final column of this table are the factors needed in order to calculate the values of y and z from the values given in the last columns of the two preceding tables respectively.

The values for y and z calculated in this way from these data for each of the four metals, zinc, aluminium, iron, and cadmium, are given in the following table: The table contains the values for x, the heat of solution of the metal in the excess of concentrated acid (repeated from the previous paper), and also the final result sought, $x + (z - y)$:

Metal concerned.	x in Calories.	y in Calories.	z in Calories.	$x + (z - y)$ in Calories.	Thomsen's values.
Zinc................	30.18	11.50	17.94	36.6	34.2
Aluminium...	126.0	47.81	48.8	127.0	115.0
Magnesium...	110.15	0	0	110.15	108.7
Cadmium	19.77	50.27	47.70	17.2	17.6
Iron....	20.55	41.57	41.85	20.8	21.3

Thus the new values for the heats of reaction sought are as follows:

$Zn + 2HCl\,aq = ZnCl_2\,aq + H_2 + 36.6$ Cal. or 153.1 kilojoules.

$Al + 3HCl\,aq = AlCl_3\,aq + 3/2H_2 + 127.0$ Cal. or 531 kilojoules.

$Mg + 2HCl\,aq = MgCl_2\,aq + H_2 + 110.2$ Cal. or 460.6 kilojoules.

$Cd + 2HCl\,aq = CdCl_2\,aq + H_2 + 17.2$ Cal or 71.9 kilojoules.

$Fe + 2HCl\,aq = FeCl_2\,aq + H_2 + 20.8$ Cal. or 87.0 kilojoules.

The comparison of the new results with Thomsen's values given in the last column shows that the new results differ in some cases considerably from the old value. These differences are to be explained partly by the defect in Rumford's method of correcting for cooling, as used by Thomsen, and partly by his having omitted to add to his results the excess of the heat of dilution of the product over that of the pure acid solution.

It is apparent that the present results are not all equally accurate. In the case of magnesium the result is obtained directly without the necessity of applying any correction for heat of dilution. It is therefore decidedly more certain than the others. In the case of zinc the individual values of the quantities x and y are not large, and supposing these values to be known within one per cent., the error of the final result probably is not more than 0.15 Calorie, or half of 1 per cent. In the case of aluminium the values y and z are larger in actual magnitude, but not larger in proportion to x, therefore the probable percentage error is about the same. In the case of cadmium and iron, the percentage of accuracy of the determination of y and z is greater because the change of temperature involved is greater, but the very large magnitude of each of these quantities (distinctly larger than that of the main reaction) more than neutralizes this advantage.

One favorable circumstance already alluded to mitigates considerably the damaging effect of these difficulties, namely, the fact that y and z are always opposite in sign and nearly equal in magnitude. Because they were observed in precisely the same way under almost similar conditions, it is reasonable to suppose that the same error, if any, applies to both, and that therefore the error would be eliminated.

In order to obtain better results, it would be necessary either to dissolve the metal in a much smaller quantity of less concentrated acid, so that the values y and z should be smaller, or else to observe with greater accuracy than was possible with any means of thermometric measurement at our disposal the heats of dilution of the several solutions. The purity of the metals used preventing the employment of a less concentrated acid because of their slow rate of solution, the latter alternative is perhaps the easier of the two. It is hoped in the near future that the experience gained in this research may be applied in a more complete manner. In the meantime the results here given must be looked upon as merely preliminary. At least it is hoped that the present papers have succeeded in putting the subject of the heats of solution of metals upon a sound scientific basis, to which the future can add nothing more than perfection of detail.

In conclusion, it is a pleasure to express our indebtedness to the generosity of the Carnegie Institution of Washington for pecuniary assistance.

Summary.

There follows in a few words a statement of the outcome of this paper:

1. The heats of dilution of the acids $HCl.20H_2O$ and $HCl.8.808$ to $HCl.200H_2O$ were determined. The results are 0.556 and 1.330 Calories (2.32 and 5.56 kilojoules) respectively.
2. The heats of dilution of the several products obtained by dissolving four metals in excess of concentrated acid were determined. The substitution of salt for acid was found, especially in the cases of zinc and cadmium, to affect seriously the heat of dilution.
3. From these data the heats of solution of a gram atom of the several metals in exactly the theoretical quantity of $HCl.200H_2O$ have been calculated as follows:

THE HEAT OF REACTION OF METAL ON $HCl.200H_2O$ CALCULATED FOR 1 GRAM ATOM OF METAL.

Metal.	Heat of reaction in 18° Calories.	Heat of reaction in Kilojoules.
Zinc	36 6	153 1
Aluminium	127.0	531.0
Magnesium	110.2	460.6
Cadmium	17.2	71.9
Iron	20.8	87.0

[CONTRIBUTIONS FROM THE HAVEMEYER CHEMICAL LABORATORY, NEW YORK UNIVERSITY.]

THE INCONSTANCY OF THE SOLUBILITY PRODUCT.[1]

BY ARTHUR E. HILL.

Received July 11, 1910.

The various assumptions made by Nernst[2] and A. A. Noyes[3] in their earlier investigations on the solubility of electrolytes have been subjected to careful scrutiny by their many successors in this field of work. As in the case of most pioneer work done in theoretical chemistry, it has here developed that many of the assumptions have been too broad, and that they must be subjected to considerable modification if they are to be adopted as a basis for the quantitative study of solutions of electrolytes. Of these original assumptions, two have been almost entirely displaced from the minds of chemists. The belief in the constancy of the concentration of the undissociated molecules of a dissolved electrolyte in equilibrium with its solid phase was shown to be untenable by the experimental work of Arrhenius,[1] which proved beyond question of doubt that this concentration diminishes as the total concentration of salts present is increased. In a like manner, the simplifying assumption that the degree of dissociation is independent of the presence of other electrolytes can no longer be made against the experimental evidence which has been accumulated by Arrhenius,[2] MacGregor, McIntosh, Archibald and McKay,[3] and most recently by Sherrill,[4] all of which makes it reasonably certain that the total concentration of electrolytes present is here also a determining factor.

Of these early assumptions, that of the constancy of the solubility product seems to be the one from which there has been least dissent. It is incorporated in the majority of our elementary text-books as a convenient help in the explanation of solubility relations, and has not lacked advocates even within recent years. Stieglitz[5] has recalculated the experiments of Arrhenius, and finds that by assuming the degree of dissociation to be in accordance with Arrhenius' isohydric principle, it is possible to find a satisfactory constancy for the solubility product, which, he maintains, we may well consider for the present to be an approximate empirical principle, in the absence of theoretical grounds upon which it may stand. Such a theoretical basis Washburn[6] considers to exist in the laws of osmotic pressure, developed with reference to "normal solutes," and "ideal solutions."

Direct experimental proof of the constancy of this value can hardly be looked for, since the concentration of the ions of the solute cannot be directly measured, the calculations based on solubility experiments are complicated by the necessity of making other assumptions as to the state of dissociation and the concentration of undissociated molecules. On the other hand, there already exists, in the solubility experiments of

Cameron[1] and of Hill and Simmons,[2] good reason for the belief that the product of the ions diminishes in value with increase in total concentration of electrolytes. Cameron noted that the solubility of gypsum was increased by addition of sodium chloride up to a certain concentration, beyond which it suffered a decrease; the same phenomenon was found to occur when silver sulphate was acted on by nitric acid solutions.[2] In both these cases, we should expect a continuous increase in solubility, due to the formation of new compounds by chemical interaction. This factor would be opposed by a small decrease in the amount of undissociated salt present, as Arrhenius'[3] experiments clearly prove. This latter factor, however, could not be expected to counterbalance the increase caused by chemical action, since the quantity of undissociated salt is practically negligible in the case of highly dissociated substances such as gypsum and silver sulphate. In order, therefore, to account for the diminution in total solubility, we must assume that the ions of the solute have been lessened in concentration, and that the solubility product accordingly has been diminished in value.

The preceding experiments do not permit any calculations as to the value of the solubility product without the use of the other complicating assumptions. In the belief, however, that the qualitative discussion above was correct in principle, other experiments have been conducted in which, without the addition of any common ion, the solubility of certain salts has been so diminished in the presence of other electrolytes as to prove conclusively, without the introduction of assumptions as to the degree of dissociation or the concentration of undissociated salt, that the solubility product is not a constant, but diminishes in value in the presence of other electrolytes.

In selecting material for the experiments, such pairs of electrolytes were chosen as would be expected to show least chemical interaction, so that the increased solubility due to this action might cease to be the determining factor at a low concentration. Thallous chloride, a salt of a strong acid, was used with acetic acid as the second electrolyte; since the solubility of this salt is not greatly increased even by nitric acid,[4] it was to be expected that the weaker acetic acid would have but little effect in this direction. Tetramethylammonium iodide and potassium hydroxide were taken as the second pair. When each of these pairs was tested, it developed that under no conditions was an increase in solubility of the salt to be noted, while the decrease became clearly marked upon the addition of very moderate amounts of the second electrolyte.

Experimental Part.

The thallous chloride used was prepared from metallic thallium and recrystallized from water. Analyses of the pure compound gave the chlorine content as 14 79 and 14.75 per cent.; calculated, 14.80. The acetic acid was Kahlbaum's c. p. preparation, whose strength was determined by titration against a standard potassium hydroxide solution; the ultimate standard was gravimetrically analyzed hydrochloric acid. The solubility equilibrium was approached from supersaturation and undersaturation. Stirring of the samples for eight hours proved to be sufficient. After equilibrium had been reached, samples were pipetted out and analyzed for their chloride content by Volhard's method, filtering off the silver chloride[1] in each case. In experiments (8) and (9), in which the chloride content was low, gravimetric analyses were made. The specific gravity of the acetic acid solution at the temperature of standardization and that of the saturated solution at 25° were determined by direct weighing of measured volumes.

The tetramethylammonium iodide used for the second set of experiments was a preparation of Kahlbaum's which was recrystallized from water. Analysis by Volhard's method gave the following figures for iodide content: found, 63.08 and 63 38 per cent.; calculated, 63.13. The potassium hydroxide was freed from carbonates by agitating a concentrated solution with slaked lime; when siphoned off and tested, it was found to be free from calcium. The alkali solutions were made up from this stock solution and titrated against a gravimetrically analyzed hydrochloric acid. Specific gravity and solubility determinations were made as in the case of the thallous chloride, the iodides being determined by the method of Volhard.

The solubility of the salt in water is found to be about one per cent. higher than the value which Walden[1] obtained in the case of an equilibrium approached from undersaturation. Walden's figure where the approach was made from the direction of supersaturation (58 9 grams per liter) shows that a true equilibrium was not attained in his experiment.

Determinations of the conductivity of tetramethylammonium iodide were made for use in the calculations of this paper. A dip cell was used for the measurements, the capacity being determined by means of $N/50$ potassium chloride solution, whose conductivity was taken as 0.002768. The water used in the dilutions had a conductivity of 0.0000029. Experiments were conducted with a saturated solution and with the customary dilutions from $N/8$ to $N/1024$.

TABLE III.—CONDUCTIVITY OF $(CH_3)_4NI$ AT 25° (±0 03°).

	Volume.	Equivalent conductivity.
1	3.74	81.20
2	8.0	88.86
3	16.0	96.54
4	32.0	103.4
5	64.0	109.3
6	128.0	113.9
7	256.0	118.2
8	512.0	121.8
9	1024.0	123.8
—	∞	(129.2)

The value of the equivalent conductivity at infinite dilution was found by extrapolation to zero concentration from the results of experiments 5 to 9, following the method of A. A. Noyes.[1]

---

[1] *Z. physik. Chem.*, 55, 708 (1906).

The limiting value 129.2 is much higher than that which would be found by taking for the migration numbers the accepted value 76.8 for iodide ion and for the tetramethylammonium ion 46 5 as calculated by Bredig[2] from conductivity measurements of the chloride. This value for the tetramethylammonium ion is surely several units too low, as appears when it is used to calculate the dissociation of tetramethylammonium hydroxide from Bredig's measurements;[3] at a dilution of 256, the base appears to have a conductivity corresponding to more than complete dissociation. If the migration number is taken from the above measurements as 52 4, the base is seen to possess only the extent of dissociation common to strong electrolytes, and the anomaly disappears.

Discussion of Results.

It has been shown that a diminution in solubility such as appears in Tables II and III gives strong qualitative indication that the value of the solubility product has also diminished. The case is capable of quantitative treatment where the decrease goes far enough. If in the case of the double decomposition

$$\underset{a}{\mathrm{AB}} + \underset{b}{\mathrm{CD}} \rightleftarrows \underset{c}{\mathrm{AD}} + \underset{d}{\mathrm{CB}},$$

we use the capital letters to indicate concentrations of free ions and the small letters to indicate concentrations of undissociated molecules, we can express the total solubility m of the compound AB in two ways:

$$(1)\ m = \mathrm{A} + a + c;$$

$$(2)\ m = \mathrm{B} + a + d.$$

If we assume the solubility product to have a constant value, we have

$$(3)\ \mathrm{A} \times \mathrm{B} = \mathrm{K}.$$

Multiplying (1) by (2) and extracting the square root, we find

$$(4)\ m = \sqrt{\mathrm{A} \times \mathrm{B}} + \mathrm{X},$$

where X is used to indicate the various other terms, all of which must have a positive value, since a, b, c and d are positive numbers. Substituting from (3), we obtain

$$(5)\ m = \sqrt{\mathrm{K}} + \mathrm{X},$$

which indicates that, on the assumption of the constancy of the solubility product, the total solubility could never be less than the value $\sqrt{\mathrm{K}}$. A value of m less than $\sqrt{\mathrm{K}}$ proves therefore an error in the assumptions of equations 1, 2, or 3. Equations 1 and 2 express the fundamental assumption of the dissociation theory, that the substances present exist as ions and as undissociated molecules; unless we are prepared to deny this, we must grant that a value of m less than $\sqrt{K}$ constitutes rigorous proof that the value of the solubility product has decreased.

---

[1] *Report of the Carnegie Inst.*, 63, 50. See also the paper of Johnston, THIS JOURNAL, 31, 1010 (1910). The value of the exponent n for this salt was found to be 1.48.

[3] *Ibid.*, p. 299.

In the following tables the values of m have been arranged with reference to the concentration of other electrolytes present; the values of the solubility product have been calculated for each salt. The solubilities have been calculated with reference to the volume of the solution and to the weight of water present, so that the meaning of the term concentration shall not be in question:

TABLE IV.—SOLUBILITY OF TlCl IN $HC_2H_3O_2$.

Volumetric normality of $HC_2H_3O_2$.	Equivalents TlCl per liter of solution.	Equivalents TlCl per 1000 gms. of H_2O.
0.00	0.01629	0.01634
0.5134	0.01580	0.01628
1.013	0.01495	0.01585
2.016	0.01321*	0.01484*
4.180	0.009945	0.01273
8.130	0.005399	0.00952
11.49	0.002590	0.00792
14.31	0.001221	0.00595
16.01	0.000478	0.00453
	$\sqrt{K}$ = 0.01486[1]	$\sqrt{K}$ = 0.01490

TABLE V.—SOLUBILITY OF $(CH_3)_4NI$ IN KOH.

Volumetric normality of KOH.	Equivalents $(CH_3)_4NI$ per liter of solution.	Equivalents $(CH_3)_4NI$ per 1000 gms. of H_2O.
0.000	0.2671	0.2774
0.250	0.2556	0.2657
0.5325	0.2377	0.2466
0.9899	0.2084	0.2162
2.0743	0.1437*	0.1491*
8.2962	0.01475	0.01683
	$\sqrt{K}$ = 0.1678[2]	$\sqrt{K}$ = 0.1743

It appears in the foregoing tables that the point at which m is found to be less than $\sqrt{K}$ occurs where the solution is at a concentration between normal and twice normal with respect to the second electrolyte. When this latter concentration is increased sufficiently, the solubility is decreased to a value of entirely different magnitude from that in pure water. We are left, therefore, no alternative but to dismiss our belief in the constancy of the solubility product, together with the other early assumptions of the theory of solutions, and to be satisfied for the present with the purely qualitative statement that the solubility product shows a diminishing value with increased concentration of other electrolytes.

---

[2] Calculated from the conductivity measurements of Table III.

Conclusion.

The results of the foregoing paper may be summarized as follows:

(1) Determinations have been made of the solubility of thallous chloride in acetic acid solutions of varying concentrations, and of tetramethylammonium iodide in potassium hydroxide solutions of varying concentrations.

(2) The electrical conductivity of tetramethylammonium iodide has been measured.

(3) The solubility product has been shown to have a value which diminishes with increase in the total concentration of electrolytes present.

I am indebted to Mr. George Barmeyer and to Mr. Charles E. Roake for the solubility determinations of Tables I and II.

[CONTRIBUTIONS FROM THE RESEARCH LABORATORY OF PHYSICAL CHEMISTRY OF THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY, NO. 54.]

A VOLUMETRIC METHOD OF DETERMINING IODIDE IN THE PRESENCE OF CHLORIDE, BROMIDE, OR FREE IODINE.

BY W. C. BRAY AND G. M. J. MACKAY.

Received July 25, 1910.

The method here described of determining iodide depends upon its oxidation to iodine in acid solution by means of potassium permanganate, the removal of the liberated iodine from the aqueous phase by carbon tetrachloride, and the titration of this iodine with a standard sodium thiosulphate solution. When the iodide contains free iodine dissolved in it this titration gives the total iodine present in solution; the dissolved iodine is determined by direct titration of the original solution with thiosulphate, and the difference between the two results gives the iodine present as iodide.

This method was suggested and used by Sammet,[1] but he gave no specific directions and no indication of its accuracy. A similar method was developed long ago by Fresenius,[2] in which carbon disulphide took the place of carbon tetrachloride, excess of nitrous acid was used instead of an equivalent amount of permanganate, and the nitrous acid in contact with the carbon disulphide was removed by repeated decantations with water. Information with regard to the accuracy of this method appears to be lacking, but it is doubtful if it would have, even if modified, any advantages over the present method.

The possibility of determining iodide in the presence of chloride or

bromide depends upon the extremely rapid rate, even in dilute solutions, of the reaction

$$5I^- + MnO_4^- + 8H^+ = 2\tfrac{1}{2}I_2 + Mn^{++} + 4H_2O,$$

and the relatively slow rates of the corresponding reactions with chloride or bromide. The reaction with chloride is so slow that there is no appreciable liberation of chlorine, even in a moderately concentrated sulphuric acid solution. In the case of bromine, however, in order to prevent the rapid liberation of bromide, it is necessary to keep the concentration of bromide and of sulphuric acid small, and to add only a slight excess of permanganate. It will be seen later that none of these precautions introduces any difficulty.

This plan of regulating the rate of reaction between halides and permanganate by means of the hydrogen ion concentration has already been used in a well-known method of detecting the halides in the presence of each other,[1] which was developed by Jannasch and Küster.[2] In this process the halogens are expelled successively from a boiling solution: iodine from a solution containing acetic acid and sodium acetate, bromine from a solution containing acetic acid and a little sulphuric acid, and chlorine from a concentrated sulphuric acid solution. The advantages in our quantitative method of working at room temperature and collecting the liberated iodine in another solvent are obvious. But in this case it was found by trial that dilute sulphuric acid must be used, instead of acetic acid, in order to prevent the formation of manganese dioxide, which interferes with the removal of the CCl_4 phase. Since the liberation of bromine cannot, therefore, be prevented by cutting down the hydrogen ion concentration to a very small value, it is important, as mentioned above, to avoid an excess of permanganate.

The addition of permanganate may be regarded as a titration; the "end point" described below in the procedure is easily determined and it is not difficult to avoid an excess of permanganate. This is possible because a solution of potassium iodide and carbon tetrachloride are both much better solvents for iodine than is pure water, so that, as the potassium iodide concentration becomes smaller, a larger proportion of the iodine passes into the carbon tetrachloride phase, and finally a colorless aqueous layer may be obtained.

The only sources of error in this method appear to be those which might arise from the addition of potassium permanganate in excess. If bromide is present, some bromine may be liberated. Also the addition of potassium permanganate in excess while considerable iodine is still present would result in the permanent formation of some iodic acid, the iodine of which would not be removed by the carbon tetrachloride. The temporary formation of bromine or iodic acid during the earlier part of the operation does not, of course, introduce an error, for each reacts with the iodide still present, forming iodine. Although these errors may be easily avoided, it has seemed worth while to add a supplementary treatment with sulphurous acid by means of which the loss of an analysis may be avoided even if too much permanganate has been added.

---

Method of Analysis.

The following *materials* are required:

A glass-stoppered separating funnel of about 250 cc. capacity in which to carry out the oxidation of the iodide. The delivery tube should be cut off short and ground at an angle in order to facilitate washing after the discharge of the carbon tetrachloride solution of iodine.

A standard sodium thiosulphate solution, say 0.1 or 0.2 normal.

A potassium permanganate solution of about the same strength.

A freshly prepared 10 per cent. potassium iodide solution free from iodate.

Carbon tetrachloride free from oxidizing or reducting agents. A liter of carbon tetrachloride may be conveniently purified for use in these analyses by treating with iodine and dilute sulphuric acid for a few hours, shaking the mixture at intervals. The CCl_4 is drawn off from the acid solution by means of a large separating funnel decolorized by shaking with a neutral sodium thiosulphate solution, and washed thoroughly by shaking with fresh portions of water.

Procedure.—Introduce into the separating funnel 25 to 30 cc. of carbon tetrachloride, 3 to 15 cc. sulphuric acid[1] (sp. gr. 1.20), and a definite amount of the potassium iodide solution to be analyzed. If bromide may be present, do not use more than 5 cc. of sulphuric acid and add 75 to 100 cc. water.

Add the permanganate solution from a burette, at the same time rotating the mixture, until the aqueous layer becomes very dark colored due to the liberated iodine; place the stopper in the separating funnel, shake vigorously, and let stand for at least half a minute. Carefully run the carbon tetrachloride solution of iodine into a glass stoppered flask containing about 25 cc. of 10 per cent. potassium iodide solution[2] and a few drops of acetic acid. Add a fresh portion of carbon tetrachloride and repeat the process until the aqueous layer is colorless.

As this stage is approached, add the permanganate solution drop by drop and shake the mixture after each addition. The decolorization of the permanganate and the liberation of iodine when the drop enters the solution can be easily observed. When the water layer appears colorless, withdraw as much as possible of the iodine by using successive small portions of carbon tetrachloride, add a drop of the permanganate, shake the mixture, and note the color of the aqueous and carbon tetrachloride layers. The end point has been reached (1) if the aqueous solution is pink colored owing to the presence of permanganate, and (2) if the carbon tetrachloride fails to show the pink color due to the presence of iodine.[1]

---

[1] Dilute nitric acid may be used instead of sulphuric, *e. g*, when barium salts are present.

[2] A fairly concentrated potassium iodide solution is used to prevent the volatilization of iodine, and to aid in extracting the iodine from the carbon tetrachloride in the later titration with thiosulphate.

Titrate the liberated iodine with the standard sodium thiosulphate solution; shake the mixture continuously as the end-point is approached to ensure the rapid transfer of the iodine from the carbon tetrachloride to the potassium iodide solution.

In practice it is well to perform a preliminary titration to determine how much permanganate solution is required. The later analyses may then be quickly performed, since slightly less than this amount of potassium permanganate may be added before removing any iodine; but in this case, also, the mixture must be shaken vigorously at intervals.

If by accident an excess of permanganate be added while iodine is still present, and the formation of bromine or iodic acid be suspected, add a little sulphurous acid solution to again form the halide, and after 2 or 3 minutes treat with permanganate in the usual way.

The method was tested by means of a large number of analyses of potassium iodide solutions of known strength. The first group of analyses (Nos. 1–8) was made in connection with the investigation described in the following paper. The remaining analyses (Nos. 9–22) were made at a later date by one of us to supplement the first analyses and to determine the best conditions of analyzing iodide in the presence of chloride and bromide.

First Group of Test Analyses.

The carbon tetrachloride was not purified as directed in the procedure, and contained a trace of oxidizing material. In each of several blank analyses with approximately the same quantity of carbon tetrachloride as was used in an actual experiment, a slight amount of iodine was liberated which corresponded to about 0.06 cc. of the thiosulphate solution.

In the first analyses the sodium thiosulphate solution was 0.07348 normal. It was standardized: (1) by comparison with an iodine solution which had been titrated against arsenious oxide by the method described by Washburn[2] and (2) against a solution of copper sulphate by the method of Gooch and Heath,[3] the copper content of this solution having first been determined by electrolysis. The results of the two methods agreed within 0.1 per cent., but it is doubtful if this accuracy could be claimed for the copper standardization. The concentration of the permanganate solution was not determined.

---

[1] This second test of the end-point is valuable when bromide is present, for the permanganate color may then disappear, but the carbon tetrachloride becomes yellow, not pink.

[2] Washburn, THIS JOURNAL, 30, 31 (1908).

[3] Gooch and Heath, *Z. anorg. Chem.*, 55, 119 (1907); *Am. J. Sci.*, 24, 65.

The potassium iodide solution was prepared by dissolving in 1 liter 15.00 grams of the pure, dry salt (Kahlbaum's guaranteed reagent). This solution was analyzed by measuring out three 100 cc. portions and precipitating the iodide as silver iodide. The precipitate was washed thoroughly with warm water by decantation, collected upon a weighed platinum Gooch filter, heated at 200° for 12 hours, and weighed. The three determinations gave for the normality of the solution,[1] 0.09054, 0.09052 and 0.09057—mean 0.9054. These results are concordant, and the mean is probably more nearly accurate than the value, 0.09030, derived from a single observation of the weight of salt taken.[2]

The results of the first eight analyses are given in Table I. The first five are with potassium iodide alone; in the preliminary analysis (No. 4 in the table) excess of permanganate was added while iodine was still present, and was reduced by the sulphurous acid treatment described in the procedure. In the remaining three analyses 25 cc. 0.1 formal copper sulphate solution were also added, which resulted in the precipitation of cuprous iodide and thus subjected the method to a very severe test. The sulphuric acid concentration was varied greatly in these experiments. In each case the burette reading given in the last column of the table has been diminished by 0.06 in accordance with the blank experiments described above. The initial volume (second column) refers to the total volume of the aqueous solution at the beginning of the experiment. All numbers are cubic centimeters.

---

[1] International atomic weights of 1908 were used in connection with the first group of analyses (Nos. 1–8). In the remainder of the work 1910 atomic weights were used. The weights of salts were not corrected to vacuum.

[2] This difference of 0.27 per cent. might be due to the presence of sodium iodide in the potassium iodide reagent.

[3] Preliminary experiment, rejected in taking the mean.

The concentration of the potassium iodide solution calculated from the mean burette reading (30.82 cc.) is 0.09041 normal, which is only 0.14 per cent. less than the value, 0.09054, given by the gravimetric analyses. An examination of the individual analyses shows that the extreme variation from the mean is 0.1 per cent., and that the result is not affected by a 20-fold variation in the concentration of sulphuric acid, nor by the presence of copper sulphate.

Other analyses made at the same time as the above gave equally satisfactory results. For example, the 0.1 and the 0.01 normal potassium iodide solutions, which were used in the conductance measurements described in an earlier paper,[1] were analyzed by this method. Four titrations of the first solution and two of the second were made. The normality obtained in the first case was almost identical with, and that in the second one about 0.1 per cent. greater than, the value calculated from the weight of the pure dry salt.

Second Group of Test Analyses.

The carbon tetrachloride used in the following analyses was purified as described in the procedure, with the result that no iodine was liberated in blank analyses and the uncertain correction applied in the above experiments was eliminated.

Two different thiosulphate solutions were used, and the relation between them was determined several times by comparing both with the same solution of copper sulphate.

The stock thiosulphate solution was standardized during the following experiments by Dr. W. D. Harkins against pure iodine[2] and was found to be 0.09577 normal. The corresponding concentration of the second thiosulphate solution was 0.1074. The latter solution was used in analyses 9–18 (Table II).

The second method of standardization tried was the comparison of one of the thiosulphate solutions with a $KMnO_4$ solution which had been standardized by Mr. A. C. Melcher against sodium oxalate. The $KMnO_4$ was added to excess of KI in a dilute sulphuric or acetic acid solution. The results were concordant, but the normality calculated for the thiosulphate solution was 0.3 per cent. less than that derived from the iodine standard. It is shown in an appendix to this paper that one-third to one-half of this difference is due to the conditions under which the permanganate solution had been standardized. There still remains, however, a discrepancy of 0.15 to 0.2 per cent. between the two standardizations, and it therefore seems improbable that the concentrations of the thiosulphate solutions derived from the iodine standard are too low.

---

[1] Bray and MacKay, This Journal, 32, 917 (1910).

[2] The iodine had been used in the experiments on the hydrolysis of iodine (Bray, This Journal, 32, 932 (1910)) and thus was free from soluble impurities, including chlorine and bromine. This was twice sublimed, and dried over calcium chloride for several days.

In the third method of standardization, however, in which the thiosulphate solutions were referred to copper as standard by the method used in the first analyses, the normalities were found from numerous careful experiments to be 0.0960 and 0.10765, *i. e.*, over 0.2 per cent. greater than those given by the iodine standard. The conclusion was finally reached that the absolute accuracy of the copper standard is not quite as high as we had at first supposed.[1]

---

[1] Since this result differs from that found in the standardization of the thiosulphate used in the first group of test analyses, it has seemed worth while to give the details of the final experiments.

The copper sulphate used was prepared from the commercial salt by recrystallizing once from sulphuric acid solution and twice from water. The copper content of the copper sulphate solutions was determined from several concordant electrolytic analyses, in which the copper was deposited from a dilute nitric acid solution on a rotating cathode. The apparatus was kindly placed at our disposal by Dr. E. B. Spear. The deposition of copper was shown to be practically complete by evaporating the solution nearly to dryness and adding ammonia.

The above normalities were derived from a series of titrations of each thiosulphate solution against the pure copper sulphate solution according to the directions of Gooch and Heath, using 5 g. potassium iodide in the presence of acetic acid and not allowing the volume to exceed 100 cc. Contrary to the statement of these investigators, the results were found to be less satisfactory in dilute sulphuric or hydrochloric acid than in acetic acid solutions. In the latter case the amount of iodine liberated after the completion of the titration was negligible in half an hour, while in the presence of sulphuric or hydrochloric acid at concentrations less than those recommended by Gooch and Heath the iodine liberated in this time corresponded to over 0.10 cc. of 0.1 normal thiosulphate, and the reaction continued at this rate for several hours. This reaction is undoubtedly the oxidation of hydriodic acid by oxygen; it was catalyzed by light, and possibly by the presence of the finely divided cuprous iodide precipitate. In the acetic acid solution the titration could be made slowly, and this was a great advantage in determining the end point.

As the end point was approached the color due to the presence of starch slowly faded, but the particles of cuprous iodide retained a slight but distinct dark color when the color in the solution was very faint. The most clearly defined end point was the change of color of the suspended precipitate from this dark shade to the yellowish white of pure cuprous iodide. The dark color of the cuprous iodide in the presence of iodine and starch indicates that iodine is adsorbed or dissolved by the cuprous iodide A possible explanation of the high thiosulphate concentration obtained in this standardization is that a trace of iodine is dissolved in the cuprous iodide and is not reduced by the thiosulphate.

In each titration from 30 to 40 cc. of thiosulphate were used, and the results were reproducible within 0.1 per cent. In the earlier experiments (in connection with the first group of analyses) a smaller volume was used, and the excess of thiosulphate added at the end point may have been a little greater than in the final experiments; both of these differences in treatment would lead to a relatively lower concentration for the thiosulphate in the first experiments.

Similar experiments were performed with a solution of commercial copper sulphate. (A small light-colored precipitate settled out in a few days and the clear solution was

The potassium iodide solution used in analyses Nos. 9–18 was prepared from the pure salt, which had been recrystallized from water. The crystals were heated for 16 hours at 150°, and 15.473 grams were dissolved and diluted to 1000.3 cc., at 25°, which corresponds to a normality of 0.09305. This value was thought to be a little high on account of the presence of a few particles of cork in the salt. Three 50 cc. portions (measured at 25°) were analyzed by Dr. W. D. Harkins by weighing silver iodide. To prevent occlusion of $AgNO_3$, the mixture was allowed to stand over night after the addition of slightly less than an equivalent amount of silver nitrate. The silver iodide precipitates were washed with cold water, and were heated 4 hours at 120° and 4 hours longer at 170°. The normalities found were 0.09285, 0.09292 and 0.09293; and the mean value, 0.09290, normal, was accepted as the concentration of the potassium iodide solution.

This solution was proved to be free from chloride by treating 100 cc. with permanganate according to the regular procedure to remove the iodide, heating the resulting solution with dilute nitric acid, filtering, and adding silver nitrate. Considerably less than 1 mg. of silver chloride was precipitated.

The results of the analyses of this solution are given in Table II. Chloride was present in Nos. 11 and 12, and bromide in Nos. 15–18. Blank experiments with potassium bromide alone under the conditions of analyses Nos. 15–18 showed that a drop of potassium permanganate was decolorized only very slowly in the dilute acid solutions (corresponding to those used in the experiments.) The thiosulphate concentrations were found to be slightly more than 0.1 per cent. greater than before. This difference disappeared or even changed sign when the $CuSO_4$ solution was treated with bromine, boiled long enough with dilute H_2SO_4 to expel the bromine, and then titrated in the usual way after adding excess of sodium acetate. It therefore seemed probable that the difference was due to the presence of a trace of ferrous sulphate or possibly of cuprous sulphate in the commercial copper sulphate.

ing to Nos. 15–16) but almost immediately in the most concentrated acid (corresponding to No. 18). The same observations were made in the actual experiments at the end point of the permanganate titration.

The results are seen to be remarkably concordant, and to be independent of the acid concentration, the volume of the solution and the presence of chloride. Bromide does not affect the result, provided that the concentration of the sulphuric acid is not too large. From these analyses, and the blank experiments already mentioned with bromide alone, the limiting concentration of acid is placed at about 5 cc. sulphuric acid (1.20) in 100 cc. aqueous solution.

From the mean burette reading (21.62), and the thiosulphate concentration based on the iodine standard, the potassium iodide solution is calculated to be 0.0929 normal, which is in perfect agreement with the concentration derived from the gravimetric analyses. The proof of the absolute accuracy of the titration is not quite complete, since slightly greater concentrations are calculated for this potassium iodide solution from the weight of potassium iodide taken, and by using the copper standard for the thiosulphate solution; but the results render it extremely probable that the use of pure dry potassium iodide as an iodometric standard would yield results accurate to within 0.1 per cent. This method of standardizing thiosulphate solutions has the following advantages: the results are perfectly reproducible; and the method is direct, since the iodine titrated was originally present in the potassium iodide weighed out. Since the iodine standard also has these advantages, and the copper standard does not, the rejection of the copper standard seems justifiable.

The question next examined was the relation between the amounts of potassium permanganate and sodium thiosulphate solutions used in these analyses. Under the existing conditions the oxidation of iodide by permanganate is essentially a direct titration of the iodide by the permanganate. The end point is definite, and the amount of potassium permanganate used in each experiment seldom differed by more than 0.1 per cent. from the mean value, 18.83 cc. It therefore seemed that it might be possible to use the permanganate titration in analyzing the potassium iodide solution, and thus dispense with the final thiosulphate titration. But when the permanganate solution was compared directly with thiosulphate by adding the permanganate to an excess of potassium iodide in a dilute acid solution and titrating the liberated iodine, it was found that 18.83 cc. of the permanganate solution was equivalent to 21.73 cc. thiosulphate solution, instead of 21.62 cc. as expected. The difference 0.11 cc. is the error in the permanganate titration of iodide; and, since the error may depend upon the experimental conditions, it is evident that the permanganate titration could be used only as an empirical method, and might not be reliable, if the conditions were altered.

The reason for this error was found to be the incomplete reduction of permanganate to the manganous state when the iodide was not present in excess. The amount of oxidizing material present in the aqueous solution, after the permanganate titration had been completed and the iodine removed, was determined in No. 14 by adding a little potassium iodide to the aqueous solution in the separating funnel; the iodine liberated was equivalent to 0.09 cc. thiosulphate, while, judging from the color, the amount of permanganate present corresponded to only 0.01 cc. The number 0.09 is the error in the permanganate titration, and it is thus possible by this method to measure this error directly.

In the final experiments (Nos. 19–22) this direct method was used to determine the error in the permanganate titration. The amounts of thiosulphate solution used are given in the last column of Table III under the heading "$KMnO_4$ error;" the values in Nos. 19 and 20 are only approximate; the more accurate ones in Nos. 21 and 22 were derived from results obtained by using a dilute thiosulphate solution. The amount of thiosulphate solution equivalent to the mean amount (19.97 cc.) of permanganate solution was determined in the presence of excess of iodide to be 25.82 cc. On subtracting the experimentally determined value of the "$KMnO_4$ error," 0.10, the result, 25.72, is seen to agree almost exactly with the thiosulphate titration, 25.71 cc.

The results of all the experiments (Nos. 9–22) show that there is a 0.4–0.5 per cent. error in the direct titration of iodide by permanganate due to the incomplete reduction of permanganate to the manganous state. The possibility that this error is present in other permanganate titrations is considered in a note at the end of this article.

In the final experiments the stock 0.09577 normal, thiosulphate solution was used.

The potassium iodide solution was prepared from Merck's "neutral reagent," which contained chloride, by dissolving 16.614 grams of the dry salt and diluting to one liter. Three 50 cc. portions were analyzed by Dr. Harkins; the average weight of the silver iodide plus silver chloride precipitate was 1.793 grams. Two 50 cc. portions were analyzed for chloride, after removing the iodide by the regular procedure with permanganate; the mean weight of silver chloride was. 0.0242 gram. The difference between 1.793 and 0.0242 gave the weight of silver iodide, from which the potassium iodide concentration was calculated to be 0.09840 normal. A similar correction of the weight of salt taken for the weight of potassium chloride present (corresponding to the amount of silver chloride found) led to the normality 0.09856. The result based on the weight of the silver salts is considered the more accurate; the difference of 0.16 is probably due to the presence of a trace of impurity other than chloride in the potassium iodide reagent.

The results are presented in the following table. The meaning of the results in the last column has already been explained.

TABLE III.—TITRATION OF 25 00 CC. OF A KI SOLUTION WITH 0.09577 NORMAL $Na_2S_2O_3$.

				$Na_2S_2O_3$ solution	
No.	Initial volume cc	H_2SO_4 (1 20). cc.	$KMnO_4$ solution cc.	$Na_2S_2O_3$ titration.	$KMnO_4$ error.
19	100	5	20 4	25 72	0.07
20	100	5	19.97	25 71	0.08
21	100	5	19 97	25 71	0 10
22	100	5	19 98	25 71	0 10

In experiment 19 a considerable excess of $KMnO_4$ was added while a large amount of iodine was still present, and the supplementary treatment with sulphurous acid was used. The fact that no error is introduced by this treatment is established by the accuracy of the final thiosulphate titration, 25.72 cc.

From the mean value of the thiosulphate titration the concentration of potassium iodide is calculated to be 0.09849, which is intermediate between the two values derived above from the weights of the silver and of the potassium salts, and does not differ from either by more than 0.1 per cent.

Summary.

In this article a method of determining iodide in aqueous solution has been described, which depends upon the oxidation of the iodide to iodine by permanganate, the removal of the liberated iodine by carbon tetrachloride, and the titration of this iodine with a standard sodium thiosulphate solution.

The test analyses (Tables I–III) with potassium iodide solutions of known concentrations show that the titration results are perfectly reproducible, and independent of the presence of chloride, bromide or copper sulphate.

From the standpoint of absolute accuracy this method is also satisfactory, since the results agreed within less than 0.1 per cent. with those based on iodine as standard. Pure, dry potassium iodide may therefore be recommended as an iodometric standard.

Two other iodometric standards yielded less satisfactory results. From a single series of experiments with a permanganate solution, standardized against sodium oxalate, the concentration of a stock sodium thiosulphate solution seemed to be about 0.15 per cent. too low; while from careful experiments with a copper sulphate solution, standardized by weighing electrolytically deposited copper, the concentration of the thiosulphate solution was found to be about 0.2 per cent. too high.

In the method of analysis here described the treatment with permanganate is essentially a direct titration of iodide by the permanganate. It is impossible, however, to replace the thiosulphate titration by this permanganate titration, since the reduction of permanganate to the manganous state was found to be not quite complete, and the resulting error corresponded to about 0.10 cc. (or 0.4–0.5 per cent.) of the permanganate solution. This error was measured directly by adding a little potassium iodide to the aqueous solution (after the removal of the carbon tetrachloride) and titrating the iodine then liberated.

BOSTON, July, 1910.

A SOURCE OF ERROR IN PERMANGANATE TITRATIONS; PRELIMINARY NOTE.

BY W. C. BRAY.

Received July 25, 1910.

In the direct titration of iodide by permanganate described in the preceding article, the permanganate was found to be incompletely reduced to the manganous state, and the resulting error was about 0.10 cc. of the 0.12 normal permanganate solution. It is therefore evident that in this reaction,

$$MnO_4^- + 5I^- + 8H^+ = Mn^{++} + 2^1/_2 I_2 + 4H_2O,$$

the reduction of the permanganate takes place in stages, and that the final stage takes place more slowly than the reaction involving the disappearance of permanganate.[1]

Since the reduction of permanganate undoubtedly takes place in stages in other reactions, a similar error is possible in other permanganate titrations, and indeed is to be expected wherever the final stage of the reaction is known to take place relatively slowly. Apparently such a case is furnished by the titration with oxalic acid; for the kinetic experiments of Skrabal[2] have shown that the reduction from the manganic to the manganous state by oxalic acid is a slow reaction, and that a stable complex is formed between the manganic salt and oxalic acid.

Accordingly the following experiments (Table IV) were undertaken to determine under what conditions the error due to incomplete reduction of permanganate was appreciable in the oxalic acid titration. As in the previous experiments (Table III), this error was measured directly, by adding a little potassium iodide to the cold solution after the permanganate end point had been reached, and titrating the liberated iodine with thiosulphate. A dilute thiosulphate solution was used and the corresponding volume of the permanganate solution is recorded in the last column of the table.[1] This result includes the "blank" correction due to the excess of permanganate added to produce the end point, which from the color was estimated not to exceed 0.01 cc. in Nos. 1 and 2, in which the volume was small, and 0.02 cc. in the remaining experiments.

---

[1] That the incomplete reduction of the permanganate is due to an equilibrium involving iodine, such as $Mn^{+++} + I^- = Mn^{++} + ^1/_2 I_2$, seems improbable, since the concentration of the iodine is kept at a very small value by the presence of the carbon tetrachloride phase.

[2] Skrabal, *Z. anorg. Chem.*, 42, 1 (1904).

In each experiment (except No. 8) a 25 cc. portion of pure sodium oxalate solution was mixed with a known amount of sulphuric acid; the mixture after dilution to the volume given in the table was heated to 90°, and the permanganate solution was added from a burette. In the last four experiments, after about 80 per cent. of the oxalate had been oxidized, the mixtures were cooled, and the titration completed at about 25°. In all cases the end point was approached very carefully, and the last drops were added slowly. In experiments 1-4 the end point was sharply defined; in Nos. 5-8 the pink color seemed to fade very slowly, but no extra permanganate was added. In Nos. 9 and 10, however, when the acid concentration was very large, the first pink color faded quickly and more permanganate was added; and at the low temperatures the end point was even less definite, especially at the large acid concentrations (Nos. 13 and 14). In experiments 2, 3, 4, and 11 the solution became slightly brown during addition of permanganate, but on standing this color disappeared, rapidly at the high temperature and slowly at the low.

TABLE IV.—TITRATION OF SODIUM OXALATE WITH 0.1 NORMAL $KMnO_4$.

Expt. No.	Oxalate solution cc.	H_2SO_4 (1 : 20) cc.	Initial volume. cc.	Final temp. about	$KMnO_4$ solution, 0.12 N	
					Titration cc.	Error cc.
1	25	10	50	80°	21.20	0.02
2	25	10	300	80	21.23	0.03
3-4	25	10	300	80	.	0.03
5	25	50	300	80	21.26	0.05
6-7	25	50	300	80	.	0.05
8	75	50	300	70	.	0.06
9	25	250	300	80	21.26	0.07
10	25	250	300	80	.	0.06
11	25	10	50	25	21.29	0.07
12	25	10	300	25	21.27	0.06
13	25	50	300	25	21.32	0.11
14	25	250	300	25	21.35	0.14

From an examination of the table it is seen that when the amounts of permanganate solution used are diminished by the numbers in the last column, the values are nearly constant, with a mean value 21.20. It is obvious that this is the amount of permanganate actually equivalent to 25 cc. of the oxalate solution, and that the numbers in the last column show the errors under different experimental conditions.

---

[1] It was shown that the liberation of iodine in the concentrated acid solutions was not due to the action of oxygen on hydriodic acid by allowing the mixtures to stand for half an hour after the titration and determining the amount of iodine liberated in that time.

On deducting the blank experiment correction, the error in the first four experiments, due to the incomplete reduction of the permanganate, is seen to be only 0.01 cc., which is negligible when the amount of permanganate used is sufficiently large. The most favorable conditions for the titration, therefore, are a small amount of acid and a final temperature of 70 or 80°. Since these conditions are those recommended in books on quantitative analysis[1] it is evident that the error due to the incomplete oxidation of permanganate need not ordinarily be taken into account.

The large errors in the remaining experiments show the importance of avoiding the following unfavorable conditions in titrating: low temperature, high acid concentration and large volume. In the last experiment, for example, the error was 0.14 cc. of which only 0.02 was due to permanganate alone.

A comparison of experiments 6 and 8 shows that the absolute error remained nearly constant (and the percentage error decreased greatly) when the concentration of manganous salt was increased threefold. This result was confirmed by a pair of experiments, in one of which a large excess of manganous sulphate was added initially. In the standardization of permanganate referred to in the preceding paper the titrations were made under the same conditions as in experiments 6–8, the volume of permanganate varied between 40 and 60 cc., and no blank correction was applied for the excess of permanganate. It follows therefore, as already pointed out, that the error in this standardization was 0.10–0.15 per cent.

From the present results it is evident that an error due to incomplete reduction of permanganate is possible in titrating other reducing agents, and that each case must therefore be carefully investigated if an accuracy of 0.1 per cent. is desired. In many instances, however, the above direct method cannot be used in determining the error. For example, in the ferrous sulphate titration the ferric sulphate formed would itself cause the liberation of iodine. In such cases the constancy of the results under widely different conditions of temperature and acid concentration would probably insure the accuracy of the method of titration. This conclusion would also be confirmed if in an investigation of the reduction of a manganic salt by the reducing agent, as ferrous sulphate, it were found that the reaction takes place rapidly and completely.

These experiments will not be continued by the author at the present time, but the question whether there is an appreciable error in the ferrous sulphate titration will doubtless be settled in the near future by the investigation of the oxalate and ferrous sulphate titrations now in progress at the Bureau of Standards. The author takes pleasure in thanking Dr. W. F. Hillebrand and Mr. R. S. McBride, of the Bureau of Standards, for their kindness in reading and criticizing this note before its publication.

THE EQUILIBRIUM BETWEEN SOLID CUPROUS IODIDE AND AQUEOUS SOLUTIONS CONTAINING CUPRIC SALT AND IODINE.

BY W. C. BRAY AND G. M. J. MACKAY.

Received July 25, 1910

This investigation was originally undertaken in order to test the generally accepted view that the cuprous ion is monatomic (Cu^+), rather than diatomic (Cu_2^{++}), and especially to check the results of Bodländer and Storbeck[1] on this subject. The work, however, was interrupted two years ago and has not been continued; the results then obtained are presented in the present article as an investigation of the law of mass action in dilute aqueous solutions.

Cuprous iodide is difficultly soluble in water, but in the presence of iodine a considerable amount dissolves, owing to the formation of cupric iodide and tri-iodide. The following two equilibria are involved:

$$CuI \text{ (solid)} + \tfrac{1}{2}I_2 = Cu^{++} + 2I^-, \text{ and } I_3^- = I_2 + I^-.$$

From the experimental results at 25° presented below, values have been determined, under widely different conditions, for the two equilibrium functions:

$$(Cu^{++})(I^-)^2/(I_2)^{\frac{1}{2}} = K', \text{ and } (I^-)(I_2)/(I_3^-) = K.$$

Bodländer and Storbeck have reported a single, apparently not very accurate experiment at room temperature (18–20°), in which 1 liter of solution saturated with both cuprous iodide and iodine was found to contain 0.01666 gram molecule of cupric salt, and 0.00946 equivalent of dissolved iodine.

The *cuprous iodide* was prepared according to the directions of Bevan Lean,[2] by adding one formula weight of potassium iodide dissolved in 150 cc. of water to a solution of one formula weight of copper sulphate dissolved in 1500 cc. of water saturated with sulphur dioxide. The resulting precipitate was washed several times with water containing sulphur dioxide, and finally with pure water until all trace of sulphate had disappeared. In each of our equilibrium experiments a large excess (about 20 grams) of solid cuprous iodide was present.

[1] Borländer and Storbeck, *Z. anorg. Chem.*, **31**, 469 (1902).

[2] *J. Chem. Soc.*, **73**, 149 (1898).

The experimental methods of obtaining saturated solutions, removing known volumes for titration, making conductance measurements, etc., were the same as were used in determining the solubility of iodine in potassium iodide solutions.[1]

The concentration of *iodine*, whenever the solid was present, was assumed to be 0.00132 molecule I_2 per liter, as determined in a recent investigation.[2] In the three remaining experiments (Nos. 1–3), in which solid iodine was absent, the equilibrium was investigated in the presence of carbon tetrachloride. The concentration of iodine in this phase was determined by titration; that in the aqueous phase was calculated by means of the partition-coefficient of iodine between carbon tetrachloride and water. The determinations of the latter were made in the presence of iodine; after 24 hours' rotation the ratio of the concentration in carbon tetrachloride to that in water was found to be 90.8 and 89.3. The smaller value agrees fairly well with that determined by Yakovkin,[3] 89.55, in the presence of solid iodine. After taking into consideration the fact that, on account of the hydrolysis of iodine in the aqueous solution, these values should be increased by about 0.08 per cent., the value 90 was chosen Yakovkin's results, however, show a decrease of the partition coefficient with decreasing iodine concentration, and, even after correcting for hydrolysis, it is possible that a value as low as 86.5 should be used in our experiments. The calculations for exps. Nos. 1–3 were accordingly repeated, using this partition coefficient and the results are given in Table II as experiments Nos. 1*a*, 2*a*, and 3*a*.

In addition to molecular iodine, the solutions contained three constituents to be determined: copper, ΣCu; iodide, ΣI; and tri-iodide, $\Sigma I_3'$; and three separate analyses were made in each case.

The *copper* was determined, usually in 100 cc. of solution, by evaporating the solution with 5–10 cc. of dilute sulphuric acid and a few drops of nitric acid until white acid fumes were given off. Ammonia was then added in slight excess, and the solution boiled to expel the excess of ammonia. Finally 50 cc. of 25 per cent. acetic acid and 5 grams of potassium iodide were added, and the mixture was titrated with sodium thiosulphate solution according to the method investigated by Gooch and Heath.[4] Another portion of the saturated solution was titrated in a similar manner directly with thiosulphate, which gave the *total dissolved iodine* and copper. Finally, in a third portion, the *total iodine* was determined by the method described in the preceding paper. Thus the three analyses were referred to a single thiosulphate solution, and the error in determining differences reduced to a minimum. The thiosulphate was standardized by comparison with a known arsenious acid solution, and checked against a known copper sulphate solution, as explained in the first group of analyses in the preceding article.

[1] Bray and MacKay, THIS JOURNAL, 32, 918 (1910).

[2] Bray, THIS JOURNAL, 32, 936 (1910).

[3] Yakovkin, *Z. physik. Chem.*, 18, 585 (1895).

[4] Gooch and Heath, *Am. J. Sci.*, 24, 65 (1907); *Z. anorg. Chem.*, 55, 119 (1907).

The method of calculating the concentrations of the separate substances is illustrated by the following example (Expt. No. 4):

$$\begin{array}{lll} \text{Total iodine} & \Sigma I + 3\Sigma I_3 + 2I_2 & = 0.08490 \\ \text{Direct titration} & \Sigma Cu + 2\Sigma I_3 + 2I_2 & = 0.06432 \\ & \Sigma Cu & = 0.02068 \\ & 2I_2 & = 0.00264 \end{array}$$

From these four equations ΣI_3 and ΣI are calculated to be 0.02050 and 0.02076, respectively.

In the solutions to which no copper salt or iodide had been added a check is furnished upon the accuracy of our analyses by the stoichiometric relation that the equivalent concentration of copper should equal the sum of the concentrations of iodide and triiodide,[1] $2\Sigma Cu = \Sigma I + \Sigma I_3$. In the above example these numbers are 0.04136 and 0.04126, respectively; this difference corresponds to an error of only 0.12 per cent. in the determination of the total iodine, or to larger and less probable errors in the determination of copper or in the direct thiosulphate titration. Accordingly, we have adopted the value of 0.02086 instead of 0.02076 for the value of ΣI, and have applied similar corrections to ΣI in the other experiments in which this stoichiometric relation could be used, except in that with nitric acid (No. 11) where the deviation is much larger and may be accounted for by a reaction between hydriodic acid and oxygen.

The experimental results are presented in Table I. The values given in the column "ΣI calculated" are derived from the relation $2\Sigma Cu = \Sigma I_3 + \Sigma I$, and have been adopted in the calculations described below. The values of "specific conductance, calculated" are derived from the concentrations of the separate ions given in Table II, by means of the following equivalent conductances at 25°, $\Lambda_{Cu} = 56.0$, $\Lambda_{I} = 76.5$, $\Lambda_{I_3} = 41.5$, $\Lambda_{K} = 74.8$, $\Lambda_{NO_3} = 70.6$.

---

[1] We have neglected the cuprous copper in solution; this is present as cuprous iodide and as a complex ion, CuI_2^-, formed by the union of cuprous iodide and iodide ion. With regard to the first substance, Bodländer and Storbeck (*loc. cit.*, page 427) have calculated from electromotive force measurements, that the solubility product $(Cu^+)(I^-)$ is equal to 5×10^{-12}; since in our experiments the concentration of I^- never is less than 0.0088, it is evident that the concentration of Cu^+ cannot exceed 0.6×10^{-9}. The same authors have shown (page 475) that the ratio $(CuI_2^-)/(I^-)$ in the presence of solid CuI is not greater than 7.8×10^{-4}. This complex is therefore present in greatest amount in expt. No. 7, where I^- has its maximum concentration, and the amount does not exceed 2×10^{-5} g. molecule CuI_2^- per liter; this corresponds to only 0.2 per cent. of the total copper present, and its neglect does not seriously alter the final results.

The time of rotation of two days was adopted after preliminary experiments with water alone, in which it was found that the concentration of copper salt after 24 hours was a few tenths of a per cent. less than that obtained after 48 hours. In No. 5 the equilibrium was approached from undersaturation, and in No. 4 from supersaturation, attained by first rotating the mixture for several hours at 35°. The agreement shows that the equilibrium is actually reached in 2 days. This conclusion is further justified by the similar results obtained in experiments Nos. 9 and 10, where the times of rotation differed by 2 days.

The concentrations of the separate ions and of the various un-ionized substances were calculated by the method of approximations which has already been explained in publications from this laboratory.[1] This depends upon the assumption that the "ionization function" of a given salt, K = (anion)(cation)/(un-ionized salt), for example $(Cu^{++})(I^{-})/(CuI_2)$ for cupric iodide, depends only on the equivalent ion concentration, and has the same value in a mixture as at the same ion concentration in a solution of the pure salt.

In the present instance accurate conductance data at 25° are not available, and the calculations are based on the following assumptions: The ionization values for CuI_2, $Cu(I_3)_2$, $Cu(NO_3)_2$, $Cu(Ac)_2$, and $Mg(NO_3)_2$ are equal to the values for $MgCl_2$ calculated from the data of Kohlrausch and

---

[1] Cf. THIS JOURNAL, 31, 754 (1909).

Grüneisen[1] at 18° taking $\Lambda_0 = 111.4$; those for KI, HI, HI_3, and HNO_3 are the values of KCl at 18° ($\Lambda_0 = 130.1$),[2] which are practically equal to our own values of KI at 25°;[3] and those for $CuSO_4$ are the values of this salt at 18° ($\Lambda_0 = 115.7$).[1] The ionization constant of acetic acid was assumed to be 1.8×10^{-5} at 25°.

The validity of these assumptions may be tested in the case of CuI_2 and $Cu(I_3)_2$ by a comparison of the calculated and measured conductances (Table I) in experiments Nos. 1-5 and 7. Since ordinary distilled water was used in these experiments the measured specific conductances must be reduced by from 2 to 5×10^{-6}, and it is at once evident that the agreement is then a satisfactory one. In experiments Nos. 9 and 10 the agreement is less satisfactory, which indicates that the degree of ionization of $Cu(NO_3)_2$ is less than that of CuI_2; a correction of 2 per cent., however, alters the value of the equilibrium function K' only from 1.62 to 1.59×10^{-4}, since the concentration of I^- remains practically unchanged.

The results of the calculations are presented in Table II Concentrations are expressed in millimols per liter in the table, but all calculations are based on molal concentrations.

[3] THIS JOURNAL, 32, 920 (1910).

An examination of the values of the equilibrium function $K = (I^-)(I_2)/(I_3^-)$ shows that in the first three experiments the values based on the partition coefficient 90 are lower and in better agreement with the remaining values than those based on the partition coefficient 86.5. Accordingly the results tabulated at Nos. 1–3 are accepted rather than Nos. 1*a*–3*a*. In neutral solutions the values of K lie between 1.32 and 1.42×10^{-3} while in acid solution (Nos. 6 and 11) the values are slightly lower.[1]

In agreement with the results in potassium iodide solutions,[2] the deviations from the law of mass action are in the direction that the values of K decrease with increasing iodide concentration. Thus when the total concentration of salt (iodide and tri-iodide) increases from 0.018 (Exp. 2) to 0.063 (Exp. 7) the values of K are 1.39 and 1.32×10^{-3}, respectively—in good agreement with the corresponding values in the potassium iodide solutions, 1.38 and 1.33×10^{-3}. From the present experiments it is evident that the presence of other salts, as copper nitrate in Nos. 8 and 9 or magnesium nitrate in No. 12, does not cause a similar decrease in the value of K. In the earlier investigation with potassium iodide solutions the conclusion was reached that the decrease of K with increasing concentration of the salt was due mainly to a decrease in the ratio of the activity[3] of tri-iodide ion to its concentration. The present experiments enable the additional conclusion to be drawn that in this reaction this influence of the salt is not general for all salts but is an individual effect for iodide-tri-iodide solutions.

From the values of the second equilibrium function $K' = (Cu^{++})(I^-)^2/(I_2)^{\frac{1}{2}}$, it is evident that this reaction conforms to the law of mass action as far as the influence of iodine is concerned. Thus K' is increased only 9 per cent. as a result of a 13-fold increase in the concentration of iodine (Expts. 1 and 4). Furthermore K' is almost unaltered by the presence of acetic acid (Nos. 5 and 6).

In the remaining experiments, however, the deviations from the law of mass action are very marked. Thus K' shows a 19 per cent. increase when the concentration of iodide ion is increased 60 per cent. (Nos. 5 and 7), and a 26 per cent. increase when the concentration of cupric ion is increased 4.6-fold (Nos. 5 and 10). Finally there is the striking effect of the presence of a salt without a common ion, as magnesium nitrate or nitric acid, which results in a 23 to 25 per cent. increase in K' (No. 5 and Nos. 11–13).

A closer examination of these results leads to the conclusion that in this reaction there is a relationship between the deviation from the mass law and the total ion or salt concentration. Thus the values of K' show a steady increase with increasing equivalent ion concentration, which is roughly independent of the nature of the salts present. To enable this relation to be easily seen, the experiments have been arranged in the table in the order of increasing ion concentration.

This result is in perfect agreement with the results of other investigations in aqueous solutions, such as the determination of the electromotive force of concentration cells, or the effects of salts on the solubility of another salt. Thus, as pointed out in an earlier paper,[1] existing evidence indicates that in the case of a single ion the activity (A) increases somewhat less rapidly than its concentration (C) (when the latter is derived from conductance measurements), or in other words, that the ratio A/C decreases with increasing ion concentration. By taking into consideration the law (based on the definition of activity) that the activity function $A_{Cu^{++}} \times A^2_{I^-}/A^{\frac{1}{2}}_{I_2}$ is constant under all conditions, it could have been predicted as probable that the equilibrium (concentration) function $K' = C_{Cu^{++}} \times C^2_{I^-}/C^{\frac{1}{2}}_{I_2}$ would increase with increasing ion concentration, which is the experimental result derived from the present measurements.

Finally, it is interesting to note that, when solid CuI and I_2 are both present, the equilibrium function $(Cu^{++})(I^-)^2$ has the same form as the solubility product of a hypothetical, difficultly soluble cupric iodide. It is therefore to be expected that the results of the present investigation will be similar to those derived from investigations of the solubility of a salt in the presence of other salts. Accordingly the increase in the value of K' in Expts. 5 13 indicates that under similar conditions the solubility product of a difficultly soluble salt will not be constant, but will increase with increasing ion concentration. This conclusion is in agreement with the results of solubility investigations already obtained in this laboratory, which will soon be published.

Summary.

The equilibrium

$$CuI(solid) + \tfrac{1}{2}I_2 = Cu^{++} + 2I^-$$

has been investigated at 25° under widely different conditions. The ionic concentrations in the various mixtures were calculated by means of the empirical relations derived from conductance measurements.

The values of the equilibrium function $K' = (Cu^{++})(I^-)^2/(I_2)^{\frac{1}{2}}$ show that this equilibrium conforms with the law of mass action only as far as the influence of iodine is concerned, and deviates from it when cupric salt, iodide, or other salt is added. In all these cases, however, the deviations are of such a nature that K' increases with increasing ion concentration.

---

[1] Bray and MacKay, *Loc. cit.* In the e. m. f. measurements of concentration cells by Jahn and by Lewis and von Ende, formerly cited as examples of this rule, the ratio A/C was practically constant at low concentrations, but the decrease was marked in 0.1 normal solutions.

This result, when examined from the standpoint of activity, as defined by Lewis, furnishes another illustration of the apparently general rule that when the concentration of an ion is based on conductance measurements the ratio of its activity to its concentration decreases somewhat with increasing ion concentration. An important consequence of this rule is that the solubility product of a salt will not be exactly constant but will increase with increasing ion concentration.

Values were also calculated for anothor equilibrium function $K = (I^-)(I_2)/(I_3^-)$. The results confirm the conclusion reached in an earlier paper that K decreases with increasing concentration of iodide, but show that other salts do not produce a similar effect.

Conductance measurements were also made with a number of the equilibrium solutions. These show that cupric iodide and cupric tri-iodide are ionized to the same extent as magnesium chloride, and that cupric nitrate is ionized to a somewhat less extent.

THE POTENTIAL OF IRON CALCULATED FROM EQUILIBRIA MEASUREMENTS.[1]

BY ARTHUR B. LAMB.

Knowing the dissociation pressure of a metallic oxide, its heat of formation, the change of its heat of formation with the temperature, the solubility of its oxide in water, and finally, knowing the single potential of the oxygen electrode, it is possible to calculate on the basis of the fundamental laws of energetics and the concentration law the potential of the metal against a normal solution of its ions.[2]

Many metals give fairly definite and easily measurable potentials, especially when an amalgamated electrode can be employed.[3] When this is the case, an indirect calculation, such as the one just outlined, depending upon measurements of such difficulty as the dissociation pressures of metallic oxides at high temperatures, would be disadvantageous. The reverse calculation, that is, the calculation of dissociation pressures from electromotive forces, would be more rational, and indeed, has most often been made. This is not, however, always the case. Many solid metals give rather variable potentials, and certain metals, such as iron, have yielded widely differing values of the potential. Thus Richards and Behr[1] found that the true potential of iron was apparently as high as 0.18 volt, for the porous form, and 0.15 volt for the massive, if the calomel electrode is taken as —0.56, while other investigators had obtained values about a tenth of a volt lower. It is evident that in such a case as this a calculation of the potential from equilibria measurements might well be of interest.

Unfortunately, measurements of the equilibrium between iron, ferrous oxide and oxygen have not been made. It is certain, too, that such measurements would be very difficult of execution, for the temperature necessary to produce a measurable dissociation of the ferrous oxide would be very high. However, equilibrium measurements upon the system iron, ferrous oxide, carbon monoxide and carbon dioxide can be used for the desired calculation, just as well as the direct measurement of the dissociation pressure of the ferrous oxide; for our knowledge of the carbon monoxide, carbon dioxide and oxygen equilibrium is relatively very satisfactory. By combining the equations for these two equilibria we can easily calculate the dissociation equilibrium of ferrous oxide.

Baur and Glaessner[2] have made the necessary measurements of the equilibrium between iron, ferrous oxide and mixtures of carbon monoxide and dioxide. They found that at 1000° absolute, a mixture containing 40 per cent. carbon dioxide and 59 per cent. carbon monoxide was in equilibrium with a mixture of iron and ferrous oxide at atmospheric pressure. We can now calculate from the results of Nernst and v. Wartenberg[3] what the partial pressure of the oxygen must have been in this mixture of carbon monoxide and dioxide at this temperature. They found that at 1000° absolute and at atmospheric pressure carbon dioxide is 1.58×10^{-5} per cent. dissociated. Since

$$K_p = \frac{p_{CO_2}}{P_{CO} \times p_{O_2}^{1/2}}$$

where K_p represents the equilibrium constant expressed in units of pressure, and p_{CO_2}, p_{CO}, p_{O_2} the respective partial pressures, it follows that

$$K_p = \frac{1}{(1.58 \times 10^{-7})\left(\frac{1.58 \times 10^{-7}}{2}\right)^{1/2}}, \text{ or } = 2.25 \times 10^{10}.$$

Substituting the values of Baur and Glaessner in this equation,

$$\frac{0.41}{(0.59)(p_{O_2})^{1/2}} = 2.25 \times 10^{10}$$

and therefore, $P_{O_2} = 0.95 \times 10^{-5}$ atmospheres, at 1000° abs.

[2] *Z. physik. Chem.*, 43, 358 (1903).

[3] *Ibid.*, 56, 556 (1906).

It is also evident that equilibrium measurements similar to the above, but with carbon present as an additional solid phase, would be equally useful for evaluating the partial pressure of oxygen over ferrous oxide. Such measurements have been carefully made by Schenck, Similler and Falcke.[1] Marked differences in the total pressures were found when different varieties of carbon were used, but the relative amounts of carbon monoxide and dioxide were found to be independent of this factor, as would be expected. Since only these relative amounts of carbon monoxide and dioxide concern us in the present calculation, we can select those measurements made in the immediate vicinity of 1000° abs., which happen to be those where amorphous carbon was used. Interpolating for 1000° we find that the equilibrium mixture contained 61 per cent. carbon monoxide and 39 per cent. carbon dioxide. Substituting these values in the above equation derived from the results of Nernst and v. Wartenberg, we obtain for the partial pressure of oxygen at 1000° abs.

$$P_{O_2} = 0.81 \times 10^{-21}.$$

This agrees excellently with the value 0.95×10^{-21} obtained from the results of Baur and Glaessner. The mean of both results is

$$P_{O_2} = 0.88 \times 10^{-21}.$$

The dissociation pressure of oxygen over the oxide at 25° can be calculated from this value by means of the van't Hoff equation, knowing the heat of formation. We cannot, however, assume that the heat of formation is constant over so long a range, and a modified form of the van't Hoff equation must therefore be used. Such an equation has been deduced by Lewis[2] and applied to a similar problem. It is

$$\ln \frac{p_1}{p_2} = -\frac{U_0}{R}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) + \frac{R - C}{R} \ln \frac{T_1}{T_2},$$

where

U_0 = twice the heat of formation of ferrous oxide at absolute zero;
T_1 = 1000° absolute;
T_2 = 298°.
p_1 = the partial pressure of the oxygen at $T_1 = 0.88 \times 10^{-21}$ atm.;
p_2 = the partial pressure of the oxygen at T_2;
C = the decrease in the heat capacity of the system $2FeO = 2Fe + O_2$, when a molecular weight of oxygen is liberated;
R = the gas constant = 1.985 cal./T.

The value of C at 25° can be computed with some accuracy. According to Pionchon's[3] formula, representing his observations below 700°, the specific heat of iron at 25° would be 0.1116 cal./T. Taking Nernst and v. Wartenberg's[1] formula for the molecular heat of permanent gases, based on Holborn and Austin's[2] measurements, the molecular heat of oxygen at constant volume would be 4.76 cal./T. The author and Mr. Barmeyer, in some unpublished measurements of the specific heat of ferrous oxide, found the specific heat of this substance to be 0.1660 cal./T at 25° to 100°, or 0.1627 at 25°, assuming that its specific heat changes at the same rate as does that of iron. Referring these values to equivalent molecular quantities, we find that

---

[1] *Ber.*, 40, 1708 (1907).

[2] *Loc. cit.*

[3] *Ann. chim. phys.*, [6] 11, 72 (1887).

$$\begin{aligned} C_{25} &= 2 \times (11.65) - 4.76 - 2 \times (6.23) \\ &= 6.08 \text{ cals.} \end{aligned}$$

The *mean* value of C over the temperature interval of 25° to 727°, which we require, can not be computed with as much accuracy, for the temperature coefficient of the specific heat of ferrous oxide is not known. An approximate value for C_{mean} can be obtained by assuming that this coefficient has the same relative value as that of metallic iron. Taking Pionchon's measurements at 710° as a basis, we find that 116.9 cal. is required to heat one gram of iron from 25° to 727°, or 13056 cals. for two-gram atoms. A gram molecule of oxygen would require 3400 cals. to be heated through the same interval. Assuming that ferrous oxide has the same temperature coefficient as iron below the recalescent point, two gram molecules of it would require 22,770 cals. It follows then that

$$C_{\text{mean}} = \frac{22770 - 3400 - 13056}{702} = \frac{6317}{702} = 9.0 \frac{\text{cal.}}{\text{T}}.$$

The uncertainty in the assumption regarding the temperature coefficient of the specific heat of ferrous oxide is so great that this value might be in error by as much as one or two calories. This inaccuracy has but a negligible effect on the final result.

The heat of formation of ferrous oxide has been measured directly by Le Chatelier,[3] using a calorimetric bomb. He found it to be 64,600 cal. at 17° and constant volume (for *one* gram molecule). The heat of formation at absolute zero may be found from the expression

$$U_0 = U + CT.$$

Therefore,

$$\begin{aligned} U_0 &= 2 \times (64{,}600) + 6\ (17 + 273) \text{ cal.} \\ &= 130{,}940 \text{ cal.} \end{aligned}$$

Substituting these values in the above equation, we obtain

$$p_2 = P_{O_2} = 4.4 \times 10^{-90} \text{ atmospheres at } 25°.$$

A cell at 25°, consisting of an oxygen electrode and an iron electrode, plunged in a saturated solution of ferrous hydroxide, would then give zero electromotive force when the pressure of the oxygen over the oxygen electrode equaled 4.4×10^{-90} atmospheres.

---

[1] *Loc. cit.*

[2] *Sitzungsber d. kgl. preuss. Akad.*, 1905, p. 175.

[3] *Compt. rend.*, 120, 623 (1895).

One can now calculate from the familiar equation of Nernst what electromotive force such a cell would have if the pressure of the oxygen were increased to atmospheric, and, knowing the solubility of ferrous hydroxide or ferrous oxide, what the electromotive force would be were the iron and hydroxyl ions present in normal concentration. Thus, were the oxygen at atmospheric pressure, the electromotive force would equal

$$E = \frac{0.059}{4} \log \frac{1}{8 \times 10^{-88}} = +1.279 \text{ volts.}$$

The solubility of ferrous hydroxide in water has been determined by Mr. Bridges and the author to be 1.35×10^{-5} mols. at 25°. Then, for the cell

$$\text{Fe/M/1 Fe}^{\cdot\cdot} / 1.35 \times 10^{-5} \text{ M Fe}^{\cdot\cdot} / \text{Fe}$$

$$E = -0.144 \text{ volt,}$$

and for the cell

$$O_2 \text{ atmospheric / M/1 OH}'/2.70 \times 10^{-5} \text{ M OH}'/O_2 \text{ atmospheric,}$$

$$E = +0.269 \text{ volt.}$$

Combining these cells we obtain for the cell

$$\text{Fe / M/1 Fe}^{\cdot\cdot} \text{ / M/1 OH}' / O_2 \text{ atmospheric,}$$

$$E = +0.866 \text{ volt.}$$

Taking the normal calomel electrode as —0.564 at 25°, the potential of oxygen against normal hydroxyl ions is —0.674, according to the recent investigations of Lewis[1] and others.[2] Hence the single potential of iron against a molecular normal solution of ferrous ion would be

$$E = \mathbf{0.192} \text{ volt.}$$

This value agrees excellently with the value 0.19 volt obtained by Richards and Behr.

The significance of this agreement can be determined only by an examination of the experimental data as regards their probable errors, and the effect of these errors upon the final result.

Of these data the one requiring the most careful scrutiny from this point of view is the heat of formation of ferrous oxide. The value 64,600 cal., used in the above calculation for this quantity, was obtained by Le Chatelier from an experiment with a calorimetric bomb. The heat of formation of HYDRATED ferrous oxide calculated from three independent series of experiments[3] has an identical value in each case of 68,300 cal. at room temperature and constant pressure, or 68,000 cal. at room temperature and constant volume. This roughly confirms the value found by Le Chatelier for dry ferrous oxide, as we should expect a higher value for the hydrated form. The difference, however, is greater than the probable heat of hydration, and would indicate that Le Chatelier's value was too low rather than too high.[1]

---

[1] *Z. physik Chem.*, **55**, 465 (1906); THIS JOURNAL, **28**, 130 (1906).

[2] *Z. physik Chem.*, **56**, 513 (1906); *Ibid.*, **59**, 313 (1907).

[3] Andrews, *Pogg. Ann.*, **59**, 439 (1843); Thomsen, *J. prakt. Chem.*, [2] **11**, 419 (1875); Berthelot, *Ann. chim. phys.*, [5] **23**, 118 (1881); see Ostwald, Lehrbuch II^2, 295.

It appears improbable from these considerations that LeChatelier's value is in error (probably low) by more than three per cent. This error would give rise to an error in the potential of iron of about 25 millivolts, and in the sense that a higher value of the heat of formation would give a higher value for the potential.

The other data involved in the calculation afford less probability of error. Thus any considerable error in the value for the partial pressure is unlikely. The partial pressure was calculated from two independent series of observations and the resulting values agreed to within a few per cent. Data on the dissociation of carbon dioxide were involved in both calculations, but their accuracy is well established. It would seem highly improbable that the mean value for the partial pressure could be in error by 100 per cent., but even then the potential of iron would be altered only by seven millivolts.

The solubility measurements were made by the Kohlrausch method and the value employed was the mean of several concordant results. It is improbable that this value is in error by more than ten per cent. An error of this magnitude would only affect the final potential by about three millivolts, and in the sense that an increase in the solubility of the hydroxide would raise the calculated potential.[2]

---

[1] This heat of formation can be roughly calculated directly from the measurements of Baur and Glaessner, for their experiments extended over nearly two hundred degrees. Applying the above combination of van't Hoff's and Kirchhoff's theorems to the experimental values at 727° and 880°, inserting the corresponding values for the dissociation as calculated from the observations of Nernst and v. Wartenberg, and using the same values for the specific heats, we obtain $U_0/2 = 72{,}000$ cal. or $U_{17}/2 = 72{,}870$ cal Or, starting from the fact that the Fe, FeO, CO, CO_2, O_2 equilibrium curve, obtained by Baur and Glaessner, shows a minimum at 680°, and that hence the heat of reaction must be zero at this temperature, we know that there the heat of formation of carbon dioxide from carbon monoxide must equal the heat of formation of ferrous oxide. Using the data collected by Haber (Thermodynamics of Technical Gas Reactions, p. 317), we find this to be 67,490 cal Correcting this to 17°, using the same specific heat as above, we obtain $U_{17}/2 = 70{,}470$ cal The accuracy of Baur and Glaessner's measurements is not, however, sufficient for calculations of this sort—and the values here given may well be in error on that account by 10 per cent. They can do no more than roughly indicate that the heat of formation of ferrous oxide at high temperatures is the same as that at low temperatures, and that LeChatelier's value for the heat of formation is perhaps too small.

[2] The uncertainty regarding the specific heat of ferrous oxide is of very slight importance in the calculation of the potential. An error of 50 per cent. in it would only affect the potential by about three millivolts. There is a slight error involved in taking the solubility of the ferrous hydroxide instead of that of ferrous oxide. The

Summarizing this calculation of the potential of iron and this discussion of the effect of the probable experimental errors on the final result, we may say:

(1) That the calculated potential of iron against a molecular normal solution of ferrous ions, taking the calomel electrode as —0.564 volt, is 0.192, in excellent agreement with the experimental results of Richards and Behr;

(2) That, in so far as errors in the experimental data involved are concerned, this result can scarcely be in error by more than three centivolts, and that it is probably too low, rather than too high.

UNIVERSITY HEIGHTS, NEW YORK CITY,

THE INVERSION OF CANE SUGAR BY INVERTASE. VI. A THEORY OF THE INFLUENCE OF ACIDS AND ALKALIS ON THE ACTIVITY OF INVERTASE.

BY C. S. HUDSON.

Received July 9, 1910.

In alkaline solutions invertase shows no activity, in weakly acid solutions its enzymotic power reaches a maximum from which it decreases with increasing acidity. The simplest theoretical interpretation of this striking fact is that acids and alkalis combine with invertase by the principles of the law of mass action and prevent it from inverting cane sugar. In the following calculations this hypothesis will be tested. If invertase combines with both acids and alkalis it is an amphoteric electrolyte and may be assumed to dissociate as follows:

(1) Invertase $\rightleftarrows \dot{H}$ + anion (acidic dissociation).

(2) Invertase $\rightleftarrows OH'$ + cation (basic dissociation).

If a units of invertase are dissolved in a unit volume of a solution containing hydrogen and hydroxyl ions in the fixed concentrations $(\dot{H})$ and (OH), it will form x units of anion and y units of cation, leaving $a - x - y$ units of undissociated invertase. The mass-action law requires the fulfilment of the following conditions when equilibrium is attained:

$$(3)\ \frac{(x)(\dot{H})}{(a-x-y)} = K_1, \text{ and } (4)\ \frac{(y)(OH')}{(a-x-y)} = K_2$$

The quantity $a - x - y$ is the concentration of uncombined or undissociated invertase, and it is here assumed that the enzymotic activity is caused by this substance and is proportional to its concentration.

---

difference, however, must be small, since, from the properties of ferrous oxide, we know that the heat of hydration is probably very small. Since the solubility of ferrous oxide, could it be measured, would be greater than that of ferrous hydroxide, this inaccuracy also tends to make the true potential higher.

Solving (3) and (4) for $a - x - y$ gives

$$\text{Activity } (i.\ e., a - x - y) = \frac{a}{1 + \frac{K_2(\dot{H})}{K_w} + \frac{K_1}{(\dot{H})}}. \quad (5)$$

where K_w is the dissociation constant for water. This formula contains the three coefficients a, K_1, and K_2, which are of unknown values; in order to determine the values of these coefficients the data which were found for the activity of invertase in three solutions containing small concentrations of hydrochloric acid are used, namely:[1]

HCl concentration Normal	Activity of invertase
0 0005	62
0 0015	61
0 008	37

These data when introduced in equation (5) give the values $a = 77$, $K_2/K_w = 133$, and $K_1 = 0.000086$, and formula (5) becomes

$$\text{Activity} = \frac{77}{1 + 133\,(\dot{H}) + \frac{0.000086}{\dot{H}}}. \quad (6)$$

From this formula the activities of invertase over a considerable range of acidity and alkalinity have been calculated and are recorded in Table I in comparison with the activities which were found experimentally

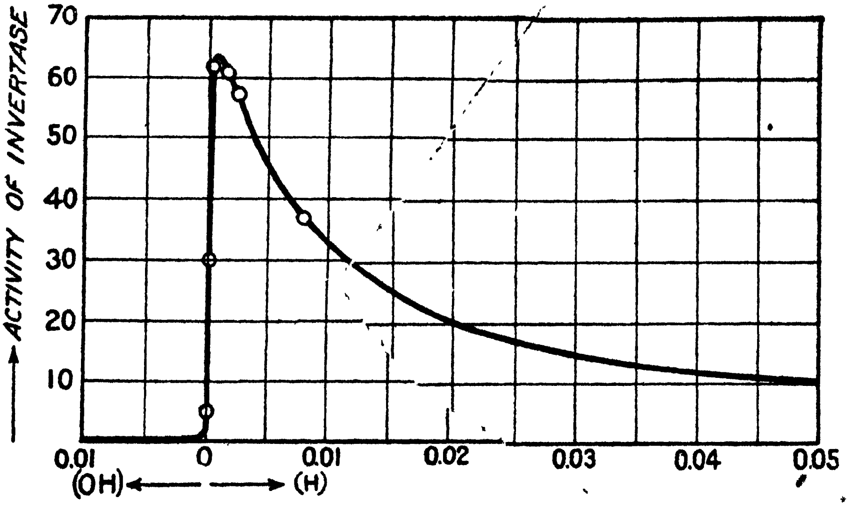
TABLE I.—CALCULATED AND OBSERVED ACTIVITIES OF INVERTASE.

HCl concentration.	Calculated activity	Observed activity.
$(10)^{-8}$ (alkaline)	0.001	0 0
$(10)^{-7}$ (pure water)	0.1	5.0
$(10)^{-6}$	0.9	. . .
$(10)^{-5}$	8.0	. . . .
0.00009	39	30
0 0005	(62)	(62)
0.0015	(61)	(61)
0.002	59	. . . .
0.003	58	58
0.005	45	. . . .
0.008	(37)	(37)
0.01	33	. . . .
0.02	21	. . . .
0.03	15	. . . .
0.05	10	. . . .

By reference to the figure it will be seen that there is a remarkably close agreement between the calculated and observed activities: the calculated values are shown by the smooth curve, the observed activities by the circles. On account of the rapid destruction of invertase at 30° by acid above 0.01 normal the relation can not well be tested beyond that concentration, but it is probable that at 0° such measurements can be made, and this will be attempted in the near future.

---

[1] THIS JOURNAL, 32, 777. In line 7 of the page referred to, the word printed "acidity" should be "activity."



Graph of the formula for the activity of invertase.

The concentration of acid for which the enzymatic activity is a maximum can be calculated from equation (5). Writing its first differential with respect to $(\dot{H})$ equal to zero and solving gives

$$(\dot{H})_{\max} = \sqrt{\frac{K_1 K_w}{K_2}}. \qquad (7)$$

Substituting in this the values previously found for these constants gives $(\dot{H})_{\max} = 0.8(10)^{-3}$ at 30°. Sörensen,[1] from his experiments at 52°, has found this value to be approximately $(10)^{-4}$; our results are thus in fair agreement with his, but they can not be strictly compared because of the different temperatures used, namely, 52° and 32°.

[Contribution from the John Harrison Laboratory of Chemistry.]

METALLIC STRONTIUM.[2]

By Ben L. Glascock.

Received July 23, 1910.

In no case has strontium been obtained in sufficient amount to admit of a thorough study of its properties. The most complete investigation thus far has been that of Guntz and Roederer,[1] who prepared the metal from its hydride, made from the amalgam.

---

[1] *Comptes rendus des travaux du Laboratoire de Carlsberg*, **8**, 132 (1909).

[2] From the author's doctoral thesis, 1909.

The purpose of the present investigation was to develop, if possible, a process or [illegible] metal could be obtained in sufficiently [illegible] study of its properties. The electrolysis [illegible] he most promising solution. It had been [illegible] and Matthiessen and by Stockem and [illegible] could be made in this way. The problem resolved itself, then, into devising an improved or simpler form of apparatus, or a change in the electrical conditions.

The objection to the method of Bunsen and Matthiessen[3] is that with external heat, in addition to that afforded by the passage of the current, it is exceedingly difficult to regulate the temperature of the furnace so that a crust of chilled strontium chloride will always cover the bath in the inner cell. Stockem and Borchers avoided this difficulty by collecting the metal at the bottom of the bath. They found that the metal did not combine with the strontium chloride to such an extent as to render their method a failure. They cooled the bottom of the furnace, however, by means of a water jacket. The furnace of these workers is complicated, necessitating, as it does, the use of heavy insulation between the poles, a threaded point or rod for the cathode, and a water jacket for cooling purposes, all of which rendered the apparatus difficult of construction.

The method of Goodwin[4] for the preparation of calcium suggested itself as a possibility for strontium. To test it, a furnace was constructed by firmly binding together four Acheson graphite blocks by means of four heavy iron straps and bolts. The dimensions of the blocks were 10 cm. × 10 cm. × 30 cm. The two upper blocks had two semicircular sections sawed from them in such a way and of such a size that when they were fitted together they formed two holes 10 cm. deep, one 7.5 cm. in diameter, the other 10 cm. These holes fitted directly over depressions in the lower set of blocks, made by chipping out the graphite. Asbestos paper was put in between the blocks and the whole tightly bound together by means of the straps and bolts. The use of the asbestos was to prevent leaks, not to serve as insulation. The furnace was then connected to the + terminal of the feed wires by means of one of the bolts; thus all four blocks were connected with the current. An iron rod 2 cm. in diameter attached to the ratchet device used in the Goodwin furnace and connected to the — terminal served as the cathode. The circuit carried a 500-ampere ammeter and a 110-volt voltmeter, and a wooden barrel rheostat. The electrodes in the barrel were ordinary slabs of scrap iron, one of which could be lowered or raised by means of a cord passing over a pulley. If such a furnace would serve for the preparation of calcium it would be an improvement over the more or less fragile and complicated furnace of Goodwin, in that it could be taken apart entirely and the chilled calcium chloride left after the run easily removed, and in that it would do away with the use of the water-cooling apparatus, the graphite blocks being massive enough to conduct the heat away as rapidly as the water coil would, and also in that it would do away with the "gravity" cell of his furnace.

[4] THIS JOURNAL, 27, 1403.

To try out the furnace, one of the holes was filled with melted calcium chloride, which had been fused in an iron dish in a wind furnace, the cathode lowered into the bath and the current switched on. Metallic calcium began at once to form on the iron, and rods of the metal as much as twenty inches in length were easily drawn out by means of the ratchet device. Each of the holes or furnaces were tried repeatedly. Each gave the same satisfactory results—they had equal efficiency. By repeated trials with varying current, it was found that about 80 amperes and 40–50 volts gave the best results with this apparatus This, of course, is a matter that is entirely dependent upon the size and depth of the bath. The furnace, when full, contained enough calcium chloride to last six to eight hours with the above current, the yield in metal being in the neighborhood of 300 grams. As the object of these experiments was merely to show whether or not the furnace could be used successfully for calcium, no careful measurements or weights were taken with a view of ascertaining the efficiency of the apparatus. No inconvenience whatever was caused by leakage. Occasionally, however, a superficial lining of calcium fluoride was put into the furnace as an additional safeguard.

The Preparation of Metallic Strontium.

The apparatus described above was used with strontium chloride as the electrolyte, but metallic strontium was never obtained. It was impossible to prevent its burning and its combination with the electrolyte. It would not adhere to the cathode and thus become protected by a layer of strontium chloride, as is calcium in its preparation from calcium chloride. This may be due partly to the fact that it is less stable in the air than calcium is, and partly to the higher temperature of the electrolyte.

A cathode 6 cm. in diameter was substituted for the smaller one, and the current was just sufficient to keep the electrolyte molten. A layer of strontium chloride mixed with a small amount of metal was found to cover the end of the iron. A considerable quantity of hydrogen was evolved when th [illegible] re was thrown into water. Three trials were made with [illegible] ith the same result.

A [illegible] bout 0.3 cm. in diameter, was next tried. The [illegible] hat the intense heat in the immediate vicinity [illegible] cause the liberated metal to fuse into globules [illegible] mitting their removal. After electrolyzing for 4–5 hours, [illegible] urrent sufficient to keep the whole bath molten, the cathode [illegible] removed. No strontium was attached to it, nor were globules of the metal observed on the surface of the bath at any time during the operation. There seemed, however, to be less burning than usual. When the cold mass was broken open, it was found to be full of violet colored spots or nodules. These nodules gave considerable hydrogen when thrown into water. The experiment was repeated several times, but the results were never different.

It was thought perhaps metal could be obtained if the temperature of the electrolyte were lowered. For this purpose baths of strontium chloride with varying amounts of strontium fluoride were used. The cathode was the same as that used for calcium—2 cm. in diameter. When an electrolyte of strontium chloride and 10–20 per cent. of strontium fluoride with a current of 140–150 amperes and 20–30 volts was employed, globules of metal formed and floated about on the surface of the bath. Several of these were taken out, but they ignited at once, burning energetically with an intensely red flame. When the burning metal was thrown on the floor it broke into pieces and flew in all directions, tracing figures, as calcium or antimony does under similar conditions. When the cathode was removed, it was found to be covered with a layer of strontium chloride about 0.6 cm. in thickness, which contained so much metal that pieces of it glowed when struck violently with a hammer, and caused a brisk evolution of hydrogen when thrown into water. If a less powerful current was used, the metal burned as fast as it was formed, and if the current was allowed to fall after the metal began to separate, the globules were seen to glow and to gradually disappear.

When a bath of strontium chloride and about 50 per cent. of strontium fluoride with a current of 125 amperes and 40 volts was employed, it was noticed that small glowing particles were distributed through the mass, and they seemed to fall slowly to the bottom. Upon removing the cold material from the furnace, a thin black layer covered the bottom of it. It contained considerable metal and carbide.

This observation led to the next logical step—a reversal of the poles. This was done by placing a strip of sheet iron between the upper and lower sets of carbon, thus forming, at once, the cathode and the bottom of the furnace. A thick piece of asbestos with a hole in it to fit the furnace was laid over the iron and the whole apparatus bound together as before, after the upper set of blocks ha[illegible] been separated from the iron straps and bolts by thick pieces of asb[illegible] carbon rod 2.5 cm. in diameter served as anode. In other w[illegible]ace of Stockem and Borchers had been arrived at, but in a m[illegible]n.

Using this furnace with the bath last described a[illegible]o amperes and 70–80 volts for three hours, a layer was formed [illegible] which contained considerable metal and carbide. The metal [illegible] in globules. With a bath of strontium chloride and 25 per cent. of stron-tium fluoride and a current of 50–60 amperes and 50–60 volts for four hours a layer was obtained next to the cathode, which, in places, contained so much metal that when it was scratched, the whole took on a metallic luster. This, of course, soon disappeared because of the instability of the metal in air. It decomposed water energetically.

A bath consisting of strontium chloride and 10 per cent. of strontium fluoride was next used. The current was passed for $7^1/_2$ hours. About half the time it registered 150 amperes and 20 volts, the other half 60 amperes and 50 volts.[1] When the cold mass was broken open, it showed globules of metallic strontium. Many of the pieces were as large as a pea. Fourteen grams of the metal were separated. In addition to the metal several nodules of a brilliant yellow substance were found. This was very brittle, and was rather stable in the air; when put into water an energetic evolution of acetylene occurred.

The experiment was repeated, with like results.

An attempt was made to fuse together the pieces of metal that were too small to be separated mechanically. The residue was put into a 2.5 cm. gas pipe, capped at the ends, and placed in a vertical position in a wind furnace. The strontium alloyed with the iron and holes appeared in the cap and pipe, although the temperature was much below that of the melting point of iron.

The preceding experiences having demonstrated that any contrivance for cooling the furnace was unnecessary, it was decided to resort to an even simpler form of apparatus. To this end a cast iron vessel of hemispherical shape 25 cm. in diameter and walls 0.6 cm. in thickness was made to serve as a container. To keep the liberated metal from contact with the air and also to carry out Stockem and Borcher's idea of a small cathode, an iron rod 1.8 cm. in diameter, bent at right angles about two inches from its lower end, and this end then hammered to a blunt point, was made to serve as the cathode. A carbon rod 2.5 cm. in diameter was used as anode. By this arrangement, the current was made to pass entirely beneath the surface of the bath, since the vessel was deep enough to prevent the current passing to it and thence to the other electrode. It also admitted of the use of a porous cell arrangement—Bunsen and Matthiessen's idea.

---

[1] During this electrolysis the carbons of the furnace attained a red heat throughout. This would indicate that a water jacket is entirely unnecessary, since the metal had been obtained under these conditions.

The vessel was filled with fused strontium chloride, the current switched on, and a porous plate interposed. The same bath was used on three different days, connection being established by drawing an arc from the iron cathode upon the anode by means of a thin carbon rod held in the hand until the electrolyte was sufficiently fused to carry the current. During the electrolysis the bath in the vicinity of the cathode was always covered with a crust of chilled chloride. A very small amount of metal was seen to burn, but when the mass was broken up after the third day, only about 1 gram of metal was found.[1]

In the next experiment the dish was made to serve both as container and cathode, the anode remaining the same. Pure strontium chloride was used as the electrolyte. A current of 75 amperes and 75 volts was passed for $3^1/_2$ hours. Fifteen grams of metal were obtained. There was a noticeable decrease in the amount of carbide observed. The globules were larger than heretofore. The mass was re-fused and a current of 75 amperes and 75 volts passed for eight hours. Toward the end of the electrolysis, globules of metal were seen to come to the surface and float to the edge of the dish and either burn there or sink. Efforts to remove these globules were not very successful. When the bottom of the electrolyte was disturbed by scraping it with a rod, large pieces of metal would rise to the surface, showing the presence of considerable strontium.

It was thought that the metal could be made to run into one large piece, if the vessel and its contents were heated in a wind furnace. This was done. The strontium alloyed with the iron, however, produced a large hole in the bottom of the dish. The temperature was far below the melting point of iron. The iron in the vicinity of the hole was very soft, almost plastic, at low red heat. When cold it was hard and brittle, and had a different fracture from cast iron. A small amount of hydrogen was given off when it was boiled with water. Some of the metal was thoroughly washed, dissolved in hydrochloric acid, the solution filtered from the insoluble matter, and sulphuric acid and alcohol added to the filtrate. A heavy precipitate formed at once. Enough strontium was present to give a dense precipitate with sulphuric acid even in the absence of alcohol.

An iron mortar 15 cm. in diameter at the top and 15 cm. high, having a capacity of 1 liter, was substituted for the iron vessel just described. A current of 45 amperes and 75 volts for 8 hours gave about 7 grams of material which contained enough metal to render it malleable. Repeated trials failed to give any better results. The vessel was too small.

---

[1] A very interesting observation was made at this point. When the residue was put into water, preparatory to recovering strontium chloride, a vigorous evolution of acetylene and ammonia took place. The odor of phenyl isocyanide was also detected. The greater portion of the carbon from the anode, however, remained as carbon when the residue was leached out with water.

Another cast iron vessel of the same dimensions as the first one was procured. A carbon anode 8 cm. × 8 cm. was substituted for the smaller one. This large carbon permitted the use of a lower current density at the anode, thus reducing the temperature of the bath. With an electrolyte of pure strontium chloride and a current of 125 amperes and 40 volts for 7 hours, 76 grams of metallic strontium were obtained, giving a current efficiency of 5.3 per cent. One piece of the metal weighed 8 grams and several as much as 3 grams. This was the best yield obtained, but 30 to 50 grams were easily isolated by duplicating the above conditions. In all 360 grams of metallic strontium were made with this apparatus, which is extremely simple and involves the use of no expensive material. It was found that passing the current longer than 6–8 hours decreased the actual yield, the best percentage yield being when a current of 135 amperes and 35 volts was passed for only two hours. 29.5 grams of metal were isolated, or a current efficiency of 6.7 per cent. was attained.

Vessels and anodes of varying size and electrolytes of varying composition were tried out, but the conditions previously mentioned gave the best results.

The best method for separating the metal from the mixture consists in crushing it on an ordinary iron plate, then sieving out the metal.

Some very interesting phenomena and products revealed themselves during the process of recovering the strontium chloride from the melts. When the melt from the pure strontium chloride bath was extracted with water, there remained a residue which was soluble in hot water. Upon cooling this solution crystals separated. They had an alkaline reaction and all the properties of strontium hydroxide.

Upon concentrating the mother liquor from these crystals, it took on a pink color, which grew more intense as the concentration proceeded. The solution was alkaline. On addition of acid the color changed to light yellow. Bases restored the pink color. This product was obtained repeatedly, but never in amounts large enough to permit of the determination of its constitution.

To remove the iron salts from the first water extract, containing most of the strontium chloride, the solution was evaporated to dryness with a small amount of nitric acid and then baked, the residue extracted with water, and the extract made ammoniacal. The ammonium hydroxide instead of giving a red-brown precipitate of ferric hydroxide gave a voluminous white precipitate that resembled aluminium hydroxide.

Examination showed that it was neither an aluminium nor a titanium compound.

When the solution was evaporated to dryness without the addition of nitric acid, a blue tint would often appear around the edges of the residue, suggesting the presence of cyanide in the solution.

Properties of Metallic Strontium.

Strontium is a very light, soft metal of a silver luster when a new surface is first exposed; this, however, rapidly changes to a yellowish tint and finally to a white non-lustrous surface as the layer of oxide forms over it. It is harder than sodium but softer than calcium; it can be cut easily with a knife. It reacts with water, with methyl and ethyl alcohols, acetoacetic and malonic esters, and aniline with the evolution of hydrogen. It reacts slowly with ethyl iodide at the boiling point of the latter. It has no action upon silicon tetrachloride in either the hot or cold condition. It alloys with iron, and seems to combine with amorphous chromium and boron when heated with them. It dissolves very easily in liquid ammonia, giving a deep blue solution from which a dark blue precipitate separates as more metal dissolves. As the ammonia evaporates from this precipitate it passes through the beautiful play of colors that a clean sheet of copper shows as it cools after being heated to a high temperature, finally exhibiting a bright bronze luster and passing into a white compound as all the ammonia evaporates. Strontium burns in an atmosphere of carbon dioxide and illuminating gas as energetically as it does in air, but not so violently as calcium does under similar conditions. Carbon is set free and some carbide is formed when it burns in the former. Hydrogen and nitrogen unite with the heated metal when they are passed over it, forming the hydride and nitride, respectively. The hydride reacts more energetically with water and alcohol than the metal does.

On analysis three different samples of the metal gave the following results:

	I	II.	III.
Insoluble	0.04	0 04	0.92
$Fe_2O_3(Al_2O_3)$	0.14	0.02	
Sr	97 11	98.50	98.54
Ca	...	...	None
Mg	...	...	None
Cl	1.75	...	...
O (by difference)	0.96	...	...
	100.00		

The specific gravity of strontium determined in dry toluene in a 50 cc. pycnometer gave the value 2.55.

The specific heat of the metal, determined in an ordinary water calorimeter, by putting a weighed amount of the metal into an ordinary test tube, covering it with a weighed quantity of dry toluene, and then the tube sealed off as near the surface of the liquid as possible, gave the following results after corrections had been made for the toluene and glass by means of a blank:

$$\left.\begin{array}{l}0.0779\\0.0701\\0.0736\\0.0757\\0.0771\\0.0681\\0.0768\end{array}\right\}\text{average, } 0.0742$$

This value multiplied by the atomic weight of strontium gives 6.5 as Dulong and Petit's constant.

Alloys.

Various alloys of strontium have been described. Willner[1] has made and analyzed alloys of strontium with tin, magnesium and aluminium.

An alloy of iron and strontium has not been mentioned in the literature. Such an alloy made in an accidental way has been noted in the first part of this communication. Hirsch and Aston[2] have shown that pressure is necessary for the alloying of calcium and iron. It was thought that strontium and iron would unite at atmospheric pressure. To test this assumption some iron, reduced by hydrogen (90 per cent.), was put into a hard glass tube, a few pieces of strontium placed on top of it, and the whole covered with iron. The tube was drawn down to a capillary and then sealed off, when the end containing the mixture was heated to low redness. It was then heated in a good blast lamp. When the fusion point of glass was reached the sides of the tube just above the iron fell inward; heat was applied until the glass began to be blown outward. When a bright red heat was reached, portions of the contents were seen to glow. Upon breaking open the tube, a lump of rather hard metallic alloy was found inside. On filing, it presented a bright homogeneous metallic surface; the luster soon disappeared, however. The alloy decomposed water readily. On analysis it gave:

	Per cent.
Insoluble	0.32
Iron	70.14
Strontium	22.95

An alloy was made by fusing iron by hydrogen in the electric furnace and then plunging strontium into the molten mass. A better one, however, was obtained, by plunging the metal into molten cast iron. Each slowly evolved hydrogen from water.

THE RAPID DETERMINATION OF COPPER, SILVER, CADMIUM AND BISMUTH BY MEANS OF THE MERCURY CATHODE AND STATIONARY ANODE.

By R. C. Benner

Received July 11, 1910

In the search for rapid methods in electrochemical analysis, all desire for simplicity seems to have departed. Various means have been used to agitate the electrolyte. The rotation of the anode or cathode by mechanical means, the use of a solenoid, and the passing of a gas through it have all been tried, but not until recently has any one thought that the evolution of the gas by the electrolytic current might stir the electrolyte sufficiently to allow the metals to be deposited in an adherent and weighable form. This has been done by Stoddard,[1] Frary[2] and the author[3] with the gauze electrode, in case of copper. It has been shown qualitatively by Stoddard[4] with the mercury cathode and stationary anode, for copper, silver, etc.

In both cases the current densities are higher than ordinarily used with stationary electrodes. With the gauze electrode of the author's there was used a current density of 10 amperes for every 100 square centimeters, and in case of the mercury cathode made use of in this work, a normal density of 35 to 40 amperes. This proves that the rate of deposition in a weighable form must be due, at least in part, to the stirring of the electrolyte by means of the liberated gas.

Therefore, in order to determine whether the evolution of gas would stir the liquid sufficiently to allow complete deposition to take place rapidly and in a weighable form, higher current densities than had been used before for this purpose, were utilized in carrying out the determination of several metals by means of the mercury cathode and a stationary anode.

In order to avoid all danger of loss by the rapid evolution of gas by high currents, taller electrodes than used by Smith were constructed. When these contained 40 to 50 grams of mercury, they did not overload the balance. The mercury used in these determinations was distilled and purified by the method of Hillebrand each time before using. In each case, after the deposition in question was complete, the mercury was washed with distilled water until the current dropped to zero. The current was then broken, leaving the beaker full of water and the anode examined for small globules of mercury by means of a magnifying glass. Mercury was frequently carried to the anode, either by washing or by the rapid evolution of gas from the cathode but could usually be removed by rinsing the anode up and down in the water contained in the beaker. After the anode had been freed from mercury, the water was either poured or siphoned off and the last part removed by means of a capillary tube. The cathode was then washed with absolute alcohol, the greater portion poured off, the last part being removed by the capillary tube. Finally it was washed with ether, the greater portion poured off and the remainder allowed to evaporate. The electrode was placed in a desiccator for one-half an hour. The removal of the last of the water by means of a siphon with a capillary end makes one washing with alcohol and one with ether sufficient.

[4] *Loc. cit.*

Copper.—Copper, being one of the easiest metals to determine electrolytically, with accuracy, under the most varied conditions, was selected for the preliminary work. To carry out these experiments, two solutions of nitrate were prepared by dissolving weighed amounts of chemically pure copper foil in the smallest possible amount of nitric acid, diluting to a definite volume with water and checking the copper content by electrolysis with platinum electrodes. The two solutions contained respectively 0.3731 and 0.1912 gram of copper in ten cubic centimeters.

The solutions were electrolyzed with currents varying from three to four amperes in 20 cc. of solution, both sulphuric and nitric acid solutions being used.

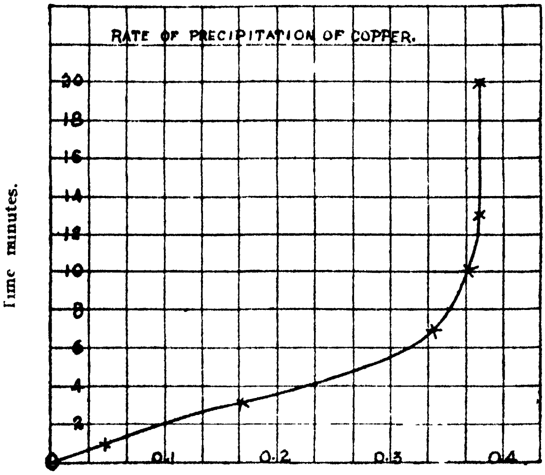
Amount of copper.						
Taken	Found.	Error.	Amperes.	Volts.	Volume of the solution.	Acid, 4 drops
0.3831	0.3835	0.0004	3–4	6–8	20 cc.	H_2SO_4
0.3831	0.3837	0.0006	3–4	6–8	20 cc.	no acid
0.3831	0.3832	0.0001	3–4	6–8	20 cc.	no acid
0.3831	0.3834	0.0003	3–4	6–8	20 cc.	4 drops nitric
0.3831	0.3831	0.0000	3–4	6–8	20 cc.	4 " "
0.1912	0.1919	0.0007	3–4	6–8	20 cc.	4 " "
0.1912	0.1911	0.0001	3–4	6–8	20 cc.	4 " H_2SO_4
0.1912	0.1913	0.0001	3–4	6–8	20 cc.	4 " "
0.1912	0.1906	0.0006	3–4	6–8	20 cc.	no acid
0.1912	0.1910	0.0002	3–4	6–8	20 cc.	no acid
0.1912	0.1912	0.0000	3–4	6–8	20 cc.	no acid

Rate of Precipitation.

In the determination of the rate of precipitation, 20 cubic centimeters of solution were electrolyzed, with a current of four amperes and six to seven volts, in the presence of four drops of concentrated nitric acid.

Time min	Amount of copper.		
	Taken.	Found.	
1	0.3831	0.0535	
3	0.3831	0.1767	
7	0.3831	0.3485	
10	0.3831	0.3782	
15	0.3831	0.3827	
20	0.3831	0.3833	Copper all out.

Examination of the preceding determinations shows that the results were equally good under any of the conditions used, being as accurate as those obtained with the rotating anode and mercury cathode. The precipitation was not as rapid in this case as where the electrolyte was agitated by mechanical means. This was more than compensated for, however, by the simplicity of the apparatus and was not enough slower to be detrimental to the use of this method. It was possible, in 20 minutes, with a current of four amperes, to precipitate 0.3833 gram of copper from 20 cubic centimeters of solution containing four drops of concentrated nitric acid. It has been observed that a black deposit, which was taken to be the peroxide, formed on the anode but redissolved as the electrolysis neared completion. The copper amalgam was washed without delay as soon as the electrolysis was complete, as oxidation takes place readily.



Weights of copper deposited.

Silver.—Silver, as well as copper, is easily and accurately determined by all electrolytic methods. To carry out the experimental work on silver, a solution was prepared by dissolving a weighed amount of chemically pure silver foil in the smallest possible amount of nitric acid and diluting to a definite volume. Ten cubic centimeters of this solution

Silver present.	Silver found.	Error.	Acid	Amperes	Volts.

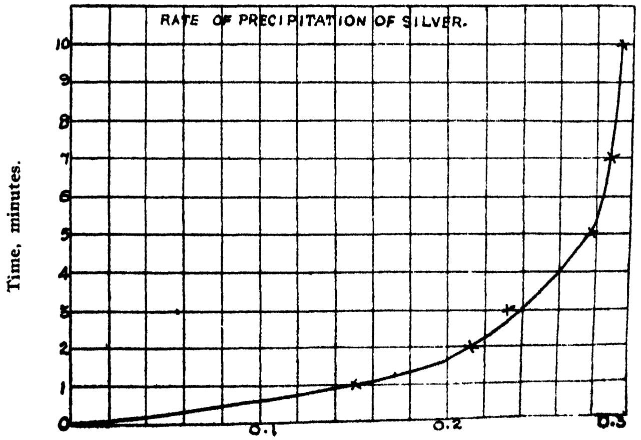
0.2141	0.2147	0.0006	"	3-4	4-5
0.2141	0.2146	0.0005	4 drops H_2SO_4	3-4	4-5

contained 0.1428 gram of silver. The solution was then electrolyzed under the same conditions as copper with the additional trial of several organic acids.

Rate of Precipitation.—In order to determine the rate of precipitation 20 cc. of the solution were electrolyzed with a current of four amperes and six to seven volts in the presence of about one drop of nitric acid.

Time.	Amount of copper taken.	Copper precipitated	
1	0.2856	0.1534	
2	0 2856	0.2167	
3	0.2856	0 2300	
5	0.2856	0 2790	
7	0.2856	0.2841	
10	0.2856	0 2862	Silver all out.

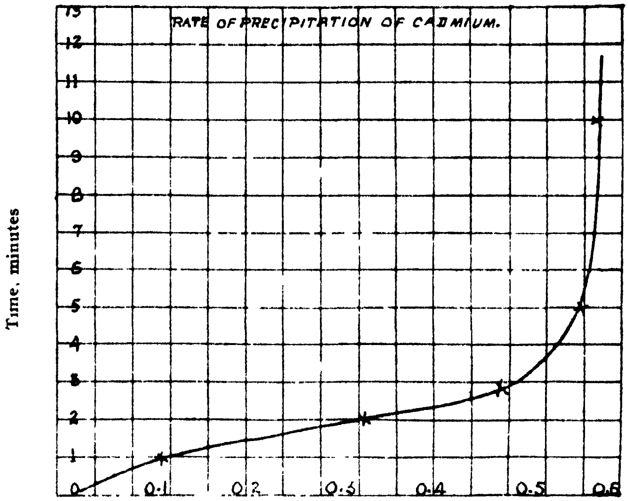
Examination of these results shows them to be comparable in every way with those obtained by means of the rotating anode and mercury cathode. It was possible to deposit 0.2862 gram of silver in ten minutes.



Weights of silver deposited

Large amounts of mineral acids retard the rate of precipitation and give irregular results. All but about one in every ten are low. Citric, tartaric, oxalic and acetic acids were used with results similar to those obtained with large amounts of mineral acids.

Cadmium.—While cadmium has been accurately determined by means of the rotating anode and mercury cathode, it may also be determined by the method used for copper and silver with equally good results. A standard solution was made by dissolving chemically pure cadmium sulphate in water. The cadmium content was found, by the ordinary electrolytic method, to be 0.4828 gram of the metal in 10 cc. This solution was electrolyzed in the usual manner, both hot and cold, with equal success, as will be seen by consulting the following results. It was possible to precipitate 0.5743 gram of the metal in the short period of ten minutes.



Weights of cadmium deposited

Amount of cadmium.							Volume.	
Taken	Found	Error	Amperes	Volts.	Time	Acid.	Temp	Soln
0 4828	0 4821	0.0007	3-4	7-8	15	4 drops HNO_3	hot	20 cc
0 4828	0 4819	0 0009	3-4	7-8	15	"	cold	20 cc.
0 4826	0 4834	0 0006	3-4	7-8	20	no acid	hot	20 cc.

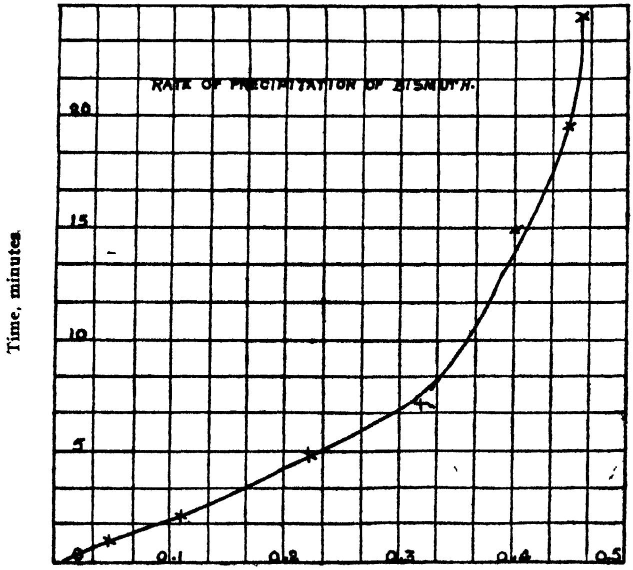
10	0.5743	0.5743	Cadmium all out.

Most methods for the determination of bismuth are far from satisfactory. This is true of most electrolytic, as well as of the common analytical methods. In the electrolytic methods the range of conditions for quantitative deposition of the metal in a weighable form is, as a rule, small, and must be strictly observed to obtain the best results. The best and most consistent results are obtained by the use of the mercury cathode, and rapid deposition may also be obtained by combining this with the rotating anode. In order that the rapid determination of this metal might be tried with the stationary anode and mercury cathode, a standard solution of bismuth was made by dissolving some chemically pure bismuth trioxide in the smallest amount of nitric acid which will hold the bismuth in solution when diluted to one liter with water. The amount of bismuth contained in 10 cc. of the solution was determined by precipitating with ammonium carbonate, igniting and weighing as the oxide. The electrolytic determinations were made under the usual conditions in the presence of varying amounts of acid, both nitric and sulphuric acids being used with equally good results, as will be seen by reference to the following table.



Weights of bismuth deposited.

Bismuth present.	Bismuth found.	Error.	Amperes.	Volts.	Time.	Acid added.
0.4650	0.4647	0.0003	3-4	6-7	20-30	none
0.4650	0.4649	0.0001	3-4	6-7	20-30	"
0.2325	0.2326	0.0001	3-4	6-7	20-30	1 cc. of HNO_3
0.2325	0.2325	0.0000	3-4	6-7	20-30	"
0.2325	0.2331	0.0006	3-4	6-7	20-30	½ cc. of H_2SO_4
0.2325	0.2327	0.0002	3-4	6-7	20-30	½ cc. of H_2SO_4
0.4650	0.4655	0.0005	3-4	6-7	20-30	none
0.4650	0.4658	0.0008	3-4	6-7	20-30	"

The original solution contained 0.85 cc. of concentrated nitric acid to every 10 cc. of solution.

The rate at which bismuth was precipitated was determined with 20 cc. of the solution containing 0.4650 gram of bismuth in the presence of 1.20 cc. of concentrated nitric acid.

Time.		Bismuth taken.	Bismuth found.
1		0.4650	0.0510
3		0.4650	0.1100
5		0.4650	0.2263
7		0.4650	0.3244
10		0.4650	0 3622
15		0.4650	0.4027
20		0.4650	0.4528
25	Bismuth all out.	0.4650	0.4645

During the electrolysis, what was taken to be the peroxide always collected on the anode, but, as in other cases, it always dissolved without any trouble before the determination was complete. The smaller the amount of acid present the more likely this was to form. In one or two cases small amounts of the oxide did not dissolve from the anode where it was rough but the amount was not weighable. A black precipitate of bismuth frequently collected under the anode on the mercury but as the electrolysis proceeded this amalgamated without difficulty. It was possible to precipitate, by means of this method, 0.4659 gram of bismuth in 25 minutes. Taking it all in all, this is as good a method as we have for the determination of bismuth.

Summary.

(1) The apparatus is as simple as any electrolytic apparatus made.

(2) The deposition by this method is nearly as rapid as by the rotating anode and mercury cathode.

(3) The results are as accurate as those obtained by other methods where mercury is used as the cathode.

UNIVERSITY OF ARIZONA, TUCSON.

THE ESTIMATION OF SMALL QUANTITIES OF NITROGEN BY PELOUZE'S REACTION.

BY A. T. DAVENPORT.

Received July 2, 1910.

During some recent work, in which the writer was engaged, it became necessary to estimate very small quantities of nitrogen occurring in the form of nitrates. Various methods for the determination were tried, but none of those which are ordinarily satisfactory, quite supplied the needs in this particular case. Among all the methods tried, that which most nearly fulfilled all the conditions imposed was one in which the following reaction, originally employed by Pelouze, was used:

$$6FeCl_2 + 2KNO_3 + 8HCl = 3Fe_2Cl_6 + 2KCl + 4H_2O + 2NO.$$

More than fifteen different forms of apparatus, employing as many different methods of procedure, have been designed for the analysis of nitrates by the ferrous chloride reduction method. This variety in methods for conducting the analysis is evidence that it is difficult to get a process universally satisfactory, and also evidence that the determination is based on good fundamental principles, and worthy of effort spent to perfect the mechanical operation.

The development of methods has followed two distinct lines. In one direction, speed and ease of manipulation have been sacrificed for accuracy—this trend is illustrated in the extreme by Schlösing's intricate but accurate method of analysis. In the other direction, accuracy has been more or less neglected in an effort to eliminate all awkward operations and time-killing refinements, and here a method devised by P. Wagner easily leads the rest in so far as simplicity is concerned. Wagner collects the evolved nitric oxide over water in graduated cylinders, which are directly compared with a similar cylinder containing nitric oxide from a weighed amount of pure potassium nitrate, and kept, as nearly as possible, under the same conditions. The most generally used of the more refined methods in which high accuracy is maintained is that one worked out by Schultze, and modified by Tiemann. In Schultze-Tiemann's apparatus the liberated nitric oxide is collected in a jacketed burette over caustic soda solution, and the volume corrected to standard conditions according to the regular procedure in gas analysis. In the method to be described below, an effort has been made to combine the good points in Wagner's, and the Schultze-Tiemann methods, and to eliminate as many as possible of the defects.

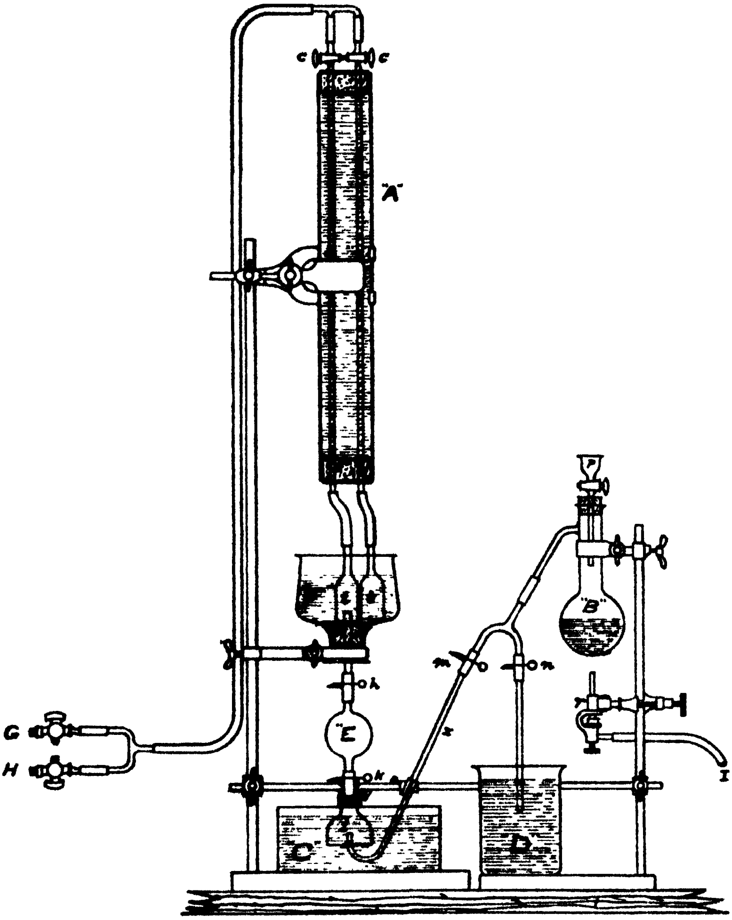
Some of the most important features found in the new method are: measurement of the gas volume over caustic soda solution in a jacketed burette graduated to 1/20 cc., as in the Schultze-Tiemann method, thereby insuring a thorough washing of the gas, and protecting it against sudden and local heating, or cooling, as may occur in Wagner's method. Correction of the gas volume by comparison with a standard volume contained in another burette under identical physical conditions which does away with lengthy calculations employed in the method of Schultze and Tiemann. Besides these features, the apparatus is so designed that it does away with several of the awkward operations belonging to the Schultze-Tiemann method, and thereby, approaches the simplicity of Wagner's procedure.

A description of the apparatus and method of operation is given below.

Details of Operation.

C and *F* are nearly filled with 25–27 per cent. caustic soda solution. By alternately opening pinchcocks *h* and *k* the caustic in *F* is allowed to replace the air in *E* and *l*. The stopcocks *cc* are opened and with a slight vacuum, the burettes are filled with caustic solution from *F*.

Next, 50 cc. of a nitrate solution, of a strength suitable to the capacity



A—Water jacket containing two burettes graduated to 1/20 cc.
B—Distilling flask in which the nitrates are decomposed.
C—Glass dish containing caustic soda solution.
D—Beaker of water to act as a seal.
E—Glass bulb filled with caustic soda for washing and cooling the nitric oxide.
F—Glass basin containing caustic soda from which the burettes are filled.
G—Compressed air
H—Vacuum.
I—Gas.
t, *t* and *l*—Glass bells for collecting gas.
p—A dropping funnel having a capillary stem.

of the burettes, is placed in the flask *B*. The pinchcock *n* is opened, and the gas burner, which is on a movable support *r*, is swung under the flask. When the liquid begins to boil, the flame is swung from under the flask, and *n* closed while *m* is opened to allow caustic from *C* to rise by suction in the outlet tube *x*, as far as the fork. Then *m* is closed, and the heating of *B* continued. As soon as pressure begins to develop in the flask, as shown by the inflation of the rubber connections, *n* is opened and all the air in *B* boiled out through the water in *D*.

Next, the flame is removed from under the flask, and *n* closed. As soon as a vacuum begins to form, 15 cc. each of concentrated ferrous chloride solution, and concentrated hydrochloric acid are introduced through the dropping funnel *p*, care being taken to close the stopcock before any air can rush through. The heating of *B* is renewed, and as soon as a slight pressure forms, the pinchcocks *m* and *k* are opened, when the liberated nitric oxide passes over and collects in *E*, where it is cooled and washed. After all the gas has passed over as shown by a cessation of bubbles, a partial vacuum is again formed in the flask, and the small amount of gas dissolved in the excess of ferrous chloride is extracted by the suction—upon reheating this residue of gas is driven over into *E*.

Next, one of the glass bells *t* is placed over the outlet from *E*, and pinchcock *k* closed, and *h* opened, when the gas passes up into the burette.

After standing for three minutes, the volume of the gas is noted. A standard nitrate solution is made by dissolving 1 gram of pure potassium nitrate in 250 cc. of distilled water. Under the conditions of the test one cc. of the standard solution gives practically 1 cc. of gas, so in case we have 10 cc. of gas in the above operation, 10 cc. of the standard solution are decomposed according to the above procedure, and the gas passed into the other burette for direct comparison with the neighboring gas volume.

At the completion of an analysis the stopcock *c* is opened, and compressed air carefully bubbled through *F*, when the burette is quickly swept free from nitric oxide.

A determination can be made in ten minutes, and the results of consecutive analyses agree very well as can be seen from the following table:

Analysis showed—

10 cc of solution to be equivalent to

10.55 cc. of NO, or	8.81 cc. of NO at 0° and 760 mm
10.60	8.85
10.60	8.85
10.50	8.77
10.65	8.89
10.60	8.85
10.70	8.93
10.65	8.89
10.61 Average	**8.86 Average**

Solutions of pure potassium nitrate were used, 1 gram of potassium nitrate in 250 cc. of water at 20°. Ten cubic centimeters of this solution are equivalent to 8.86 cc. of nitric oxide at 0° and 760 mm.

Considering the average volume 10.61 cc. of NO as being equivalent to 8.86 cc. of NO at 0° and 760 mm. the factor 0.835 was deduced with which the column of corrected volumes was obtained.

If there is a doubt as to whether the nitrate used for standard is pure, or whether all the gas is being driven over it is a simple matter to transfer the gas to a Hempel burette, and measure it under atmospheric pressure.

The direct comparison of gas volumes not only simplifies calculations, but also introduces the safeguards of a duplicate test against error.

The method of analysis has been in use at this laboratory for more than a year, and the article is published with permission of the E. I. du Pont de Nemours Powder Co.

THE ANALYSIS OF TIN-ANTIMONY ALLOYS.

BY LEROY W MCCAY.

Received August 9, 1910

The fact that hydrogen sulphide precipitates the antimony only from a dilute hydrofluoric acid solution containing tin in the higher and antimony in the lower stage of oxidation serves as an excellent means for the quantitative separation of these two elements.[1] If the solution be a hydrochloric or sulphuric acid one, the addition of hydrofluoric acid converts the metals into their fluorides, and the solution can then be diluted indefinitely without becoming turbid. The mixture of stannic sulphide, antimonious and antimonic sulphides and free sulphur obtained in the regular course of analysis was, until recently,[2] always dissolved in warm concentrated hydrochloric acid in a small platinum dish, hydrofluoric acid added, the solution filtered into a large platinum dish holding about 500 cc., and from the diluted solution the antimony precipitated in the cold with hydrogen sulphide as antimonious sulphide. The objection, however, to this method of dissolving the tin and antimony sulphides is that the accompanying sulphur, along with that which separates from the pentasulphide, forms, or seems to form, a protecting coating about some of the antimonious sulphide, so that it remains unattacked by the hydrochloric acid. Even after two extractions with the warm, concentrated acid antimony can generally be detected in the sulphur.

---

[1] THIS JOURNAL, 31, 373 (1909).

[2] The neutralization of the solution with sodium hydroxide and the addition to it, after introducing the hydrofluoric acid, of an excess of sodium acetate has proved unnecessary. See original paper, *loc. cit.*

If the treatment of the sulphides with the acid be carried out in a small flask attached to a reflux condenser, the reaction is soon complete, for here the acid can be boiled and kept boiling without there being any danger of antimonious chloride escaping. However, such a method for bringing the antimony into solution is far too tedious. The difficulty is avoided if concentrated sulphuric acid heated to strong fuming be employed as the solvent. The reaction goes on smoothly and rapidly, and is complete in from twenty to thirty minutes. The tin is converted into stannic, the antimony into antimonious sulphate. During the reaction, sulphur dioxide escapes along with the fumes of sulphur trioxide, and considerable sulphur volatilizes, a part of which condenses upon the clock-glass covering the dish in which the solution is made. The sulphur which remains is in the form of yellow or brown globules. I have tested it again and again for antimony, but have never found that it contained more than a trace. In each case the washed globules were dried and rubbed to a fine powder in an agate mortar, the mass was extracted with warm, concentrated hydrochloric acid, the solution filtered and hydrogen sulphide passed into the filtrate. Some attempts made to determine the antimony colorimetrically go to show that it never amounts to a tenth of a milligram. When the solution of the sulphates as above obtained is cool, it, together with the sulphur, is transferred to a small platinum dish with a minimum amount of water, the hydrofluoric acid added, the liquid heated, cooled, diluted and filtered (paraffined funnel) into the large platinum dish where the precipitation of the antimony with hydrogen sulphide is made. A platinum or paraffined glass tube is used for introducing the gas into the solution. The antimonious sulphide precipitated from a sulphuric acid solution containing hydrofluoric acid is pure, barring a trace of sulphur which can be rapidly and completely extracted with a mixture of equal parts of absolute alcohol and carbon disulphide.[1] Dried at 110° it is free from water, nor does it after such drying suffer any loss when heated to blackness in a current of carbon dioxide. The sulphide is not absolutely insoluble in the liquid from which it is thrown down. The solubility, however, is very small, and can in most cases be neglected. Some experiments made with Kahlbaum's purest antimony indicate that the filtrates from the sulphide contain on an average 0.0004 gram antimony.[2] The solubility seems to increase with the quantity of hydrofluoric acid employed. When just enough of the latter (8–10 drops of a 48 per cent. solution) is added to prevent hydrolysis, the precipitation of the antimony by hydrogen sulphide is complete.[1] The sulphide is best collected in a Neubauer crucible and washed with water saturated with hydrogen sulphide and strongly acidified with acetic acid. The filtrate is evaporated in platinum on the sand bath, heated to fuming, and the thick liquid poured into a liter of water:

---

[1] Thiele, *Z anal Chem.*, 30, 479

[2] The volume of the solution from which the antimony was in each case precipitated amounted to roughly 450 cc. The solution contained 8–10 cc. concentrated sulphuric acid and 5 cc. hydrofluoric acid.

$$Sn(SO_4)_2 + 4H_2O = H_4SnO_4 + 2H_2SO_4.$$

Before weighing, the stannic oxide should be strongly ignited in the presence of ammonium carbonate.

Concentrated sulphuric acid heated to fuming or, if necessary, to boiling is also admirably adapted for decomposing the alloys of tin and antimony. Unless the amount of lead in such an alloy be very great it remains behind as pure lead sulphate which, after diluting the solution somewhat, adding hydrofluoric acid and then water and alcohol, can be filtered off, washed, dried and weighed. The advantage of separating and determining the lead at this stage of the analysis, and in such a simple manner, will be evident to all familiar with the difficulties ordinarily encountered in separating lead from antimony. The filtrate is caught in a paraffined beaker, one of ceresin,[2] or in the large platinum dish placed under a bell-jar resting on a ground-glass plate, and furnished with the necessary adjustments for filtering by suction. The hot sulphuric acid converts the tin into stannic, the antimony into antimonious sulphate. The alloy should be in the form of filings or very fine borings, and the treatment with the acid carried out in a covered porcelain or quartz dish, heated on the sand bath. Half an hour after the acid commences to fume strongly the decomposition is ordinarily complete, and the contents of the dish are then transferred to one of platinum in which 5 cc. of hydrofluoric acid[3] diluted with 20 cc. of water have been placed. The stannic and antimonious sulphates are converted into fluorides, while the lead sulphate remains undissolved. When hard leads and type metal containing over 50 per cent. of lead are treated in this way the resulting lead sulphate is apt to be gray and contain several milligrams of antimony. In such a case the lead sulphate should, after drying, be mixed with six times its weight of a mixture of equal parts of sulphur and sodium carbonate, and fused in a covered porcelain crucible at a barely red heat for fifteen minutes. In making this fusion I find it best to use a small burner flame about 5 cm. long. The ring carrying the triangle and crucible is lowered until the tip of the flame not only touches

[1] This observation and the fact that the antimonious sulphide when dry is free from all foreign matter have led me to undertake a revision of the determination of the equivalent of antimony.

[2] Baker Chem. Co , Phillipsburg, N. J.

[3] The amount of hydrofluoric acid necessary will depend, of course, on the quantities of tin and antimony present. For all of the alloys which I have thus far examined 5 cc. of the 48 per cent. acid have proved sufficient.

the bottom of the crucible but spreads out so as to lick the sides to some extent. The mixture of sulphur and antimony sulphides obtained by acidifying the sulpho-salt solution is dried, dissolved in a small amount of hot, concentrated sulphuric acid, diluted somewhat, a little hydrofluoric acid added (small platinum dish), and the filtrate from the sulphur combined with the main tin and antimony solution. The lead sulphide is then converted into the sulphate and weighed as such.

Hydrogen sulphide precipitates from the filtrate from the lead sulphate not only the antimony but any copper which may be present.[1] Their separation is best effected with colorless sodium sulphide or hydrosulphide. Mr. G. W. Thompson uses for this purpose a concentrated solution of potassium hydroxide. Although I prefer the colorless sodium sulphide as a solvent for the antimonious sulphide, the method of Mr. Thompson has given me very satisfactory results. The cupric sulphide can be dissolved in nitric acid and the copper determined electrolytically. To determine the antimony I collect the precipitate from the sulpho-salt solution in a Gooch crucible and heat it to blackness in a current of carbon dioxide. The operation is conducted as follows: The crucible with its contents is placed in a ring on the end of a platinum wire and lowered to the bottom of a large test tube of hard glass. The test tube which is 25 cm. long and 4.2 cm. internal diameter, is clamped at an angle of 45°, so that the lower end is about 35 cm. above the top of the table, and closed with a doubly perforated rubber stopper carrying two tubes. The one through which the carbon dioxide is introduced passes through the center of the stopper and is shoved down until the end is just opposite the mouth of the crucible; the lower end of the other tube, which is short, is flush with the stopper, and simply serves for the escape of the gas. When all the air in the test tube has been displaced by carbon dioxide, the upper part of the full flame of a Bunsen burner is moved briskly around and in contact with the bottom of the tube, and in from fifteen to twenty minutes all the sulphur is driven off. During the operation, I have never noticed the volatilization of any antimonious sulphide due to overheating. The apparatus is exceedingly simple, and the results obtained with it leave little to be desired. The crucible should cool in the current of carbon dioxide. To remove the crucible without having it come in contact with the condensed sulphur, slip a piece of glazed paper down the tube and draw the crucible up over it.[2]

The filtrate from the antimonious and cupric sulphides is heated in a platinum dish on the sand bath, and when the water and most of the hydrofluoric acid have evaporated, the remaining liquid is heated more strongly until sulphuric anhydride fumes are given off freely. When the solution has cooled it is poured at once into an excess of water. The hydrolysis of the stannic sulphate can be hastened by neutralizing most of the free acid with ammonia water and heating the solution to boiling. Equally good results can be obtained by precipitating the tin as stannic sulphide and converting this into the oxide by roasting, or by transforming the sulphate into the double oxalate of tin and ammonium and determining the metal electrolytically according to Classen's method.

---

[1] Bismuth, cadmium and arsenic(ous) are also precipitated. Since the alloys thus far examined by me contain no bismuth or cadmium, and only traces of arsenic, the separation and determination of these elements have not been considered.

[2] Henz, *Z. anorg. Chem.*, 37, 11 (1903).

Since I have received a number of letters requesting information as to the details of the general scheme observed by me in applying this hydrofluoric method to the analysis of tin-antimony alloys, I would say that the following course of procedure will be found satisfactory in most cases. If the directions given are in places not sufficiently full and clear, the reader is referred to the preceding pages.

Place from 0.5–1.0 gram of the alloy, preferably in the form of filings or fine borings, in a quartz or porcelain dish, cover the dish with a clock-glass, and introduce through the lip 10 cc. of concentrated sulphuric acid. Place the dish on the sand bath, heat it rapidly until fumes of sulphuric anhydride begin to escape, and continue the heating for about half an hour. If at the end of this time the solution is clear, and the underlying lead sulphate pure white, remove the dish from the bath, let it cool, and transfer its contents at once to a platinum dish of 250 cc. capacity containing 5 cc. 48 per cent. hydrofluoric acid and 20 cc. of water. Use a rubber-tipped rod and the least possible amount of water for removing the lead sulphate adhering to the porcelain dish. Heat the solution to boiling, stirring all the time with a platinum spatula to prevent bumping. Dilute to 150 cc., cool, add 50 cc. of 95 per cent. alcohol, stir, and let the lead sulphate settle. Collect the lead sulphate in a Neubauer crucible, or on a filter paper fitted in a paraffined funnel, wash thoroughly with water containing one-fourth its volume of alcohol and a little sulphuric acid, dry, ignite, and weigh. If the Neubauer crucible is used, place it in a larger one of porcelain and then ignite. When the alloy contains more than 50 per cent. of lead the sulphate is apt to be gray and contain antimony. In such a case the sulphate should be fused with soda and sulphur according to the directions already given. The filtrate from the lead sulphate, as above obtained, is caught in the large platinum dish placed under the bell-jar provided with the various adjustments for filtering by suction. To avoid splashing it will be found well to cover the dish with a paraffined clock-glass with a hole in the center, through which the end of the stem of the funnel or crucible support is passed. Dilute the filtrate to about 450 cc. and introduce the hydrogen sulphide through a platinum or paraffined tube which is suspended above the center of the dish and lowered until the end in the solution is a centimeter above the bottom of the dish. Let a rapid current of the gas pass through the solution for one hour. Permit the precipitate to subside, filter and wash with water containing acetic acid and saturated with hydrogen sulphide. Suck the precipitate as dry as possible, unfold the filter paper and spread it out in a shallow porcelain dish, add some colorless moderately concentrated sodium sulphide, cover with a clock-glass, and place on the water bath. Add water, filter off the clear fluid, treat the residue again with sodium sulphide, digest a short time, repeat the same operation a third time, bring the residue onto the filter, and wash it with water containing a little sodium sulphide. Dissolve the cupric sulphide in nitric acid and determine the copper electrolytically. Collect the precipitate obtained by acidifying the sulpho-salt solution with sulphuric acid in a Gooch crucible, wash it with water containing hydrogen sulphide, dry and heat it to blackness in a current of carbon dioxide in the apparatus described. The tin in the filtrate from the cupric and antimonious sulphides can be determined according to any one of the three methods mentioned above.

Personally, I prefer to throw down the tin in the form of stannic acid by pouring the thick sulphuric acid solution into an excess of water. The stannic acid so obtained is very pure, barring a little sulphuric acid which, however, is readily expelled by igniting the stannic oxide in the presence of ammonium carbonate.

Mr. G. W. Thompson, of the National Lead Co., has very kindly sent me two alloys which I have analyzed according to the above scheme. Mr. Thompson has also given me the formulas according to which the alloys were prepared, and furnished me the analyses. His process for separating tin from antimony is a modification of the Clarke method.[1] Alloy 2 was also examined by one of our fellows, Mr. H. E. Rankin, who analyzed it according to both the Thompson and hydrofluoric acid methods.

Alloy 1.—Samples taken at random from various parts of the bottle did not give me sufficiently constant results, so I took from the bottom of the mass about five grams which, since the alloy is quite brittle, I ground to a fine powder in an agate mortar. This powder was employed in making the analyses. My results, along with those reported, are given in the following table.

I did not examine the alloy for arsenic. In each case the amount of lead sulphate obtained was too small to weigh. This alloy does not seem to be homogeneous in composition.

---

	100	100.04	100.19	99.94	99.98

No attempts were made to determine the arsenic. The alloy is undoubtedly very homogeneous in composition.

The fact that this method for separating tin from antimony involves the use of a platinum dish holding 500 cc. militates seriously against its general use.[1] I have recently found that the analysis of an alloy can be made in glass vessels, provided one possesses a platinum dish holding 250 cc. in which the lead sulphate can be separated from the tin and antimony with the rather concentrated hydrofluoric acid, and the filtrate from the cupric and antimonious sulphides evaporated to fuming in order to expel the acid. The hydrofluoric acid solutions are so dilute during the other operations that they have little action on good glass, and the salts formed all remain in solution provided one works rapidly. The solution left on evaporating in platinum the filtrate from the cupric and antimonious sulphides contains a little calcium sulphate and possibly some silica; but on diluting the solution the former dissolves and the latter can, if necessary, be filtered off. Of course, the dilution should not be too great, nor should the diluted liquid be heated prior to filtration, for hydrolysis might take place and some stannic acid separate out. I have analyzed both alloys, using an ordinary 250 cc. platinum dish, and Jena beakers, with the following results:

Now these results are fully as good as those obtained by working entirely in platinum. In closing I would say that by first treating alloys very high in lead with dilute nitric acid, evaporating, and then adding concentrated sulphuric acid and heating to fuming, the alloys appear to be completely decomposed. Whether in the presence of such large amounts of lead sulphate 5 cc. of 48 per cent. hydrofluoric acid are sufficient to transform all the accompanying stannic and antimonious sulphates into fluorides remains to be seen. Any antimonic acid formed by the nitric acid can be reduced to antimonious oxide by sprinkling some sulphur over the concentrated sulphuric acid, after all the nitric acid has been expelled, and again heating to strong fuming for about fifteen minutes. The reduction is of course effected by the sulphur dioxide formed.

THE DETERMINATION OF INDIUM WITH THE USE OF A MERCURY CATHODE.

BY LILY G. KOLLOCK AND EDGAR F. SMITH.

Received July 23, 1910.

Thiel[1] recommends the use of a silver-plated platinum cathode for the deposition of metallic indium. Dennis and Greer[2] found that this metal may be readily precipitated on a rotating platinum dish cathode from solutions of its chloride or nitrate in the presence of pyridine, hydroxylamine or formic acid.

The purpose of the present communication is to offer the results obtained in the electro-analytical behavior of indium toward a mercury cathode.

A solution of indium sulphate (10.15 grams of metal in 500 cc.) containing a small amount of free acid was the electrolyte. A mercury cup of the usual form was employed.[3] The method followed and precautions taken were identical with those described in the determination of other metals with the same apparatus.

With a total dilution of 10 cc., a current varying from 2 to 4 amperes, an e. m. f. of 7.5 to 6.5 volts, and an anode rotating 750 times per minute, the following results were obtained:

0.1013, 0.1008, 0.1010, 0.1013, 0.1011, 0.1010, 0.1011, 0.1011 gram

---

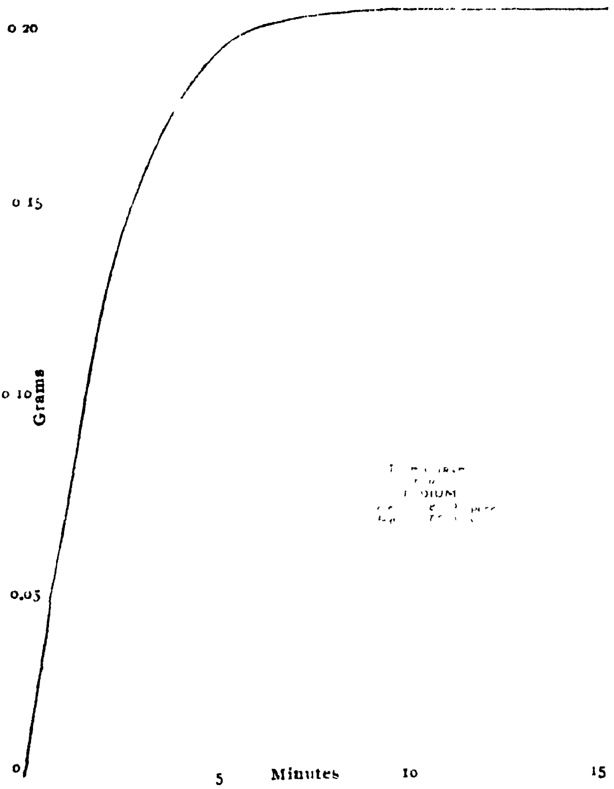
[2] *Ber.*, 37, 75; THIS JOURNAL, 26, 438.

[3] Smith's *Electro-analysis*, p. 58, 4th Ed.

The time for actual electrolysis was 15 minutes. Doubling the quantity of solution also gave concordant results after 18 minutes' action of the current:

0.2021, 0.2021, 0.2020, 0.2021, 0.2019, 0.2021 gram



The accompanying time curve was made under the following conditions:

Vol. of sol	10 cc.
Indium present	0.2020 gram
Current strength	2.5 amperes
E. m. f.	7.5–5.5 volts
R. p. m. of anode	750

Dr. John Frazer, of this Laboratory, conducted a number of determinations of indium, using a platinum cathode with a platinum spiral anode, rotating 250 to 400 times per minute. In the presence of 0.1 cc. of concentrated sulphuric acid and a few drops of gelatin a beautiful, adherent deposit of indium was obtained with a current of N. D_{100} = 3 amperes and a pressure of from 4.5 to 5 volts. The precipitation was complete in twenty-five minutes.

A potassium cyanide electrolyte proved satisfactory; while in the presence of 2 grams of sodium acetate, 0.2 cc. of normal acetic acid and several drops of gelatin, a current of 5.6 amperes and 4 volts deposited the metal in a beautiful, adherent form in forty minutes. The temperature of the electrolyte was maintained at 60°. The most satisfactory deposits of this metal were obtained, however, from an electrolyte containing from 0.75 gram to 1.5 grams of Rochelle salt. They were brilliant in appearance and perfectly adherent. They resembled such coatings as are produced by fresh aluminium paint. They were preserved without alteration or loss of luster.

UNIVERSITY OF PENNSYLVANIA

[CONTRIBUTIONS FROM THE HAVEMEYER LABORATORIES, COLUMBIA UNIVERSITY, No. 180.]

A NEW VOLUMETRIC METHOD FOR THE DETERMINATION OF MANGANESE.

BY F J METZGER AND ROBERT F MCCRACKAN

Received July 20, 1910

In a previous number of THIS JOURNAL[1] mention was made of the fact that manganese, in sulphuric acid solution, was oxidized to the quadrivalent form by means of sodium bismuthate, and that the manganese remained in solution in this state of oxidation. It is the purpose of this paper to describe a method based on the above principle whereby the manganese may be accurately determined.

Solutions Used.—A 0.1 *N* potassium permanganate solution, and a solution of ferrous sulphate of about equivalent strength. A solution of manganous sulphate was prepared and carefully standardized gravimetrically by weighing as pyrophosphate.

Method.—Place 50 cc. of the standard manganese solution in a 300 cc. Erlenmeyer flask, add 10–15 cc. of concentrated sulphuric acid and allow to cool. Add 1–2 grams of finely powdered sodium bismuthate in such a way that none of the powder sticks to the sides of the flask. Place the flask in a beaker of water so that the level of the solution is several inches below the level of the water in the beaker. Heat slowly to boiling and boil till the precipitate of basic bismuth compound settles well and has a granular appearance (about 20 minutes' boiling is usually necessary). Remove the flask and cool under running water, add a known excess of ferrous sulphate solution, dilute to about 200 cc. and titrate back with standard permanganate solution.

---

[1] Metzger and Heidelberger, THIS JOURNAL, 32, 643.

The manganese standard of the permanganate is calculated from the reaction which may be represented thus:

$$Mn^{++++} + 2Fe^{++} \longrightarrow Mn^{++} + 2Fe^{+++}.$$

Or the value of the permanganate in terms of iron multiplied by 0.4918 gives the value in terms of manganese.

The following table of results will give an idea of the accuracy of the method:

No.	Mn taken.	Mn. found	Error.
1	0.0981	0.0979	−0.0002
2	0.0981	0.0975	−0.0006
3	0.0981	0.0973	−0.0008
4	0.0981	0.0974	−0.0007
5	0.0981	0.0980	0.0001
6	0.0981	0.0981	±0.0000

The method is quite rapid and the end point is sharp and distinct, being the usual pink color in a solution containing a white precipitate. The application of the method to the analysis of spiegel and manganese ores is now under way, and we hope to work out a method which will be rapid and accurate and not possess the disadvantages inherent in the Volhard method.

QUANTITATIVE LABORATORY

THE USE OF ORGANIC ELECTROLYTES IN CADMIUM SEPARATION.

BY MARY E HOLMES AND MARY V DOVER

Received August 1, 1910.

In a previous paper[1] it was shown that currents below one ampere possess undoubted advantages for electrolytic separations when the rotating anode is employed, that study was concerned with the separation of cadmium from the metals of Groups III and IV and from magnesium at currents of 0.3-0.4 ampere, using the sulphuric acid and also the acetate electrolyte, and comparing the results obtained with those of other investigators working at high currents. It was clear that the possibilities of work in the line of electrolytic separations were almost limitless and that the work on cadmium alone called for a much more extended investigation, using other metals and a greater variety of electrolytes.

The present work was undertaken in order to test further the usefulness of low currents in cadmium separations. The alkaline earth metals were used and the acetate, formate, and lactate electrolytes. Corresponding separations were made with both low and high currents (*i. e.*, five amperes), but in no case did the high currents prove desirable. Whether cadmium was used alone or in presence of other metals, the deposits were dark in color, spongy, not adherent, difficult to dry, and in most cases very evidently not worth weighing. Whenever they were weighed, the results were very high. In the case of low currents, however, interesting and accurate results were obtained, though the deposits varied considerably in character and in accuracy with the different electrolytes employed.

---

[1] THIS JOURNAL, 30, 1865.

During this work it has been evident that each variety of ion present in the solution exerts a very definite influence on the deposit. The presence of two kinds of ions in a solution may produce a decidedly different deposit from that obtained by the influence of either ion alone. For instance, in the previous work conducted with cadmium sulphate solutions with the sulphuric acid electrolyte, smooth adherent deposits of fine crystalline structure were obtained. The deposits from a cadmium sulphate solution using the acetate electrolyte were more coarsely crystalline, and if another metal were present, *e. g.*, aluminium, the crystals tended to sponginess and therefore to occlusion of the mother liquor, unless carefully washed with hot water. These same conditions were observed when a cadmium acetate solution was used with the acetate electrolyte, so that in general it may be said that the sulphate ion aids in forming a finely crystalline, compact deposit, while the acetate ion causes the deposit to be more coarsely crystalline with a tendency to sponginess. The presence of the sulphate ion always seems to improve the character of a deposit, no matter what other ion may be present.

As in the previous work, a platinum dish of about 200 cc. capacity was employed as the cathode, but as a dish anode was not available, the ordinary spiral anode was used, the time required being not much more than is necessary with the dish anode, *i. e.*, forty-five minutes to one hour. It is possible that the dish anode may produce firmer deposits, but certainly the spiral anode has proved to be very useful in such cases. Solutions of cadmium salts containing not more than 0.2 gram of cadmium metal in 10 cc. were used.

I. The Acetate Electrolyte.[1]

The acetate electrolyte was first suggested since it was impossible to use the sulphuric acid electrolyte with all the alkaline earth metals. To 10 cc. of cadmium acetate solution, 2 grams of ammonium acetate and 1 cc. of acetic acid were added, the solution diluted to about 125 cc., heated to the boiling point, and electrolyzed for one hour, using 0.3 ampere and 2.4–3 volts. As a result, 0.1744 gram of cadmium was repeatedly deposited and the remaining solution showed no test for cadmium when treated with hydrogen sulphide. Then a series of separations was made of cadmium from the alkaline earth metals under the same conditions. About 0.2 gram of metal was represented by the amounts of calcium, strontium, and barium acetate solutions used. Two separations from calcium gave 0.1744 gram of cadmium, two from strontium, 0.1742 gram and 0.1744 gram respectively, and one from barium 0.1746 gram. Another separation was tried from a mixture of all three metals, calcium, strontium, and barium, the cadmium obtained weighing, as before, 0.1746 gram.

---

[1] This Journal, 27, 1275.

Owing to the fact that calcium sulphate is comparatively easily soluble, it was found that the separation of cadmium from calcium is possible, using a cadmium sulphate solution with an acetate electrolyte. Better results were obtained, however, when the free acid was omitted from the electrolyte. To 10 cc. of a cadmium sulphate solution, 2 grams of ammonium acetate were added, the solution diluted as usual, and after heating to the boiling point, electrolyzed, using 0.3 ampere and 2.5–3 volts for one hour. In two successive determinations, 0.1968 gram and 0.1970 gram were deposited, no test for cadmium being obtained in the solution. When 1 gram of calcium acetate was added to 10 cc. of the same cadmium sulphate solution and electrolyzed under the same conditions, 0.1968 gram of cadmium was obtained. These deposits were very satisfactory, clean and smooth, with few crystals of any size, easily washed and dried, showing the valuable influence of the presence of the sulphate ion. The character of the deposit was not changed by the presence of calcium. Determinations corresponding to these were made, using as electrolyte 1 cc. of acetic acid in addition to the 2 grams of ammonium acetate. The character of the deposits was almost as good as in the other cases, but the weights were low. From the cadmium sulphate solution alone, only 0.1958 gram and 0.1956 gram were deposited in two successive trials instead of 0.1968 gram. In presence of 1 gram of calcium acetate, 0.1960 gram and 0.1962 gram were obtained. The solutions all gave slight tests for cadmium with hydrogen sulphide. Hence it was concluded that in these cases the free acid hindered the complete precipitation of the cadmium. Similar trials were made, using the cadmium sulphate solution with strontium and barium acetates, but as was to be expected, precipitates of strontium and barium sulphates interfered with the work.

II. The Formate Electrolyte.[1]

The effect of the formate electrolyte was next investigated Conditions were first determined for the complete deposition of cadmium from a cadmium formate solution; then the separation of cadmium from calcium, strontium, and barium was effected, using the formates of these metals. The electrolyte used was ammonium formate in presence of formic acid. With 10 cc. of the cadmium formate solution were mixed 2 grams of ammonium formate and 1 cc. of formic acid, the solution diluted as usual, heated to the boiling point, and electrolyzed for forty-five minutes, using 0.3 ampere and 1–2 volts. In one trial, 0.1942 gram of cadmium was deposited and again, 0.1944 gram. In presence of 1 gram of calcium formate, under the same conditions, 0.1944 gram of cadmium was obtained. Using 1 gram strontium formate, the deposit weighed 0.1946 gram, and with 1 gram barium formate, 0.1946 gram. In all these cases, no other ion was present except the formate ion, so that the character of the deposits was due entirely to that ion. Whereas the deposits were crystalline and adherent and of good color, and the weights obtained were concordant, very careful washing was necessary, particularly when the alkaline earth metals were present. The results on the whole were better than when the acetate electrolyte was used alone.

---

[1] THIS JOURNAL, 27, 1275.

When cadmium sulphate solution was used, however, with the formate electrolyte, very excellent deposits were obtained, showing again the influence of the sulphate ion. To 10 cc. of the same cadmium sulphate solution (containing 0.1968 gram of cadmium metal in 10 cc.) were added 2 grams of ammonium formate and 0.5 cc. of formic acid. After diluting and heating to the boiling point, the solution was electrolyzed for one hour, using 0.3 ampere and 0.8–1 volt. A deposit was obtained weighing 0.1968 gram. In another trial 0.1970 gram of cadmium was obtained. Upon the addition of 1 gram of calcium formate, using similar conditions, 0.1968 gram of cadmium again came down. The deposit seemed not to be altered in any way by the presence of calcium. Some free acid was found necessary in all these determinations, as cadmium formate is somewhat difficultly soluble; and if a formate is used alone as electrolyte, a white precipitate of cadmium formate interferes with the work.

A third series was made using cadmium acetate as a starting point with the formate electrolyte. From 10 cc. of a cadmium acetate solution, it was found that the cadmium could be fully deposited in forty-five minutes, using 0.3 ampere and 0.8–1 volt, the electrolyte being as before 2 grams of ammonium formate and 0.5 cc. of formic acid. The deposit weighed 0.1760 gram. Mixed with 1 gram of calcium formate, 0.1760 gram of cadmium was obtained; and with 1 gram of strontium formate and 1 gram of barium formate, respectively, 0.1762 gram and 0.1760 gram of cadmium were thrown down. The character of these deposits was also good, though perhaps not quite so firm as in the case of those obtained from the sulphate with the formate electrolyte. The deposits were finely crystalline and adherent, but slightly porous.

III. The Lactate Electrolyte.[1]

The action of the lactate electrolyte was then investigated. As before, the first trial was made with only lactate ions present. The electrolyte used was 2 cc. of lactic acid with 1 cc. of ammonium hydroxide. This was added to 10 cc. of a solution of cadmium lactate, diluted as usual, and electrolyzed at boiling temperature for one hour, using 0.3 ampere and 2.8–3 volts. The weights of cadmium obtained, although fairly concordant, were not considered reliable. The greater part of the deposit was fine and adherent, but had also coarse crystalline plates which scaled off and were not easily handled. Again, however, the use of the same electrolyte with the cadmium sulphate solution resulted in the formation of a very excellent deposit. It was silvery-white, very finely crystalline, clean, and easy to wash. The same excellence was seen in the metal deposited from the cadmium sulphate solution in presence of 1 gram of calcium lactate. To 10 cc. of cadmium sulphate solution were added 2 cc. of lactic acid and 1 cc. of ammonium hydroxide, the solution diluted, heated to boiling, and electrolyzed for one hour with a current of 0.3 ampere and 2.6–3 volts. The weights of cadmium obtained in two trials were 0.1964 gram and 0.1966 gram. When 1 gram of calcium lactate was added, 0.1966 gram and 0.1965 gram were successively obtained.

---

[1] This Journal, 27, 1275.

An attempt was made to use cadmium acetate solution with the lactate electrolyte, but the deposits again showed coarse crystalline plates which scaled off in washing and the weights were always low.

With a solution of cadmium formate, however, the results were better. Although the same tendency to scaling off was observed, it could be controlled more easily. It was found better to make the quantity of lactic acid a little less, a scant 2 cc. giving the best results. From 10 cc. of the cadmium formate solution used, 0.1944 gram of cadmium had been previously obtained. Using the same amount of this solution, with 2 cc. of lactic acid and 1 cc. of ammonium hydroxide, diluting, and heating to the boiling point, 0.3 ampere and 2–3 volts used for one hour gave successively 0.1944 gram and 0.1946 gram of cadmium. A series of separations was then tried from calcium, strontium, and barium. On adding 1 gram of calcium formate to the solution as prepared above, 0.1946 gram of cadmium was obtained; with 1 gram of strontium formate 0.1944 gram, and with 1 gram of barium formate 0.1946 gram of cadmium was precipitated. The character of the deposit was not materially altered by the presence of the alkaline earth metals, although with the barium formate, there seemed to be a tendency towards the formation of coarser crystals.

In conclusion, it seems evident that in work with the rotating anode:

1. Low currents are preferable for the deposition of cadmium, when organic electrolytes are used.

2. Each electrolyte has a decided influence on the character of the deposit, which is not to be foreseen.

3. A mixture of ions improves the character of the deposit. This is most evident when the sulphate ion is present, the best deposits being

obtained from the cadmium sulphate solution, using the acetate, formate, or lactate electrolyte. The formate ion also seems to exert a good influence on the deposit, cadmium acetate solution with the formate electrolyte giving satisfactory results even in presence of the alkaline earth metals, and cadmium formate solution with the lactate electrolyte also giving good deposits. It is of interest to observe that the acetate and lactate electrolytes when used alone are not so successful, and the combination is an extremely poor one.

It is clear that other organic electrolytes should be investigated, and that many interesting and valuable relations may be found in the comparison of the nature of the deposits from different electrolytes and from their combinations. It is hoped that this investigation may be continued in this laboratory.

DETERMINATION OF AMMONIA NITROGEN IN WATER IN THE PRESENCE OF HYDROGEN SULPHIDE.

BY EDWARD BARTOW AND B. H. HARRISON.

Received July 4, 1910.

The tests for free and albuminoid ammonia, since their introduction in 1867, have played an important role in the sanitary examination of drinking-water. They have been criticized because of inaccuracies due to interferences from substances in solution, and it is this phase of the subject that we have been investigating. In the experimental work we have taken the usual precautions to have a uniform rate of distillation, a uniform temperature for Nesslerization, a uniform organic content in comparative tests, all glass apparatus and a room free from ammonia fumes. As an illustration of the necessity for the last precaution we found that 0.036 part per million of ammonia nitrogen was added to a water exposed for 24 hours in the distilling room, which adjoined a room where dogs were kept for experimental work in physiological chemistry, and that 0.566 part per million was added to water in the room where the dogs were kept.

Natural waters sometimes contain substances which may cause interference if these combine with ammonia to prevent its distillation or if they are distilled with the ammonia and interfere with the Nessler test. Of the former class are acids like sulphuric acid, which, as is well known, must be neutralized before distillation. Of the latter class is hydrogen sulphide, which will distil over with the ammonia and will give false results.

We have studied the effect of three substances, calcium acid carbonate, magnesium chloride and hydrogen sulphide. Our results indicate that calcium acid carbonate and magnesium chloride in the amounts ordinarily found in natural water do not interfere materially with the determination of free ammonia. Kober[1] has stated that in the presence of magnesium chloride all the ammonia is not given off. This may be true if the concentration of the magnesium chloride is very high. Our experiments with an amount of magnesium chloride in excess of the amounts found in any of the Illinois water supplies lead us to conclude that the interference is not material

Hydrogen sulphide, however, interferes with the Nessler test. When the amount of ammonia is large the hydrogen sulphide might be removed by precipitation with a lead or zinc salt and the ammonia determined by direct nesslerization, but if small and it is desirable to distil and nesslerize the distillates, the results are very inaccurate. This is shown in our first test. We added 0 06 part per million of ammonia nitrogen to a water in which 56 parts per million of purified hydrogen sulphide gas had been absorbed. Nesslerization after distillation showed 0 082, 0.214 and 0 376 part per million of nitrogen when only 0 06 part per million had been taken. A repetition of the experiment gave similar inaccurate results.

The hydrogen sulphide must evidently be prevented from interfering either by distilling it off in the presence of something that will hold the ammonia or in holding it back while the ammonia is being distilled. The use of sulphuric acid to retain the ammonia in the Kjeldahl process led us to try it To 500 cc. of a water containing 20 parts per million of hydrogen sulphide and a known amount of ammonia nitrogen, 50 cc. of normal sulphuric acid was added and 100 cc. of water distilled over. The first tube was cloudy and smelled strongly of hydrogen sulphide gas; the second tube was practically clear. 50 cc. of a normal solution of sodium hydroxide was then added and 200 cc. of water distilled and nesslerized. On the first series with 0 06 part per million taken 0 082,

0.080, 0.078 and 0 082 part per million was found. This showed the necessity for control tests which were run in succeeding series. The readings with the corrections are shown in Table I. The results are sufficiently accurate.

With respect to the holding of the hydrogen sulphide and the distillation of the ammonia, the addition of sodium hydroxide would not be satisfactory as the sodium sulphide formed would hydrolyze and hydrogen sulphide would be found in the distillate.

Phelps,[1] in discussing the direct nesslerization of sewage, suggests the precipitation of the hydrogen sulphide with lead or zinc acetate. We have tried lead acetate and have compared it with the sulphuric acid method, as shown in Table II:

TABLE II. DETERMINATION OF AMMONIA NITROGEN BY ADDITION OF SULPHURIC ACID OR LEAD ACETATE. RESULTS IN PARTS PER MILLION

so-called albuminoid ammonia, a series of waters were analyzed with and without the addition of sulphuric acid. The results of the analyses of nine typical Illinois waters as given in Table III show that the sulphuric acid has no appreciable effect on the amount of ammonia obtained. While the results are not identical, the variations are within the limits of experimental error.

URBANA, ILL.

THE COMPOSITION OF SOME GREEK VASES.

BY WILLIAM FOSTER

Received July 18, 1910.

The purpose of this article is to give an account of some chemical tests made in order to determine the nature and composition of the black glaze of the black-figured and red-figured Attic styles and the red glaze of the Mycenaean style of vases.

This investigation was undertaken at the request of my colleague, Dr. O. S. Tonks, who is interested in Greek pottery from the standpoint of an archaeologist.

Guided by the results of these chemical tests, Tonks has confirmed some of the observations by synthesis, a partial account of which has already been published.[1]

1. Experiments with the Black Glaze.

(1) *Historical Introduction.*—The nature and composition of the fine black glaze on Greek pottery has been a subject of discussion and more or less speculation for many years. As far back as 1761 Caylus,[2] as a result of his investigations, claimed that the glaze was made up of a ferruginous earth, which he classified as manganese. He claimed that this substance baked red, but could be rendered black by an admixture of color, or other earths.

According to Blumner,[3] some later investigators have advanced theories that the materials of the glaze might be graphite and magnesia, that the glaze is made up of an earth but not a metal, and that a combination of the oxides of iron and manganese may have produced the black. Blumner claimed, however, that the real nature of the black color had not been finally determined.

Of the earlier experiments carried out with a view to discover the composition of the glaze, perhaps those of Salvétat,[4] at the Sèvres potteries, are the most worthy of consideration. While Salvétat, in reporting his analysis, did not give any *percentage* of manganese, he claimed that the oxide of manganese is an indispensable component of the composition, and this view is shared in by Brongniart.[1] This the writer hopes to disprove.

[4] Brongniart, "Traité des Arts Ceramiques," I, pp. 549–52.

Among the later writers, H. B. Walters[2] believes that the problem is still unsolved. He distinguishes between a glaze which was applied to the surface before the application of what he terms the black varnish and the black varnish itself. Birch, Blümner and Brongniart hold views that are somewhat similar. They consider that the glaze and black are different from each other.

Fürtwangler and Reichhold[3] are of the opinion that the black glaze is apparently made up of two parts, namely, a thin, reddish, shining, flowing material and some substance, which, by firing, gives the black. This I do not believe to be likely.

"The nature of the glaze which is to be seen on the finished vase in both the black- and red-figured styles, and the methods of its application, raise puzzling questions about which there is as yet no general agreement."[4]

It is hoped that the following experiments will aid somewhat in solving the puzzle as to the composition of the glaze.

(2) *Experimental.*—Experiments were conducted, in the first place, to find out whether manganese is present as an essential constituent of the glaze, as claimed by Salvétat, or whether its presence is accidental.

Experiment 1.—A fragment of a Greek vase[5] covered with fine black glaze and weighing about 51 grams was placed in a large silver crucible and fused with potassium hydroxide until all the glaze was removed from the clay.[6] The melt thus obtained had a faint greenish tinge, suggestive of a very small quantity of manganese. This melt was treated by the usual methods for the separation of silica and iron, and then hydrogen sulphide was conducted into the ammoniacal filtrate to precipitate any manganese that might be present. A *very* small dirty precipitate was obtained, which, when treated with a borax bead, gave no indication whatever of manganese. This test was confirmed by various other tests. The occurrence of manganese in the glaze must have been *accidental*, therefore, and not an *essential* component of it.

[5] From the American excavations at the Heraeum.

[6] NOTE.—A considerable quantity of the *body* of the vase was necessarily removed at the same time. The writer has tried different methods for removing the glaze, such as chipping it off, and scratching the surface with a fine diamond point; but in all cases the mass of the clay removed from the body of the vase was always much greater than that of the glaze itself. For this reason, since the glaze is exceedingly thin, it was impossible to get enough of the latter for chemical analysis.

Experiment 2.—In the second place, tests were made to find out the amounts of manganese in the black glaze and in the *body* of the vase.

Some fragments of a vase covered with black glaze were treated with a mixture of sulphuric and hydrofluoric acids until all the glaze was removed and disintegrated. After expelling the excess of hydrofluoric acid by repeated evaporations with sulphuric acid, the residue was dissolved in water and nitric acid, and the manganese determined by the colorimetric method of Walters,[1] *i. e.*, by oxidizing the manganese to permanganic acid by means of ammonium persulphate and then diluting in a Nessler cylinder to the mark. The amount of manganese calculated as the oxide (MnO) was 0 06 per cent.

The experiment was repeated with a similar sample taken from the body of the vase. The percentage of manganese was identical (0.06).

The experiment was repeated with a different sample of vase, in this case a diamond point being used to remove the glaze, and 0.04 per cent. of MnO was found in the glaze and also in the body of the vase.

These experiments go to show that the amount of manganese in the glaze is the same as that in the body of the vase. This small amount of the element (average 0.05 per cent) might very well be *accidental*, for it is well known that ordinary clays and rocks containing iron usually contain more or less manganese.

Experiment 3.—It was suspected by the writer that the black glaze might be due primarily to ferrous silicate, therefore the following experiments were carried out to test this hypothesis.

(1) Three grams of a fragment of a vase covered with glaze (the sample was not ground up) were placed in a platinum crucible and treated with a mixture of sulphuric and hydrofluoric acids, great care being exercised to exclude all air. The solution thus obtained was evaporated to dryness, the residue taken up with dilute sulphuric acid, and the ferrous iron determined by means of dilute potassium permanganate. 0.6 cc. of the permanganate were required. The same test was applied to an equal amount of the vase without the glaze. In this case 0.2 cc. of the permanganate was required to oxidize the ferrous iron.

(2) Two grams of a fragment of a vase covered with glaze were crushed to a powder and treated as in (1), the final titration being made with $N/50$ potassium permanganate. Amount of ferrous oxide (FeO) present, 0.50 per cent.

Two grams of the body of the vase were next treated in a similar way. Amount of FeO present, 0.30 per cent.

Several other tests were made, and invariably more ferrous iron was found in the glaze than in the body of the vase.

---

[1] *Chem. News*, 84, 239 (1901); *Proc. Eng. Soc. West. Pa.*, 17, 257 (1901); Hillebrand *Bulletin* 422 (U. S. G. S.), pp. 116–8.

Owing to the fact that it was impossible to get the glaze anything like free from the clay, it was not possible to determine the absolute amount of iron in the ferrous condition in the former; but enough evidence was obtained to indicate that *ferrous iron* (probably as ferrous silicate) is responsible for at least a part of the fine black color of the decorating medium of some of the Greek pottery.[1]

II. Experiments with the Red Glaze of the Mycenaean Style.

If the Greeks employed compounds of iron in the ferrous condition for the production of black glaze, it is reasonable to assume that they employed compounds of the element in the ferric condition to obtain the red glaze, and I dare say that it has been quite generally believed by writers on the subject that iron in the ferric condition had much to do with the production of the red glaze. If this be the case, one would expect to find more ferric iron in the glaze than in the body of the pottery, and less ferrous iron in the glaze than in the body. To test this hypothesis the following experiments were conducted:

Experiment 4.—(1) A fragment of a Mycenaean[2] vase covered with red glaze was found by the analytical method already described to contain 0 44 per cent. of iron calculated as ferrous oxide (FeO). An equal weight of the body of the vase gave 0 56 per cent. of FeO.

A second sample, from another vase, gave 0 35 per cent. FeO in the glaze and 0.43 per cent. in the body, and a third and still different sample gave 0.17 per cent. in the glaze and 0.25 per cent in the body of the vase.

From these experiments it would appear that the body of the pottery covered with red glaze contains more ferrous iron than the glaze—just the opposite of the observation made in the case of the black glaze.

---

[1] Tonks has succeeded, it appears, in confirming these observations by synthesis. He says: "Not to be tedious by enumerating the number of trials I made before getting the desired result, I may say that it proved eventually that a combination of eight parts of nitrate of soda to one of clay, fritted together, and then mixed in the proportions of two parts of frit to one of ferrous oxide, produced a glaze identical with that on Greek vases" (*Amer. J. Archaeology*, XII, 1908, p. 424). Tonks used pipe clay and he claims that if it had been a more fusible variety, the amount of sodium nitrate could have been much less.

It might be objected by some that the Greeks knew nothing about ferrous oxide, inasmuch as the pure compound is a modern preparation of the chemical laboratory. Compounds containing ferrous oxide or iron in the ferrous condition are abundant enough in nature, however, *e. g.*, magnetic oxide of iron, or ferroso-ferric oxide, and ferrous carbonate. Tonks informs me that he has recently succeeded in reproducing the black glaze by the use of the magnetic oxide of iron in place of pure ferrous oxide, but he has not as yet completed his experiments.

[2] Picked up by Tonks at Mycenae. Mycenaean vases were manufactured by the Greeks as far back as 1200–1300 B. C. The other specimens of vases with red glaze experimented on by the author were of the Mycenaean style, but from the Heraeum.

Experiment 5.—The total iron as ferric oxide (Fe_2O_3) was next determined, both in the red glaze and in the body of the clay. The surface of a fragment of vase covered with red glaze was scratched thoroughly with a diamond point and the powder analyzed. Total Fe_2O_3 present, 8.16 per cent. A sample of the same vase without the red glaze contained 7.36 per cent. total iron as Fe_2O_3. After allowing for the ferrous iron, the glaze was found to contain considerably more ferric iron than the body of the clay. A second experiment, on a different fragment of vase, confirmed this observation.[1]

III. Analyses of Mycenaean Vases.

So far as the writer knows, no analyses of Mycenaean pottery have been published. It was thought worth while, therefore, to make a complete analysis of a fragment of a vase of the Mycenaean style, and a partial analysis of another fragment. These results will be given below, and, for the purpose of comparison, the average *approximate* results of the analysis of four fragments of Attic pottery (with black glaze) made in the Harvard University laboratory under the direction of Professor Richards[2] will be given, and also the mean of Salvétat's[3] analyses:

ANALYSES OF ANCIENT POTTERY.

	Fragments of Mycenaean vase. Foster		Fragments of jars and vases (Attic). Widtsoe & Lyon (Harvard Univ.)	Campanian pottery. Salvétat.
Silica (SiO_2)	40 60	47 51	56 10	55 88
Aluminium oxide (Al_2O_3)	17 07	20 40	17.25	18.88
Ferric oxide (Fe_2O_3)	6 93	8 89[4]	8.95	15.80
Ferrous oxide (FeO)	0 56	..	. .	...
Calcium oxide (CaO)	19 80	13 82	5.52	7 48
Magnesium oxide (MgO)	4 42	4.41	5 00	1.63
Potassium oxide (K_2O)	2 96	.	3 26	...
Sodium oxide (Na_2O)	0 21	. .	2.35	...
Carbon dioxide (CO_2)	5 40	2.78	...	...
Water (H_2O)	2 95		2 20	...
	100 90		100 63	

By a comparison of the figures in the different columns, it may be observed that the Mycenaean pottery contains considerably less silica than the Attic and the Campanian. They all contain about the same amount of alumina. The Mycenaean and the Attic appear to contain approximately the same amounts of ferric iron, but the Campanian ware contains about twice as much of this substance. The Mycenaean pottery is *much* higher in lime than the other varieties, and also contains (*i. e.*, the samples analyzed) considerable carbon dioxide. The amounts of magnesia in the Mycenaean and the Attic varieties are nearly equal, but it is considerably less in the Campanian. The potassium oxide is approximately the same in the samples analyzed at Harvard and in the one sample of Mycenaean pottery in which this constituent was determined. While the former contained over 2 per cent. of sodium oxide, the latter contained but a small amount (0.21 per cent.).[1] Owing to the fact that the Mycenaean clay analyzed is low in silica and comparatively high in lime, it should be more fusible. It was observed that in determining the loss of this variety of clay by ignition in a platinum crucible, it melted quite completely.

---

[1] Tonks has been conducting some experiments to confirm these analyses synthetically, and he has already met with considerable encouragement.

CHEMICAL LABORATORY,
PRINCETON UNIVERSITY

CONDITIONS AFFECTING THE ELECTROLYTIC DETERMINATION OF COPPER.

BY W C BLASDALE AND W. CRUESS.

Received August 10, 1910.

Although the electrolytic method for the determination of copper has been in use since 1864, and the literature of the subject is now voluminous, the application of the method to the analysis of ores and metallurgical products often presents difficulties, which are either ignored or but vaguely suggested in the current descriptions of the process. The frequent failures made by students in this laboratory in attempting to use the process have served to emphasize these difficulties, and have led to the series of experiments, the results of which are recorded below. In carrying out these experiments the needs and resources of the practical analyst have been kept constantly in mind.

Effect of Different Forms of Electrodes upon the Rate of Deposition and the Character of the Deposit.

The results obtained with the use of mechanical stirring devices during the last seven years have emphasized the desirability of maintaining a rapid circulation of the electrolyte during electrolysis. It has not been so generally recognized that the circulation of the electrolyte may be increased by taking advantage of the convection currents produced by the gases liberated at the anode or cathode, and by the substitution of Winkler gauze electrodes for those of the Mansfield type.[2] It seems probable that the relative efficiencies of the different forms of stationary electrodes depend almost entirely upon the extent to which they favor circulation of the electrolyte, and the equal distribution of the current density over the entire surface of the cathode.

---

[1] Chemical analyses of the different varieties of clay used by the ancient Greeks are still too inadequate to throw much light on the manufactures of different localities.

[2] See, however, the Benner article, p. 1231.—EDITOR.

In order to obtain definite data upon this point the rates of precipitation of known amounts of copper under identical conditions, except as regards the electrodes used, were determined. Each of the solutions contained exactly 0 1975 g. of copper as sulphate, 2 cc. of concentrated sulphuric and one of concentrated nitric acids, and water to make 140 cc. They were electrolyzed with a practically constant current of 0.34 ampere and the copper deposited during definite time intervals determined. Except where Classen dishes were employed, the stand to which the electrodes were attached was raised at the end of the desired time interval, and the electrodes plunged in a beaker of water, the current allowed to run for some three minutes longer, after which the cathode was removed, washed in two changes of alcohol and dried and weighed. It was shown, both by determining the rate of action of solutions of this composition on recently precipitated copper, and by testing the washings of the electrodes that this method of removing the cathode involves no recognizable error, it is extremely rapid and convenient.

The cathodes used in the various experiments were as follows:

A. A Classen dish of 200 cc. capacity, with 140 cc. of electrolyte; this gave an available surface of about 120 sq. cm The anode used with it consisted of a disk of foil with six radially distributed openings near its rim; it was 4.1 cm. in diameter, and was suspended by a stout wire in the center of the dish, slightly below the level of the liquid retained by the latter.

B. A cylinder of foil 2 5 cm. in diameter and 5 cm. in length welded to a supporting wire one mm. in diameter and 12 cm. in length. The total area exposed to the solution was 79 sq. cm. The anode used was a cylindrically coiled spiral of platinum wire suspended in the center of the cylinder. Both electrodes extended nearly to the bottom of the beaker containing the solution; the beaker used was approximately 5 5 cm. in internal diameter.

C. A cylinder of the same dimensions as B, but pierced with 270 holes one mm. in diameter, distributed at approximately equal intervals over its entire surface. The anode and containing vessel were of the same form and size as with B.

D. A cylinder of gauze 3.2 cm. in diameter and 5.5 cm. in length, the gauze composed of platinum wire 0.06 mm. in diameter, with 41 meshes per linear cm. The cylinder was supported by a wire 0.54 mm. in diameter and 13 cm. in length. Assuming that the entire surface of the wire composing the gauze was in contact with the solution, its available area was 93 sq. cm. The anode and containing vessel were the same as those used with B.

E. A cylinder of gauze of the same form and dimensions as D. The anode, however, consisted of a stout wire coiled to form a horizontal spiral, suspended at the bottom of the containing vessel. This was of the same dimensions as with B.

F. A cylinder of gauze 4 cm. in diameter and 4 cm. long; the gauze composed of wire 0.1 mm. in diameter with 25 meshes per linear cm. This was supported by a wire 1 mm. in diameter and 12 cm. long. The calculated surface area was 80 sq. cm. The anode and beaker used were of the same form and dimensions as with B.

The results obtained with these electrodes are shown in part in the series of curves of Plate 1, in which the abscissas represent time in minutes, and the ordinates the copper deposited, in milligrams. The superiority of the gauze electrode D over all others is at once apparent. Its efficiency is due to the fact that it interposes almost no obstacle to the development of convection currents, the direction and intensity of which are easily observed by placing a few mg. of precipitated silica in the solution. It can be shown by this device that the gas liberated at the anode is here distributed over a limited area and produces a current of considerable intensity, which draws the solution through the meshes of the cathode from the periphery. Where foil electrodes are used there is but little interchange of solution between the annular space surrounding the cathode and the cylindrically bounded area within. Further, while the current density is nearly equally distributed over the entire exposed surface of the gauze cathode, it is much greater on the inside than the outside of the foil electrodes, and it is easy to show that only a small percentage of the copper deposited on electrodes of this style separates on the outside of the cylinder.

A comparison of the results obtained with D and F shows that the efficiency increases somewhat with the fineness of the mesh and the wire of which the electrode is composed. This, taken together with its extreme lightness and consequent low cost, places D at the head of the list as regards economy. Although D was somewhat fragile and had to be handled more carefully than F, two such electrodes have been in general use for over three years and are still in good order.

A comparison of the results obtained with B and C show that by providing a number of openings in the foil composing the cathode the efficiency is appreciably increased, but the superiority of the gauze form still remains most striking.

A comparison of the results obtained with E and D shows that the cylindrical form of anode possesses a slight advantage over the disk form. This is due to the distribution of the liberated gas over a greater horizontal area. Still another difficulty arises from the fact that much of the liberated oxygen comes in contact with the precipitated copper and may produce an appreciable amount of oxidation; dark deposits were frequently obtained wherever the disk form of anode was used. With this exception the deposits obtained in the entire series of experiment were satisfactory. A comparatively small increase in the amperage used gave poor deposits where foil electrodes were used.

The comparative efficiencies of the different forms of electrodes used are summarized in the following table, in which the last column represents the time needed for the precipitation of 0.1975 g. of copper to within ±0.02 mg.

	Cathode used.	Surface exposed.	Wt. in g	Time needed. Minutes.
A	Classen dish . .	120	38	400
B.	Mansfield	79	11.0	450
C.	Mansfield with holes	78	11.0	390
D.	Winkler	93	4.2	50
E.	Winkler..	93	4.2	60
F.	Winkler .	80	9.4	100

Effect of Varying Amperage upon the Rate of Deposition.

If all the current which passes through the solution were carried by the ionized copper salt the rate of precipitation would be directly proportional to the amperage. In practice other electrolytes are always present and carry more or less of the current. The electrolysis of neutral salts yields free acids, and acid is usually necessary to prevent the separation of other metals present. So long as the decomposition voltage of the copper ions is somewhat smaller than that of the other cations present, and so long as their concentration is sufficiently large as compared with the amperage used, the greater part of the positive current will be carried by them, but as their concentration decreases the proportion of the positive current carried by them must rapidly decrease and finally become zero. Rapid circulation of the solution brings larger numbers of copper ions within the sphere of attraction of the cathode within a given time interval, and increases the proportion of positive current carried by the copper ions during the later stages of the deposition. Increasing the amperage not only increases the rate of deposition directly, while the solution contains a comparatively high concentration of copper ions, but also indirectly by increasing the circulation of the solution through the gases liberated at the anode and cathode.

In order to determine the actual effect of varying current strength the rates of precipitation were determined under identical conditions except as regards amperage. The solution used contained 0.1975 g. of copper as sulphate, 2 g. of ammonium nitrate, 4 cc. of concentrated nitric acid and water to make 140 cc The gauze electrode D was used throughout. The curves 1, 2, 3, 4, and 5, shown on Plate II, represent the results obtained where currents of 0.19, 0.34, 0.5, 0.78 and 5.5

amperes, respectively, were used. The details of manipulation were the same as in the previous series of experiments. In all but the last series the amount of copper finally obtained differed from the correct amount by less than 0.3 mg.; when 5.5 amperes were used the solution attained a temperature of 60° and the solvent action of the large amount of nitric acid present was so great that the final result was 1.2 mg. low. This loss was due in part to copper in the wash water and in part to copper left in the original solution. The depolarizing action of the large concentration of nitrate ions present was sufficient to prevent the liberation of hydrogen even with the highest currents used. The deposits were all dense and compact; those obtained with the higher amperage showed a slight tinge of brown in place of the normal red color.

It might be noted here that some experiments by Stoddard,[1] which involved the use of a gauze cathode, a volume not exceeding 50 cc., and the presence of only one cc. of nitric acid, gave more rapid precipitation than that here noted. His work has been criticized by Price and Humphreys,[2] who found the time needed under similar conditions somewhat greater than that used by Stoddard.

Effect of Varying Concentrations.

The proportion of positive current carried by copper ions in a series of solutions containing the same amount of copper salt should be greater,

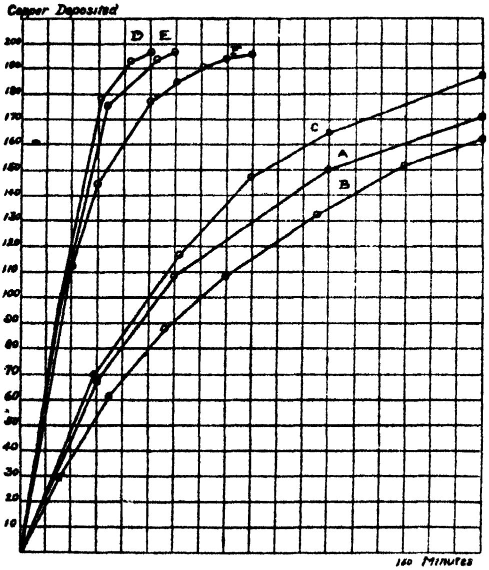

Plate I.—Results with varying types of electrodes.

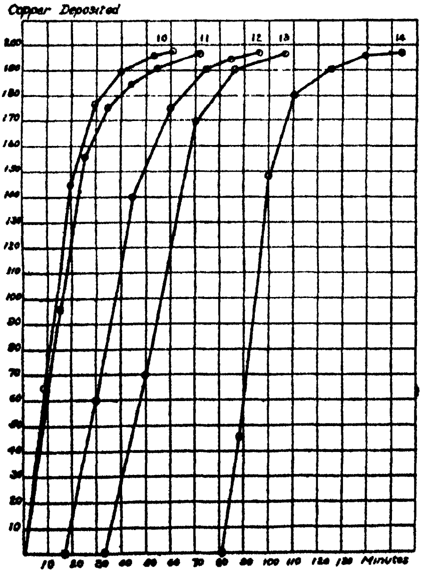

Plate IV.—Results with varying amounts of iron.

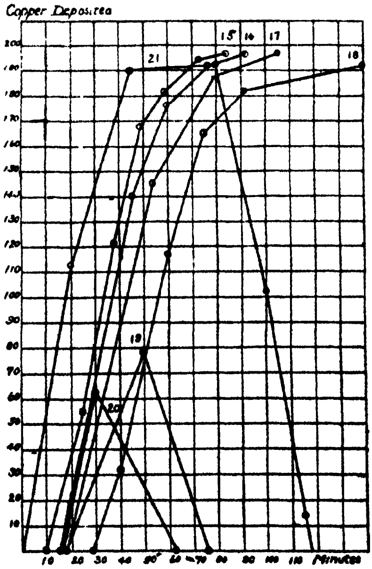

Plate V.—Results with varying concentrations of iron and nitric acid.

especially as the deposition approaches completion, with solutions of high than with those of low concentration. The importance of this factor has been shown by Richards,[1] although the method which he recommends for effecting the precipitation is scarcely feasible in routine analytical work.

Some data showing the effect of varying concentration on the speed of precipitation are represented by curves 6, 7, 8 and 9 of Plate III. The solutions used contained 0.1975 gram of copper as sulphate and were diluted to 70, 140, 210 and 280 cc., respectively. They contained nitric and sulphuric acids corresponding to a concentration of one cc. of the former and two of the latter, for each 140 cc. of total solution. The gauze electrode D and a current of 0 34 ampere were used in all cases, but the size and form of the beakers containing the solutions were necessarily changed somewhat from those used in the previous experiments.

The curves show that the time interval during which the rate of precipitation remains practically constant increases greatly with the concentration. Even when the volume is 140 cc. this rate remains practically constant till 90 per cent. of the copper present has been precipitated; beyond this point the rate decreases rapidly. With larger volumes the change in rate occurs earlier and becomes increasingly greater with the larger volumes. This may be taken to mean that up to the point at which the rate shows a decided change the current is carried entirely by the copper ions; beyond this point it is carried to an increasing extent by the hydrogen ions. The final form of the curve is the net effect of the actual change in concentration and the change in stirring efficiency of the anodic gas, owing to the increased volume of liquid to be stirred.

Amount and Nature of Acid Present.

Although copper is readily separated by the electric current from neutral or alkaline solutions, the application of this method to the analysis of ores almost invariably demands the presence of a slight concentration of hydrogen ions. If sulphuric acid is used, and if the cathode consists of a Classen dish or a foil, the current density must be kept low or the deposits are spongy. The difficulty becomes increasingly large as the concentration of the copper ions decreases, and can be remedied, as shown by Richards,[2] by making reductions in the current strengths as the deposition progresses. Rapid circulation largely overcomes the difficulty, since larger numbers of copper ions are thereby rendered available for the transport of the current and virtually increase their effective concentration. A somewhat extended experience has convinced us that this difficulty is reduced to a negligible factor by the use of gauze electrodes. We have not yet obtained a spongy deposit where these electrodes were used. This has been noted and used by Förster.[1]

---

[1] THIS JOURNAL, 26, 530 (1904).

[2] *Loc. cit.*

Where a sufficient concentration of nitrate ions is present, the danger of obtaining spongy deposits is small, but another difficulty arises from the formation of brittle, crystalline aggregates, which grow out from the lower edge of the cathode, and sometimes at the point where the sustaining wire emerges from the solution. Apparently this difficulty is also avoided by sufficient circulation of the solution, for it has not been noted where the solution was stirred, or where a gauze cathode was used.

Differences in the comparative solvent action of the two acids on precipitated copper might be expected to affect the rate of precipitation and the difficulty of removing the cathode from the solution without resolution of appreciable amounts of the precipitate. The amount of copper dissolved from a copper-coated gauze cathode by dilute solutions of these acids during a definite time interval was found to vary greatly, but in every instance the action of the nitric acid was much greater than that of the sulphuric acid, and was increased to a much greater extent by increasing the temperature to 60°. In one instance 78 mg. of copper were dissolved by a solution containing 2 cc. of nitric acid per 140 and heated to 60°. The precipitation of the last few milligrams of copper from such solutions is not easily effected and we have not found either the rotating anode or the gauze cathode satisfactory where the solution was heated either externally, or internally by the current. The residual solutions usually showed the presence of copper by the ferrocyanide test, and occasionally faint traces of the same could be detected in the wash water. Where currents of five or more amperes are used, nitric acid should not be present, except in small concentrations.

If the temperature of the solution does not rise above 30° the concentration of the solution with respect to copper is easily reduced below the point recognized by the ferrocyanide test, even where the concentration amounts to as much as 4 cc. of either acid per 140 cc. of solution. The time needed for complete precipitation from such solutions is practically the same, though the rate at which the last ten milligrams are precipitated is slightly less with the larger concentrations of nitric acid.

Effect of Iron Salts upon the Rate of Precipitation.

A. In the Absence of Nitrate Ions.—The curves plotted on Plate IV show how the rate of precipitation is affected by the presence of iron salts. The solutions used contained in every instance 0.1975 g. of copper as sulphate, and 2 cc. of concentrated sulphuric acid, and were diluted to 140 cc.; they were electrolyzed with the gauze electrode D, using a current of

---

[1] *Z. angew. Chem.*, 19, 1848 (1906).

0.34 ampere. The curve numbered 10 represents the results obtained where no iron was present; No. 11, where the solution contained 0.8 g. of iron as ferrous sulphate. The comparatively large amounts of ferrous ions present reduced perceptibly the normal rate of precipitation during the later stages of the deposition, but did not otherwise affect the precipitation.

The results represented in curves numbered 12, 13 and 14 represent the results obtained with solutions containing respectively 0.2, 0.4 and 0.8 g. of iron as ferric sulphate. They show that no copper is deposited for a definite interval, which is roughly proportional to the amount of ferric salt present. A similar series of solutions were electrolyzed under the same conditions and titrated with a solution of potassium permanganate, at the point at which the copper first began to separate. The results showed that the appearance of the deposit was correlated with the reduction of the concentration of the ferric ions to an approximately fixed value. Evidently we are here dealing with a complex equilibrium in which the important factors are the strength of the current used, the concentration of the ferric ions, and the reaction constant of the equation

$$2Fe''' + Cu \longrightarrow Cu'' + 2Fe''.$$

The value of this constant is evidently large, for if a copper-coated electrode is allowed to stand in a solution of a ferric salt till equilibrium is attained, the concentration of the resulting solution with respect to ferric ions is reduced almost to zero. By titrating still another series of solutions it was shown that the reduction of the iron progresses during the deposition of the copper and was completed before the copper was all deposited.

B. In the Presence of Nitrate Ions. General Phenomena.—The curves plotted on Plate V show the effect upon the rate of precipitation of varying combinations of ferric salts and nitric acid. The solutions contained in all cases 2 cc. of concentrated sulphuric acid and water to make 140 cc. and were electrolyzed with the gauze electrode D, using a current measuring 0.34 ampere. In 15 the solution contained 0.2 g. of iron as ferric sulphate and no nitric acid; in 16, 17, 18 and 20 they contained 1, 3, 4, and 5 cc., respectively, of concentrated nitric and 0.2 g. of iron as ferric sulphate; in 21 it contained 0.2 g. of ferrous sulphate and 4 cc. of concentrated nitric acid; in 18 it contained 0.4 g. of iron as ferric sulphate and 3 cc. of concentrated nitric acid. In some cases only a few points on the curves were determined and the exact position of the maxima is only approximately represented. The extreme rapidity with which the resolution sometimes took place, and the difficulty of accurately controlling all the factors concerned, especially the temperature, make accurate determinations difficult; an approximate accuracy is all that the present work requires.

The curves show that so long as the concentrations of both nitrate ions and ferric ions are kept low, the rate of precipitation is merely retarded, but where either of these factors, especially the nitrate concentration, becomes large, deposition may take place normally up to a certain stage, then a rapid resolution of the deposited copper. This phenomenon is well known to analysts, who have had much experience in applying the electrolytic method to the analysis of pyritiferous ores and has been described by Larison[1] and by Farlie and Boone.[2]

Probable Cause of the Phenomenon.

The rapidity with which the process of resolution takes place, and the fact that with a constant amperage it may not take place at all until a large amount of the copper has been precipitated, make it improbable that either nitric or sulphuric acids or ferric salts are the effective agents concerned. Its frequent association with the blackening of the solution (presumably due to the nitroso compound of ferrous sulphate) suggests that the action is due to the presence of one or more of the products resulting from the reduction of nitric acid.

A systematic study of the action of solutions of nitric acid containing the various lower oxides of nitrogen has led to the conviction that nitrous acid is the reagent which is chiefly concerned in this phenomenon, though nitric oxide may play some part in it. Some of the data upon which this statement is based are as follows.

(*a*) The copper in a solution containing 0.5 g. of copper sulphate, 2 cc. of concentrated nitric acid and water sufficient to make 100 cc. was deposited on a gauze electrode. The latter was then removed and after saturating the solution with nitrous oxide gas was again placed in the solution. The amount of copper dissolved at the expiration of forty minutes was 0.017 g.

(*b*) A solution and electrode prepared exactly as in (*a*) were saturated with nitric oxide gas (prepared from copper turnings and nitric acid). The amount of copper dissolved from the cathode by this solution at the expiration of forty minutes was 0.074 g.

(*c*) A solution and electrode prepared exactly as in (*a*) were partly saturated with nitrogen peroxide prepared from tin and nitric acid. The copper-coated cathode immersed in this solution for forty minutes lost 0.140 g.

(*d*) A solution was prepared which contained 2 cc. of concentrated nitric acid and 2 cc. of a solution saturated with respect to both ferrous sulphate and nitric oxide, and water sufficient to make 100 cc. The copper-coated cathode lost 0.007 g. as the result of immersion in this solution for forty minutes.

---

[1] *Eng. Min. J.*, 84, 442 (1907).

[2] *Electrochem. Met. Ind.*, 6, 58.

(*e*) A solution prepared as in (*a*) was treated with a mixture of nitric oxide and nitrogen peroxide (prepared from starch and nitric acid). The entire amount of copper on the cathode, that is, 0.1975 g., was dissolved within five minutes.

Recognizing the fact that nitrogen peroxide in contact with water immediately forms a mixture of nitrous and nitric acids, and that the nitric oxide prepared from copper and nitric acid probably contained appreciable amounts of the peroxide, it seems probable that the phenomenon under discussion is mainly due to the presence of nitrous acid. It has been clearly shown by Millon,[1] Veley[2] and others that this acid has a pronounced catalytic action on the dissolution of copper in nitric acid. There is also reason to believe that the acid itself has a remarkable solvent action on the metal. A one-tenth normal solution of potassium nitrite acidified with an equivalent amount of sulphuric acid dissolved 0.1 g. of deposited copper in five minutes, liberating a large amount of nitric oxide gas. A half-normal solution also acidified in like manner dissolved 0.14 g. in three minutes. Its action is much greater than that of corresponding concentrations of either sulphuric or nitric acids. There is nothing surprising in this statement. If it is true that the dissolution of copper by nitric acid depends first upon the comparatively high dissociation constant of nitric acid, and second upon the ability of nitrate ions to reduce the concentration of the liberated hydrogen to an exceedingly small value, it would not be surprising to find a still greater effect with nitrous acid. The latter acid may possess a slightly smaller dissociation constant, but it is probable that the nitrite ions are more efficient in reducing the concentration of the liberated hydrogen than the nitrate ions.

Formation of Nitrous Acid during Electrolysis.—That nitrous acid is actually produced during the electrolysis of solutions containing sufficient concentration of nitric acid and a ferric salt can be shown by titrating such solutions with potassium permanganate. Thus by electrolyzing a series of solutions, all containing 0.196 g. of copper, 0.1753 g. of iron as ferric sulphate, two cc. of concentrated sulphuric and three of concentrated nitric acids, and water to make 140 cc., for definite time intervals, weighing the precipitated copper and titrating the residual solution, the following results were obtained:

Time interval. Minutes.	Weight of copper deposited.	Reducing power of soln. Fe.
60	0.1762	0.1574
90	0.1925	0.1939
120	0.1946	0.2441
180	0.1958	0.2112

---

[1] *J. prakt. Chem.*, 29, 338.

[2] *Proc. Roy. Soc., London* 48, 458.

Although the current strength here used was sufficient to prevent any recognizable re-solution of the precipitated copper, it is interesting to note that the rate of precipitation after ninety minutes had elapsed, even for the low concentration of copper concerned, was far below the normal value.

The exact conditions necessary for the formation of nitrous acid and the mechanism of the reaction have not yet been determined and we have never obtained evidence of the formation of nitrous acid in the electrolysis of copper nitrate solutions containing free acid unless an appreciable concentration of an iron salt was present. Apparently also a low concentration of hydrogen ions favors the formation of it. We offer no theory of the mechanism of the reaction.

The Use of Urea in Destroying Nitrous Acid.—It has been shown repeatedly that the addition of a sufficient amount of urea to solutions in which re-solution of the precipitated copper had taken place, resulted in the liberation of a large amount of gas and prompt precipitation of the entire amount of copper. It was further shown that the addition of urea to solutions containing several cc. of nitric acid before electrolysis is started will often permit of complete deposition of the copper, whereas in an exactly parallel test, in which the urea was omitted, complete deposition was impossible. The rate of precipitation is, however, still lower than normal, even where 5 g of urea per 100 cc of solution are used, which means presumably that this reagent is still unable to reduce the concentration below a value which affects the normal rate of precipitation to an appreciable extent.

Since entirely satisfactory deposits can be obtained with the gauze electrode in the entire absence of nitrate ions, it is undoubtedly preferable to electrolyze solutions of ores containing only copper and iron in he presence of sulphuric acid only. When it becomes necessary to separate copper from solutions containing both iron and nitric acid, urea may be added with advantage, to prevent the accumulation of undesirable concentrations of nitrous acid in the solution.

Effect of the Presence of Arsenic.

Where solutions containing a salt of copper and arsenic acid are electrolyzed mere traces of arsenic are often separated during the deposition of the copper; larger amounts may separate after most of the copper has been precipitated, and is then easily recognized by the smoky color which it imparts to the precipitate, or if large amounts have separated, by its loosely adherent character and black color. Several devices have been used to avoid the resulting error.

Solution of the precipitate in nitric acid and reprecipitation from a solution containing a reasonable amount of nitric acid can be depended on to give good results in practically all cases.

The removal of mere films of arsenic from the surface of the cathode by carefully heating the latter over a gauze often gives good results, but is not entirely reliable, owing to the difficulty of entirely avoiding oxidation.

Attempts to separate the two metals by the constant voltage method we have found unsatisfactory, even where low amperages were used and is incompatible with the rapid methods of precipitation.

The addition of oxidizing agents for the purpose of keeping the arsenic in the pentavalent form has been generally recommended. Hollard[1] claims that the addition of ferric sulphate effects the desired object, but as the iron is itself reduced during the electrolysis, this seems improbable, and we find that the electrolysis of solutions containing arsenic acid and a ferric salt, in addition to copper, give large deposits of arsenic, provided the solution contains no nitrate ions. Since the solution used by Hollard contained nitric acid, we attribute his success to the latter reagent. The exact concentrations of nitrate ions necessary to prevent precipitation of arsenic depend on the concentration of the latter and upon many other factors. We find that where the solution has a volume of 100 cc. and contains 2 cc. of concentrated sulphuric acid and 50 mg. of arsenic, separation of the latter is effectually prevented by the presence of 5 g. of ammonium nitrate, even though the current is allowed to pass through the solution for several hours after the copper, also present, was deposited. Under similar conditions one cc. of concentrated nitric acid prevented the separation of arsenic from a solution containing 10 mg. of the latter. These results were obtained with the gauze cathode using currents of as much as 0.75 ampere. The limits given are only the roughest kind of approximations.

Effect of the Presence of Salts of Zinc and Aluminium.

The addition of either zinc or aluminium to the extent of 0.4 g. has but little effect on the time needed for complete deposition of copper. The solutions used in determining this fact contained only sulphates and sulphuric acid, and were electrolyzed with the gauze electrode, using 0.34 ampere. A very slight decrease in the rate at which the last four mg. were deposited was noted, which increased the time needed by about five minutes.

A second effect has been observed in the electrolysis of solutions containing large amounts of zinc in addition to copper with electrodes of the Mansfield type, namely, a greater tendency for the formation of unsatisfactory deposits. These effects were never observed where gauze electrodes were employed.

---

[1] *Analyse des Metaux par Electrolyse*, 83.

Effect of the Presence of Lead Salts.

This element may separate in large amounts with the copper from solutions containing sulphuric acid. A large concentration of nitrate ions prevents this, but the amount needed is in excess of that which is desirable, if iron is also present in large amounts. As most of the lead present as ore is usually changed into the sulphate, in preparing the solution, it is preferable to use sufficient care to separate it as completely as possible in this form. We find that, if the insoluble precipitate of the sulphate is left in contact with the solution, very large amounts may be dissolved and precipitated as the deposition progresses.

Practical Application to the Analysis of Ores.

The data presented in the previous sections indicate the difficulties to be avoided in applying the electrolytic method to the analysis of pyritiferous ores. If one-gram samples of such ores are used the resulting solutions may possibly contain 0.2 g. of copper, 0.4 g. of iron and variable amounts of zinc, arsenic and lead.

Assuming first that arsenic is not present and that lead has been carefully removed as sulphate, it should be possible to separate all the copper by the use of the Winkler electrode and a current of 0.75 ampere within ninety minutes, provided the volume does not exceed 100 cc. and the solution does not contain more than five cc. of concentrated sulphuric and no nitric acid. To test the suggestion, a series of solutions containing 0.1956 g. of copper and 0.4 g. of ferric iron were electrolyzed under the conditions named, using the gauze electrode F. The results obtained were:

0.1957 0.1957 0.1958

Assuming that arsenic is also present, either the solution should be electrolyzed under the conditions named above, the deposit dissolved in nitric acid and re-electrolyzed; or, where the amount is small, good results might be expected from a single precipitation by adding to the solution from one to two cc. of nitric acid and 5 g. of urea. To test this suggestion, a series of solutions containing 0.1956 g. of copper and 0.4 g. of ferric iron and 0.01 g. of arsenic (added in the form of H_3AsO_4) were electrolyzed as before, after the addition of one cc. of nitric acid and 5 g. of urea. The results obtained were:

0.1959 0.1948 0.1957 0.1959

CHEMICAL LABORATORY,
UNIVERSITY OF CALIFORNIA

NOTE.

New Normal Solution and Reagent Bottle.—The new normal solution bottle which I have designed is the simplest and most effective of any that has come under my notice. The bottle is of the long narrow type, having a ground-glass cap. The cap and bottle are each provided with a groove which, when turned to coincide, allows the free entrance of air, while when turned in any other position forms an air-tight seal.

Into the bottle are drilled two small holes, one at the upper portion, the other near the bottom. A burette is procured whose delivery tube is bent at two right angles (or an ordinary burette which has been bent into this form). At the base of this burette an opening is blown, right in line with the graduated tube. To this opening a piece of glass tubing which is provided with a glass stopcock, and also has been bent at right angles, is fused. To the top of the burette another piece of glass tubing which has also been bent at right angles, is fused. The two ends which are now at right angles with the burette, and pointing in directly opposite direction from the delivery tube, are placed in their respective holes in the bottle and fused.

The support for the bottle is a light wooden frame, which in turn is suspended between two triangular racks by trunions, which allow the bottle free motion backward and forward. The bottles are never removed from these frames. When refilling is necessary the frame is lifted from its bearings and when the bottle is filled the frame is set back into position. On the base of each stand, between the triangular supports, a piece of white tile is fitted on which the titration is performed.

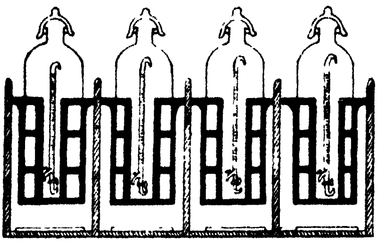

FIG. 1.

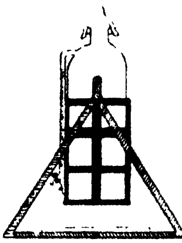

FIG. 2.

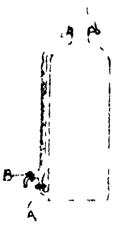

FIG. 3

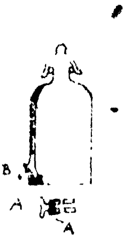

FIG. 4

In order to manipulate the bottle stopcock *A* (Fig. 3) is opened, stopcock *B* closed, the grooves in the cap and neck are brought to coincide, the bottle is then grasped by the neck and tilted forward, which allows the solution to flow up into the burette. Stopcock *A* is then closed while the bottle is still in its inclined position, preventing the solution from passing from the burette back into the bottle, the bottle is then allowed to regain its original upright position, and the burette is ready for operation. These bottles are arranged in series, as shown in Fig. 1, which is very convenient and requires very little space.

The new reagent bottle, as shown in Fig. 4, is constructed in the same manner as the normal solution bottle, excepting that the burette is part of the bottle and stopcock *A* is set into the bottle, allowing the bottle to be handled as any ordinary reagent bottle, as well as supplying a long-felt necessity, that of knowing the amount of reagent one is using either in qualitative or quantitative work, without going to the necessary trouble of using cylinders, pipettes, etc. One is also positive that no other reagent or dirt of any kind has come in contact with the measuring apparatus.

This bottle is manipulated in the same manner as the normal solution bottle, only held in the hand instead of a support. FRANK M. DAVIS.

METATHETICAL REACTIONS: ETHER-THIOUREAS AND THEIR RELATION TO PSEUDOAMMONIUM BASES.

BY TREAT B. JOHNSON AND HERBERT H. GUEST.[1]

Received June 18, 1910.

Contents.

I. Pseudoammonium Bases and Their Alcoholates. II. Ether-thioureas and Their Behavior towards Alcohols. III. Experimental Part

I. Pseudoammonium Bases and Their Alcoholates.

A characteristic feature of cyclic, quaternary bases (ammonium bases) is their tendency to undergo isomerization in aqueous solution. The hydroxyl group of the base migrates from nitrogen to a carbon atom, giving trivalent-nitrogen compounds or pseudoammonium bases (*ψ-ammonium bases*).[2] Decker calls these rearrangement products *oxydihydro* or *carbinol* bases.[3] These transformations in the acridine (I), quinoline (II) and isoquinoline (III) series are represented by the following formulas:

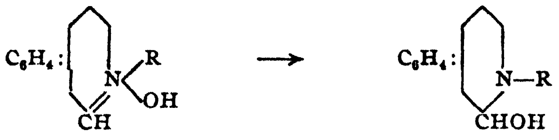
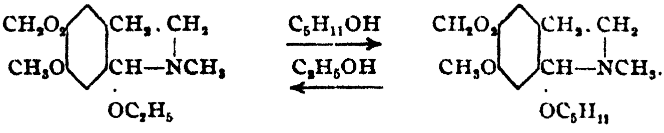
[3] *Ber.*, 25, 3327.



III. VI.

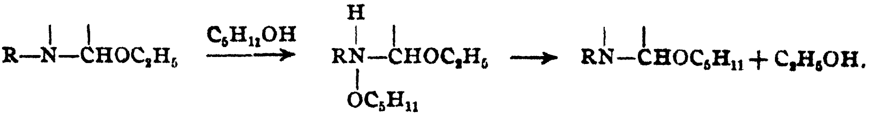
The pseudoammonium bases IV, V, VI (pyridines, quinolines, isoquinolines and acridines) are especially characterized by their behavior towards alcohols. They react at ordinary temperature, with loss of a molecule of water, giving alcoholates or ethers (Sauerstoffäther)[1] which are capable of undergoing unique transformations when warmed with alcohols. The characteristic behavior of these cyclic alcoholates is summarized in the following quotation from a paper by Decker[2] on the alcoholates of some quinoline pseudoammonium bases:

"Gegenüber Alkoholen mit anderen Radikalen verhalten sich die Alkoholate in der Weise, dass sie ihren an Sauerstoff gebundenen Alkylrest leicht und glatt gegen den Rest des in Überschuss angewandten anderen Alkohols umtauschen. So wurde das Methylalkoholat in einem Überschuss von Benzylalkohol unter Erwärmen gelöst und nach erkalten krystallisirte das characteristische Benzylalkoholate heraus." Kuntze,[3] for example, has recently shown that ethoxyhydrocotarnine (VII) and *l*-amoxyhydrocotarnine (VIII) react with *l*-amyl and ethyl alcohol, respectively, on warming, with transposition of their alkyl groups.



VII. VIII

Two theories have been advanced to explain the mechanism of this reaction of an alcoholate with alcohols. According to Decker[4] the alcohol first adds to the nitrogen atom of the alcoholate giving an unstable addition product, which then loses a molecule of alcohol giving a new alcoholate. This change involves necessarily a rearrangement of an alkoxy group from nitrogen to the carbon atom. These changes are represented by the following formulas:



$$R{-}\overset{|}{N}{-}\overset{|}{C}HOC_2H_5 \xrightarrow{C_5H_{11}OH} R\underset{\underset{OC_5H_{11}}{|}}{\overset{\overset{H}{|}}{N}}{-}\overset{|}{C}HOC_2H_5 \longrightarrow R\overset{|}{N}{-}\overset{|}{C}HOC_5H_{11} + C_2H_5OH.$$

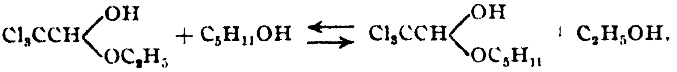
[3] *Arch. Pharm.*, 246, 110 (1908).

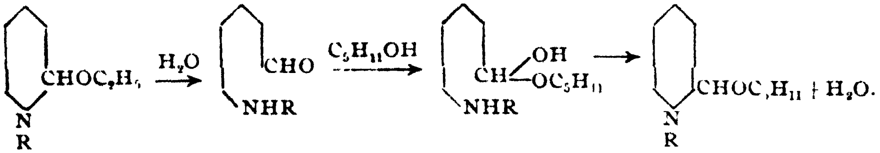
[4] *Ber.*, 33, 1715.

Gadamer[1] takes issue with Decker[2] and interprets these transformations of quinoline and isoquinoline alcoholates by typical, aldehyde reactions. According to him, the reaction is perfectly analogous to the action of alcohols on chloral alcoholates.[3] He assumes that the cyclic



$$Cl_3CCH\begin{matrix}OH\\OC_2H_5\end{matrix} + C_5H_{11}OH \rightleftarrows Cl_3CCH\begin{matrix}OH\\OC_5H_{11}\end{matrix} + C_2H_5OH.$$

alcoholates undergo partial dissociation in solution into alcohol and an aldehyde base. The latter then reacts with the alcohol in excess, by mass action, giving an aldehyde alcoholate, which then condenses to a new alcoholate of the pseudobase. These changes are represented by the following formulas:



He writes:[4] "Jedenfalls ist die Auffassung Deckers bezuglich der Ueberführung eines Alkoholates in ein anderes nicht haltbar. Man massenwirkung annehmen müssen. Diese setzt aber veraus, dass die Alkoholate in Aldehydbase und Alkohol dissoziiert sind."

The mechanism of these characteristic, metathetical reactions is still a subject of polemic. Therefore, with the possibility of obtaining new data which might contribute to our present knowledge of these transformations, it seemed desirable to investigate the behavior, towards alcohols, of some acyclic nitrogen compounds related in structure to cyclic pseudoammonium alcoholates. We selected, therefore, for our study some representatives of a new class of thioureas—*ether-thioureas*—recently described in this laboratory.

II. Ether-thioureas and Their Behavior towards Alcohols.

In a previous paper from this laboratory, the writers[5] have shown that certain primary halogen-ethers (IX) react smoothly with potassium thiocyanate giving isothiocyanates (X). We described isothiocyanodimethyl-, isothiocyanomethylethyl- and isothiocyanomethylisoamyl ethers and also several representatives of a new class of thioureas—*ether-thioureas* (XI). The latter were obtained by the action of these isothiocyanates on organic bases.

$RO.CH_2Cl$	$RO.CH_2NCS$	$ROCH_2NHCSNHR'$
IX.	X.	XI.

($R = CH_3, C_2H_5$. $R' = C_6H_5$, etc.)

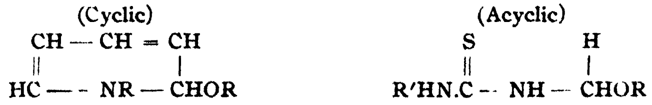
[4] *Arch. Pharm.*, 246, 96.

[5] *Am. Chem. J.*, 41, 337 (1909).

If a comparison is made of the structural formula of a pyridine alcoholate with that of an ether-thiourea, the fact is revealed that the thiourea and cyclic derivative are very closely related. In fact, the thiourea contains the same linking $=\underset{|}{C}.\underset{|}{N}.\underset{|}{CH}.OR$ as the cyclic alcoholate, and may be regarded as an acyclic pseudoammonium compound. These thioureas, therefore, might be expected to undergo transformations with alcohols analogous to those which have been observed to take place with the cyclic alcoholates. Our observations have confirmed such an assumption.



$(R = CH_3, C_2H_5.\ R' = C_6H_5, C_7H_7, \text{etc.})$

We find that it is a characteristic feature of every ether-thiourea which we have examined, to react with alcohols, on warming, with transposition of the alkyl groups. In order to purify them by crystallization from an alcohol it is necessary to use, as solvent, an alcohol containing the same alkyl group as that attached to oxygen in the ether-thiourea. Furthermore, the reactions are reversible and are not influenced by the boiling points of the alcohols, or by the size of the alkyl groups involved in the change.

$$R.NHCSNHCH_2OC_2H_5 + CH_3OH \rightleftarrows R.NHCSNHCH_2OCH_3 + C_2H_5OH,$$

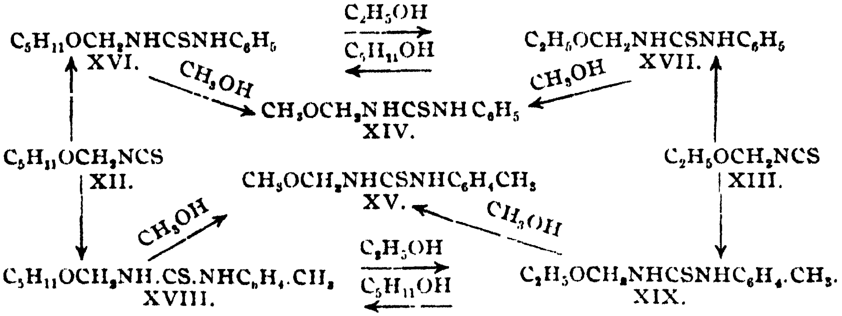
Our experiments were performed with the phenyl and *p*-tolyl ether-thioureas obtained by the action of aniline and *p*-toluidine on isothiocyanomethyl-, -methylethyl and -methylisoamyl ethers.[1] 1-Phenyl-2-isoamoxymethylthiourea (XVI) and 1-phenyl-2-ethoxymethylthiourea (XVII) were both converted smoothly into 1-phenyl-2-methoxymethylthiourea (XIV) by crystallization from methyl alcohol. The structure of this methoxy compound was established by the fact that it was identical with the methoxythiourea obtained by the action of aniline on isothiocyanodimethylether. Crystallization of 1-phenyl-2-isoamoxymethylthiourea (XVI) from ethyl alcohol gave 1-phenyl-2-ethoxymethylthiourea (XVII) which is changed practically quantitatively into the original isoamoxy compound by recrystallization from isoamyl alcohol.

Analogous transformations were obtained with the corresponding *p*-tolyl compounds: 1-Paratolyl-2-methoxymethylthiourea (XV) was prepared by the action of isothiocyanodimethyl ether on *p*-toluidine. This same thiourea was also formed smoothly when 1-paratolyl-2-isoamoxymethylthiourea (XVIII) and 1-paratolyl-2-ethoxymethylthiourea (XIX) were crystallized from methyl alcohol. Crystallization of 1-paratolyl-2-isoamoxymethylthiourea (XVIII) from ethyl alcohol gave 1-paratolyl-

---

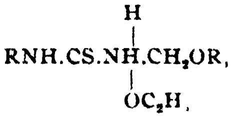
[1] Johnson and Guest, *Loc. cit.*

2-ethoxymethylthiourea (XIX), which is converted smoothly into the original isoamoxy derivative when warmed with isoamyl alcohol. These various transformations are represented by the following formulas:



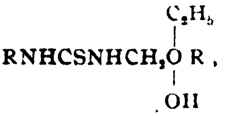
It is therefore possible, by application of this reaction, to prepare a whole series of ether-thioureas, RNH.CSNH.CH$_2$OR′, from one isothiocyanomethylether, R′OCH$_2$.NCS. In case it should be observed that certain primary, aliphatic halogen-ethers do not react, or perhaps react abnormally with potassium thiocyanate giving stable thiocyanates R.SCN, this reaction might be indispensable for the preparation of their corresponding thiourea derivatives.

It appears to the writers that the simplest explanation of these characteristic transformations of ether-thioureas is to assume the intermediate formation of unstable addition products, which then break down, giving a new thiourea and alcohol. Whether this involves an addition of the alcohol to nitrogen, as assumed by Decker, giving a compound XX, or an addition to the oxygen atom giving a carboxonium compound XXI, or thirdly a polymolecule XXII, we have at present no knowledge.



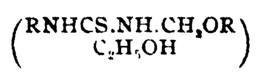
$$RNH.CS.\overset{H}{\underset{OC_2H_5}{N}}H.CH_2OR,$$

XX.



$$RNHCSNHCH_2\overset{C_2H_5}{\underset{OH}{O}}R,$$

XXI



$$\left(\begin{matrix}RNHCS.NH.CH_2OR\\ C_2H_5OH\end{matrix}\right)$$

XXII

The results which we have obtained do not support the theory advanced by Gadamer to explain the mechanism of the reaction of a cyclic alcoholate with alcohol. According to this interpretation, when an alcoholate reacts with alcohol, there is first a rupture of the bond between carbon and nitrogen of the alcoholate with intermediate formation of an aldehyde. In the case of an acyclic compound like 1-phenyl-2-ethoxymethylthiourea (XXIII), therefore, according to this explanation, formaldehyde (XXV) and phenylthiourea (XXIV) would be intermediate products of the reaction.

$$\underset{\text{XXIII.}}{C_6H_5NHCSNH.CH_2OR} \xrightarrow{H_2O} \underset{\text{XXIV.}}{C_6H_5NHCSNH_2} + \underset{\text{XXV.}}{CH_2O} + HOR.$$

If a hydrolysis of this character takes place then one would expect to obtain the same ether-thiourea by simply dissolving phenylthiourea in an alcoholic solution of formaldehyde. The facts do not support such a conclusion. We obtained no evidence of the formation of ether-thioureas when phenylthiourea or *p*-tolylthiourea were crystallized repeatedly from a methylalcohol solution of formaldehyde. They separated unaltered, and melting constantly at 154° and 188°, respectively.

III. Experimental Part.

1. Crystallization from Methyl Alcohol: 1-Phenyl-2-methoxymethylthiourea, $C_6H_5NHCSNHCH_2OCH_3$.—This thiourea was formed smoothly by recrystallization of 1-phenyl-2-ethoxymethylthiourea (m. 125–6°) from methyl alcohol. It separated in prismatic crystals melting at 133° (Kjeldahl):

Calculated for $C_9H_{12}ON_2S$: N, 14.28; found, 14.28.

This same thiourea, melting at 133°, was also obtained by crystallizing 1-phenyl-2-isoamoxymethylthiourea (m. 109°) from methyl alcohol (Kjeldahl):

Calculated for $C_9H_{12}ON_2S$: N, 14.28; found, 14.10.

1-Paratolyl-2-methoxymethylthiourea, $CH_3.C_6H_4NHCSNHCH_2OCH_3$, was prepared by crystallizing 1-paratolyl-2-ethoxymethylthiourea (m. 120°) from methyl alcohol. It melted at 129° to a clear oil. The same thiourea was also formed smoothly when 1-paratolyl-2-isoamoxymethylthiourea was crystallized from methyl alcohol (Kjeldahl):

Calculated for $C_{10}H_{14}ON_2S$: N, 13.33; found, 13.42, 13.30.

2. Crystallization from Ethyl Alcohol.—(*a*) When 1-phenyl-2-isoamoxymethylthiourea (m. 109°) was dissolved in hot, absolute ethyl alcohol and the solution cooled, pure 1-phenyl-2-ethoxymethylthiourea separated and melted at 125–6°. A mixture of this thiourea and the thiourea made from aniline and isothiocyanomethylethyl ether melted at the same temperature (Kjeldahl):

Calculated for $C_{10}H_{14}ON_2S$: N, 13.33; found, 13.08.

(*b*) When 1-paratolyl-2-isoamoxymethylthiourea was crystallized from hot, absolute ethyl alcohol it was converted smoothly into 1-phenyl-2-ethoxymethylthiourea melting at 120° to a clear oil (Kjeldahl):

Calculated for $C_{11}H_{16}ON_2S$: N, 12.43; found, 12.40.

3. Crystallization from Isoamyl Alcohol.—(*a*) 1-Phenyl-2-ethoxymethylthiourea (m. 125–6°) was crystallized two times from isoamyl alcohol when it was completely changed to 1-phenyl-2-isoamoxymethylthiourea melting at 109°. A mixture of this thiourea and the thiourea prepared from isothiocyanomethylisoamyl ether and aniline melted at the same temperature (Kjeldahl):

Calculated for $C_{12}H_{20}ON_2S$: N, 11.11; found, 10.99.

(*b*) 1-Paratolyl-2-isoamoxymethylthiourea (m. 119°) was obtained when 1-paratolyl-2-ethoxymethylthiourea was crystallized from isoamyl alcohol (Kjeldahl):

Calculated for $C_{14}H_{22}ON_2S$: N, 10.52; found, 10.56.

NEW HAVEN, CONN.

PHENYL ETHER AND SOME OF ITS DERIVATIVES.

BY ALFRED N. COOK

Received July 12, 1910

Bromination of Phenyl and Tolyl Ethers.

The ethers employed were all prepared by distilling the aluminium salts of the corresponding phenols. While the yield of phenyl and metatolyl ether was good, the yield of the ortho- and paratolyl ether was so small that, in some instances, it was found difficult to obtain a sufficient amount of some of the bromine derivatives to purify sufficiently to yield very satisfactory results on analysis, which accounts for some instances given below where there is considerable difference between the results of analysis and the requirements of calculation. The best yield of phenyl ether was obtained by distilling aluminium phenolate with a sharp heat; but in case of the tolyl ethers, the best yield was obtained by distilling with a low heat. A sharp heat gives rise to a greater proportion of higher boiling substances and less of the ether.

On distilling some aluminium paracresolate with a sharp heat, a peculiar phenomenon was observed, which was not noted in connection with the distillation of any other aluminium salt of the phenols. Bright flashes of light followed one another in quick succession on the surface of the boiling and decomposing liquid. This recalls the fact noted in connection with the distillation of aluminium phenolate in the preparation of phenyl ether, that the escaping gases occasionally ignited spontaneously on coming in contact with the air. In the present case, however, the evolving gases had not yet come in contact with oxygen and the phenomenon could not have been due to combustion.

On distilling some aluminium paracresolate which had been kept for a couple of months in a bottle with a defective cork, through which air had gained access and acted upon the substance, it was found that it yielded paracresol and almost no paratolyl ether and higher boiling substances. It did not melt down as the freshly prepared substance does, even when highly heated. It was found to dissolve very readily in absolute alcohol, carbon disulphide and various other organic solvents. On adding a little water to the solution there was thrown down a voluminous gelatinous precipitate. Its action is therefore exactly analogous to that of aluminium phenolate to which air in limited amount has had access for some time, and which has been described in a previous paper. *An* *investigation into the character and causes of these changes is now in progress in the chemical laboratory of the University of South Dakota.*

Bromination of Phenyl Ether.—Hoffmeister[1] prepared dibromophenyl ether by slowly adding bromine to phenyl ether dissolved in carbon disulphide, kept well cooled until the red color of the bromine ceased to vanish. Melting point, 55°. In an endeavor to prepare a higher bromine derivative, I added a large excess of bromine to some phenyl ether and allowed it to stand for three days with occasional shaking. The carbon disulphide was removed by evaporating on the water bath, which operation also removed a portion of the bromine not acted upon. The remainder of the excess of bromine was removed by washing with caustic soda solution. There was obtained a light yellow liquid of the consistency of glycerol, which failed to solidify on standing three months. It boiled at 240–260° at 30 mm. On analysis it yielded 59.6 per cent. of bromine. Theory would require 65.84 per cent. for the tetrabromo derivative and 48.78 per cent. for the dibromo derivative. It was apparently a mixture of the dibromo and tetrabromo derivatives, 36.5 per cent. of the former and 63.5 per cent. of the latter. From the experiments described below, one would not expect that a higher bromide would be found in the mixture.

Tetrabromophenyl ether ($(C_6H_3Br_2)_2O$) was prepared by gradually adding an excess of bromine to phenyl ether dissolved in carbon disulphide, to which had been added a little iodine to act as a carrier, and shaking meanwhile. The addition of iodine greatly facilitated the reaction, which was clear cut and rapid. In the beginning hydrobromic acid was given off very rapidly but gradually subsided and seemed to cease when sufficient bromine had been added to form the tetra compound. The solution was allowed to stand at room temperature for some time and then heated on the water bath to drive off the carbon disulphide and excess of bromine. There was obtained a red, viscous substance which became milk-white on washing with a solution of caustic soda, and on stirring with cold water it suddenly solidified. The yield of the crude product was quantitative and quite pure It distilled at 280–290° at 25 mm. and at 410–425° under ordinary atmospheric pressure. It is soluble in carbon disulphide and petroleum ether and insoluble in water, alcohol and most organic solvents. It crystallized in large, radial aggregations of swordlike needles The crystals obtained were about three-fourth inch in diameter. On cooling, *per se*, it likewise collects in radial masses on solidification. It is odorless and tasteless and colorless, but on continued exposure to light it turns slightly brownish. It melts at 83–84°. On analysis it yielded 65.56 per cent. of bromine. Calculated for $(C_6H_8Br_2)_2O$, 65.85 per cent.

[1] *Ann.*, **159**, 210.

Attempts were made to prepare the hexabromo, octobromo and decabromo derivatives. A little more than the calculated amount of bromine in each case was allowed to stand in contact with phenyl ether in the presence of iodine for several days with occasional shaking. In every case there was obtained only the tetrabromophenyl ether as shown by the melting point and analysis for bromine.

Dibromometatolyl ether ($CH_3C_6H_2Br—O—BrC_6H_2.CH_3$) was prepared by adding very gradually, with constant shaking, a little more than the theoretical amount of bromine to metatolyl ether dissolved in several times its weight of carbon disulphide. When the calculated amount of bromine required to form the dibromo derivative was added to the substance, *per se*, or in solution in carbon disulphide, in the dark, in direct sunlight, heated to the boiling point, at the temperature of the boiling water bath, at room temperature or at —20°, there was always formed, with equal facility, a dibromo compound which was identical in every instance. The yield was little short of quantitative. It was purified by repeated distillation, discarding the highest and lowest boiling portions each time. A portion was obtained which melted at 48°, but began to soften a few degrees lower. The substance boils at 340–350° (uncor.) under ordinary atmospheric pressure and at about 250° under 15 mm. pressure. The dibromo compound is a white, crystalline solid, which turns yellow with age. It tends to crystallize in warty aggregations on cooling from the molten state. It is soluble in carbon disulphide, alcohol, ether and several other organic solvents; sparingly soluble in absolute methyl alcohol and insoluble in water.

The substance was boiled with water and then with a strong solution of sodium hydroxide in the hope of introducing the hydroxyl group in place of the halogen atom, but without result. It was then heated in a closed tube to 200° for several hours with a strong solution of sodium hydroxide but there was no indication of any reaction. On analysis it yielded 44 55 per cent. of bromine. Calculated for $C_{14}H_{12}OBr_2$, 44 94 per cent.

Tetrabromometatolyl ether ($CH_3C_6H_2Br_2—O—C_6H_2Br_2.CH_3$) was found to be best prepared by adding an excess of the bromine required by calculation directly to the metatolyl ether in the presence of a little iodine and heating on the water wath to drive off the surplus bromine. The yield was very good. The substance was purified by repeated fractional distillation under diminished pressure. It boils at 260–270° under 35 mm. pressure, but decomposes when distilled under ordinary atmospheric pressure.

It is a light yellow, sticky, viscous substance, which crystallizes in warty aggregations on standing for some time. It becomes fluid on gently warming and is sôluble in carbon disulphide, but is insoluble in alcohol, ether, and most common organic solvents. The compound was boiled with water, a strong solution of potassium hydroxide, and water and precipitated calcium carbonate, respectively, for some hours, without any evidence of chemical action. It was heated in a closed tube with each of these reagents for three or four hours, at 200–300°. The tube containing potassium hydroxide showed some signs of chemical action, but it was by no means complete—in fact, it was only in the initial stage. The filtrate yielded a precipitate with silver nitrate in the presence of nitric acid which was soluble in ammonium hydroxide, and a small quantity of an organic substance, presumably, a hydroxymetatolyl ether, was precipitated by neutralizing with an acid. An analysis yielded 61.85 per cent. of bromine. Calculated, 62.26 per cent.

In one experiment in the bromination of metatolyl ether, the bromine was added to the metatolyl ether, *per se*, at 150° in direct sunlight, but the bromine, as shown by various experiments, was as firmly bound as in brominating at 0°. When double the amount of bromine was added, or even a much larger excess, there was produced, with equal readiness, a tetrabromo compound under varying conditions of sunlight and darkness, heat and cold. Some of the tetrabromo compound always appeared to be formed in preparing the dibromo derivative by employing the amounts of reacting substances required by calculation, and there always remained some of the other unacted upon, but only a very small amount. The reaction was quite clear cut and the two foreign substances were readily separated from the dibromometatolyl ether by fractional distillation. In the preparation of the tetrabromo derivative by employing the amounts of the reacting substances required by calculation, there was obtained a little tar and a very little of the dibromo compound was obtained, but the reaction was far more clear cut than is usual in similar cases. It proved impossible to induce metatolyl ether to combine with more than four atoms of bromine, no matter how large an excess was added. No carrier was used in these experiments. Subsequently metatolyl ether was brominated in the presence of a little iodine in order to determine whether a higher derivative would be formed, but only the tetrabromo compound was obtained, nor did the presence of iodine seem to facilitate the reaction to any extent. It would appear, therefore, that metatolyl ether is more easily brominated than phenyl ether.

I believe, for the following reasons, that the bromine enters the nucleus and not the side chain in these experiments. The bromine derivatives effectually resisted all attempts to prepare from them compounds analogous to benzyl alcohol and benzaldehyde by all of the common methods. The bromine is very firmly linked in these compounds, and all attempts to introduce the hydroxyl group in its place were unsuccessful. This is in accordance with what would be expected if the halogen entered the nucleus. Neither of the two compounds, when purified, gave off vapors which attack the mucous membrane of the eyes, as in case of substances formed by the halogen entering the side chain, but when freshly prepared, and before purification, they did have this property, indicating the possible formation of a small quantity of the side chain compounds. Perhaps the halogen might be induced to enter the side chain by employing a still higher temperature, in direct sunlight, but [illegible]riment was not tried on account of lack of both time and ma- [illegible]

[illegible]lyl ethers are markedly different from toluene and its homologs in their action toward bromine, for in these the halogen enters the side chain in direct sunlight, or at the boiling point of toluene, and it enters the nucleus in the dark, when cold.

4-Methyl-2',4'-Dinitrophenyl Ether and Derivatives.

Having carried out a number of reactions between potassium phenolate and the potassium cresolates, which have been reported in this and other journals, it was thought that it might be interesting and profitable to extend the study to bromdinitro benzene.

4-Methyl-2',4'-dinitrophenyl ether ($CH_3C_6H_4OC_6H_3(NO_2)_2$) was prepared by mixing molecular equivalents of potassium paracresolate and 1 bromo-2,4-dinitrobenzene and warming very gently to start the reaction. (In one instance when the two reacting substances had been finely powdered and intimately mixed, the reaction took place at ordinary room temperature, with considerable rise of temperature.) When the action was well started a gentle ebullition took place, which gradually died down when the reaction was completed.

The resulting substance was dissolved in hot alcohol, filtered from the precipitated bromide, and allowed to crystallize. After three recrystallizations it melted sharply at 93°. The yield was nearly quantitative. It is a yellow-colored substance, very soluble in hot alcohol, but sparingly soluble in the cold. It is also quite soluble in various other organic solvents. Analysis for nitrogen yielded 10 64 per cent. Calculated, 10 22 per cent.

On adding a solution of sodium hydroxide to some of the substance a reaction at once set up with evolution of heat. The compound was apparently saponified with the production of paracresol and 2,4-dinitrophenol.

The free sulphonic acid ($(NO_2)_2C_6H_3OC_6H_3CH_3SO_3H$) was prepared by dissolving the ether in concentrated sulphuric acid, by the aid of the boiling water bath, precipitating the excess of sulphuric acid with freshly prepared lead chloride, and then precipitating the lead with hydrogen sulphide and evaporating to crystallization.

It is very soluble in water and shows a tendency to crystallize in radial aggregations of fine needles, like many other derivatives of phenyl ether.

On heating to 85° in the air bath in contact with air it melted and lost in weight corresponding to one and one-half molecules of water of crystallization. However, when heated in a melting-point tube, it did not melt until the temperature of 150° was reached and then with apparent decomposition. When a weak water solution was mixed with sodium carbonate, calcium carbonate, and barium carbonate, it caused a brisk evolution of carbon dioxide. Its water solution is only slightly yellow but a solution of the barium salt in water is quite yellow, which becomes much more intense on heating. A solution of the sodium salt is much yellower still and intensifies on warming a few degrees.

Analyses resulted as follows:

Calculated for $C_{13}H_{10}O_8S + 1^1/_2H_2O$: S, 8.4 ; H_2O, 9 61
Found: S, 8 28; H_2O, 9 69, 9 53.

The barium salt, $((NO_2)_2C_6H_3OC_6H_3CH_3SO_3)_2Ba$, was prepared by dissolving the ether in concentrated sulphuric acid and diluting with a large amount of water, treating with an excess of barium carbonate to precipitate the sulphuric acid and change the sulphonic acid to the barium salt and evaporating to crystallization. Attempts to prepare the barium salt as in case of the mononitrophenyl ether, by precipitating the excess of sulphuric acid with barium chloride and then adding a sufficient amount to change the sulphonic acid to the barium salt, were unsuccessful. In attempting to crystallize the product formed, it seemed to decompose and form a compound insoluble in water.

The barium salt is light yellow in color, but when heated to 100° it assumes a much deeper tint. The water solution is much yellower than the salt itself. It is different from most of the barium salts of the sulphonic acid derivatives of the phenyl ethers thus far prepared in that it does not contain any water of crystallization.

On adding a few drops of concentrated hydrochloric acid to a solution of the barium salt, it clears up immediately, probably due to the formation of barium chloride and the liberation of the free sulphonic acid, which is nearly colorless. Two analyses yielded 16.30 and 16.29 per cent. of barium; calculated for $(CH_3.(NO_2)_2.C_7H_6OSO_3)Ba$, 16.34 per cent.

The sodium salt $((NO_2).C_6H_3OC_8H_8.CH_3SO_3NO)$ was prepared by precipitating the barium of the barium salt with sodium carbonate and also by neutralizing the free sulphonic acid with sodium carbonate and evaporating to crystallization in each case. When dry, the salt is light yellow in color but when moist it is brilliant yellow. Its water solution is very yellow. On adding a few drops of strong acid to a solution in water, the yellow color almost entirely disappears. It melted at 145°. On heating to 100°, it loses in weight, corresponding to one and one-half molecules of water of crystallization. On coming in contact with the air again for a few hours, it absorbs moisture from the air until it attains its original weight. An analysis resulted as follows:

Calculated for $C_{13}H_9O_8N_2SNa + 1^1/_2H_2O$: Na, 6 00; H_2O, 2.29.
Found: Na, 6.11; H_2O, 2.55.

Other Salts.--Attempts were made to prepare the chromium and cobalt salts by precipitating the barium from the barium salt by means of chromium sulphate and cobalt sulphate. Substances were obtained which were supposed to be the salts sought but they both decomposed on attempting to purify them by crystallization.

2 : 4-Dinitro-p-phenoxybenzoic acid ($(NO_2)_2.C_6H_3OC_6H_4.COOH$) was prepared by dissolving the dinitrophenylmethyl ether in glacial acetic acid and, while warming on the water bath, adding a solution of chromic anhydride in water until a test portion would yield a precipitate on addition of a large volume of water which would completely dissolve on addition of an alkali.

The acid was purified by dissolving in a dilute solution of ammonia, boiling off the excess of ammonia, precipitating the free acid again by adding hydrochloric acid and washing the precipitate free from chlorine. The acid is of a canary-yellow color. It is insoluble in water, ether, petroleum ether, methyl alcohol and benzene. It is only slightly soluble in ethyl alcohol It did not melt when heated to 200°.

The silver salt ($(NO_2)_2.C_6H_3OC_6H_4.COOAg$) was prepared by precipitation by adding silver nitrate to a solution of the ammonium salt obtained as described above. It is of a canary-yellow color at ordinary temperature, but darkens when heated to 100°, but does not lose in weight. Analysis yielded 26 09 per cent. of silver. Calculated, 26 27 per cent

Only one other of the nitrophenyl ethers heretofore prepared has yielded a carboxylic acid by oxidizing the side chain with chromic acid in acetic acid solution.

2,4-Dinitrophenyl Ether and Derivatives.

(The experimental work of this chapter was carried out by Mr. Carl Englund, under my direction.)

2,4-Dinitrophenyl ether ($C_6H_5OC_6H_3(NO_2)_2$) was prepared by grinding up in a mortar equimolecular quantities of potassium phenolate and 1,2,4-bromodinitrobenzene. A reaction began in the cold which was carried to completion by heating on a water bath. There resulted dinitrophenyl ether in the form of a brown oil and solid potassium bromide. The oil distilled without decomposition at 230–250° under a pressure of 27 mm. and solidified after standing for a short time. It was crystallized from hot alcohol several times and then melted sharply at 70°. The yield was quantitative.

2,4-Dinitrophenyl ether is very soluble in alcohol and various other organic solvents and slightly soluble in water. It has a faint odor and a burning, biting taste. An analysis for nitrogen yielded the following results: Calculated for $C_{12}H_8O_5N_2$, 10.70 per cent; found, 10.75 per cent.

Attempts to reduce the nitro groups with tin and hydrochloric acid were unsuccessful. The base decomposed immediately on exposure to the air.

Some of the 2,4-dinitrophenyl ether was heated with water at 100° for several hours in closed tubes with the idea of hydrolyzing the substance, but without effect. However, when heated under the same conditions with sodium hydroxide, chemical reaction had taken place. The tube was filled with ammonia gas and crystals of a foreign substance were deposited on standing. On account of lack of time, however, they were not studied farther.

2,4-Dinitrophenylethersulphonic acid ($(NO_2)_2.C_6H_3OC_6H_4.SO_3H$) was prepared by gently warming 2,4-dinitrophenyl ether with concentrated sulphuric acid. It yielded a solution which was not precipitated by the addition of water. The excess of sulphuric acid was precipitated by the addition of barium chloride On evaporating the filtrate on the water bath, the sulphonic acid was obtained in the form of pearly white flakes. It is easily soluble in water and has a strong, bitter taste much like picric acid.

The analysis for sulphur (though now lost) yielded results which corresponded with the requirements of theory.

The barium salt ($((NO_2)_2C_6H_3OC_6H_4.SO_3)_2Ba + {}^1/_2H_2O$) of the sulphonic acid was obtained by adding an excess of barium chloride to the solution of the sulphonic acid in dilute sulphuric acid, obtained as described above. On evaporating over the water bath, the barium salt of the sulphonic acid was obtained in the form of pearly flakes which do not melt without decomposition. It is difficultly soluble in cold water but readily soluble in hot water. On heating in the air bath to 200°, it lost in weight corresponding to one-half molecule of water of crystallization. Two analyses for barium yielded 16.93 per cent. and 16 86 per cent., respectively. Required by calculation, 16.85 per cent.

Several unsuccessful attempts were made to prepare other salts. Strontium carbonate, copper carbonate, and potassium carbonate were added to solutions of the pure sulphonic acid, and although effervescence took place in each case, no well defined salts were isolated.

Trinitrophenyl ether, $C_{12}H_7O(NO_2)_3$, was obtained by dissolving the dinitrophenyl ether in strong nitric acid. On pouring this mixture into water, there was precipitated a gummy mass, which solidified on rubbing up with cold water. It was crystallized from methyl alcohol and obtained in the form of warty masses and radiating clusters of yellow prismatic crystals. Two analyses yielded 14.29 and 14.23 per cent., respectively, of nitrogen. Calculation requires 13.77 per cent.

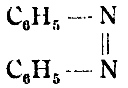
THE STEREOMERIC AZOBENZENES.

By Catherine V. Gortner and Ross Aiken Gortner

Received June 10, 1910.

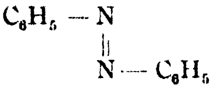
Introduction.

It is apparent from the structural formula of azobenzene that two stereomeric modifications should exist, one in which both aromatic nuclei are on the same side of the nitrogen bridge or *syn*-azobenzene (I), and the other where the nuclei are opposite each other or *anti*-azobenzene (II):



$$\begin{array}{r}C_6H_5-N\\ \|\\ C_6H_5-N\end{array}$$

(I)



$$\begin{array}{l}C_6H_5-N\\ \qquad\quad\|\\ \qquad\quad N-C_6H_5\end{array}$$

(II)

Although many such examples of syn and anti forms are known in the diazo compounds,[1] the authors are not aware of any such isomerism having been observed in the azo group.

Some years ago one of us had occasion to prepare azobenzene during a course in "organic preparations," but could not by any means obtain a compound melting at 68°, the melting point of azobenzene as described in the literature. Crystals were, however, obtained which melted at "about 23°," as the notes were then recorded. It afterward seemed probable that this was the unknown stereomeric form and we have recently taken up the subject again, obtaining results which lead us to believe that such was the case.

Experimental.

The azobenzene was produced by the dry distillation of azoxybenzene and clean iron filings from a small non-tubulated retort. The azoxybenzene was prepared according to the method of Lachman.[2]

Thirty grams of nitrobenzene were added to 250 cc. of methyl alcohol containing 40 grams of sodium hydroxide and the mixture heated during three hours on an actively boiling water bath. The methyl alcohol was then distilled off and the residue poured into ice-water. The azoxybenzene separated as an oil which soon became solid. This solid was well washed, melted with dilute hydrochloric acid to remove traces of aniline, washed free of acid, and recrystallized from 90 per cent. alcohol. Prepared in this manner, azoxybenzene forms small straw-colored needles, which melt at 36° (cor.); yield, 15–18 grams.

---

[1] Holleman, "Lehrb. d. Organ. Chem.," Leipzig, 1908, p. 362.

[2] This Journal, 24, 1178 (1902).

The azoxybenzene was dried on a porous plate and lastly at 110° for four hours. It was then finely pulverized and mixed with twice its weight of clean, dry iron filings and the mixture distilled. The distillate, in every case, was a red liquid containing a crystalline substance. The red portion was easily soluble in ligroin, leaving a mass of light gray needles, insoluble in ligroin, soluble to a considerable extent in alcohol and ether, containing nitrogen and melting at 237° (cor.), yield, about 1 per cent. of the azoxybenzene taken. This substance was not further investigated.

The deep red ligroin solution was thoroughly washed with cold dilute hydrochloric acid and then with water, filtered, and allowed to evaporate. In a number of instances preparations of azoxybenzene were obtained which yielded only ordinary azobenzene (m. p. 68°) crystallizing in prisms (see fig.). In several cases, however, only a deep red liquid was obtained, which, for a long time, we despaired of obtaining pure, as with the small amount available, distillations always resulted in considerable decomposition. This same red liquid was, also, often found in the mother liquors from which the 68° compound had crystallized.[1] At last, however, crystals were noticed in one preparation, from which other preparations were easily seeded. The crystals so obtained were pressed out on a porous plate, dissolved in ether, and the ether allowed

Crystals of Azobenzene

---

[1] Gattermann ("Practical Methods of Organic Chemistry," New York, 1903, p. 200) states that "if, on heating, a sudden but harmless explosion should occur, it is due to the fact that the substances were not dry; the experiment should be repeated." The authors have found that if the distillation is continued *after the explosion* a small yield of the "red liquid" usually results which can be easily separated from the "tar" by solution in ligroin. In several instances we have obtained fair yields of 25° azobenzene in this manner, but in no instance have we obtained the 68° modifications from the explosion residue.

to evaporate, the crystals again pressed out on a porous plate and the process repeated until the melting point remained constant. For analysis the product was dried *in vacuo* over concentrated sulphuric acid:

0.1171 gram gave 15.2 cc. nitrogen at 16.5° and 772 mm. Calculated for $C_{12}H_{10}N_2$: N, 15.38 per cent.; Found: N, 15.35 per cent.

This variety of azobenzene forms orange-red, stellate groups of needles (see fig.), is easily soluble in ether, ligroin, alcohol, acetone, methyl alcohol, etc., and melts at 25° (cor.) to a deep red liquid. It will not crystallize when "seeded" with the 68° substance, but in two instances we have succeeded in quantitatively transforming the 25° substance into the 68° substance, once by boiling with dilute hydrochloric acid, and in the other instance the cause of conversion is unknown to us. We can give no method which will always insure conversion, nor have we been able to transform the 68° substance into the 25° modification. According to Holleman,[1] the *syn* modifications are the least stable, so it seems probable that the new compound is *syn*-azobenzene. When a mixture of the two compounds occurs, the 68° isomer easily crystallizes out, leaving the 25° azobenzene practically free of the higher melting substance.

Reduction of the 25° Azobenzene.—1.75 grams of azobenzene melting at 25° were dissolved in 60 cc. of 50 per cent. alcohol and an excess of sodium amalgam was added. The reaction was allowed to proceed in the cold until all color had been discharged. The hydrazobenzene was precipitated from this solution by dilution, filtered off, and washed with dilute alcohol and then with water, dried at 100°, and recrystallized from ligroin, yield 1.50 grams, or 83 per cent. of the theoretical yield, m. p. 126° (cor.). When this hydrazobenzene was allowed to oxidize in the air, in the presence of alkali, and the oxidation mixture extracted with ether, only the 68° azobenzene was found to be present.

Summary.

1. A second stereomeric azobenzene has been isolated.

2. The new modification differs from the 68° isomer by melting at 25° (cor.) and crystallizing in stellate groups of needles.

3. From a mixture of the two isomers the 68° compound may be easily separated by crystallization, leaving the 25° isomer in the mother liquor.

4. The 25° azobenzene (probably *syn*-azobenzene) has been converted into the 68° isomer, but the reverse change has not been accomplished.

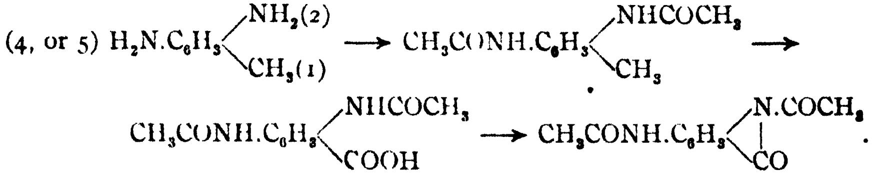
RESEARCHES ON QUINAZOLINES (TWENTY-FIFTH PAPER). THE SYNTHESIS OF 6- AND 7-AMINO-2-METHYL-4-QUINAZOLONES FROM 4- AND 5-ACETAMINOACETANTHRANILS.[1]

BY MARSTON TAYLOR BOGERT, CARL GUSTAVE AMEND AND VICTOR JOHN CHAMBERS.

Received August 10, 1910.

The 4- and 5-acetaminoacetanthranils were prepared from the corresponding diaminotoluenes by acetylating, oxidizing the acetyl derivatives with potassium permanganate in neutral solution, and treating the diacetamino acids with excess of acetic anhydride:

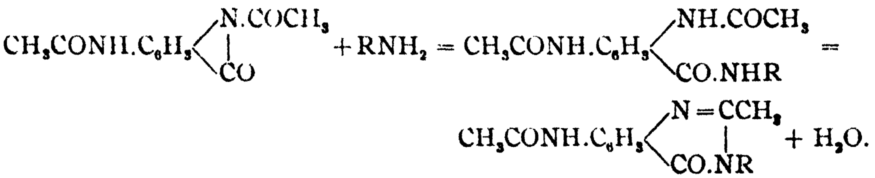


$$(4,\text{ or } 5)\ H_2N.C_6H_3\Big\langle\begin{matrix}NH_2(2)\\ CH_3(1)\end{matrix} \longrightarrow CH_3CONH.C_6H_3\Big\langle\begin{matrix}NHCOCH_3\\ CH_3\end{matrix} \longrightarrow$$

$$CH_3CONH.C_6H_3\Big\langle\begin{matrix}NHCOCH_3\\ COOH\end{matrix} \longrightarrow CH_3CONH.C_6H_3\Big\langle\begin{matrix}N.COCH_3\\ |\\ CO\end{matrix}.$$

The oxidation of the 2,5-diacetaminotoluene proved much more troublesome than that of the 2,4-isomer, and the yield of diacetamino acid considerably less.

By condensing these anthranils with primary amines,[2] acetamino-4-quinazolones result:



$$CH_3CONH.C_6H_3\Big\langle\begin{matrix}N.COCH_3\\ |\\ CO\end{matrix} + RNH_2 = CH_3CONH.C_6H_3\Big\langle\begin{matrix}NH.COCH_3\\ CO.NHR\end{matrix} =$$

$$CH_3CONH.C_6H_3\Big\langle\begin{matrix}N=CCH_3\\ |\\ CO.NR\end{matrix} + H_2O.$$

On splitting off the acetyl group, the free 6- or 7-aminoquinazolones were obtained, from which in turn other derivatives were produced.

The amines used in the experiments were ammonia, methyl, ethyl, normal propyl, secondary butyl and isoamyl amines, aniline, *p*-anisidine, *p*-phenetidine, *p*-aminobenzonitrile, α-naphthylamine, hydrazine, phenylhydrazine, and 7-amino-2-methyl-4-quinazolone. Of these, the condensation with the secondary butylamine (2-aminobutane), for some unknown reason, stopped at the amide stage. The other amines all gave quinazolones.

Of the four possible Bz-monaminoquinazolines, the 5-amino derivatives have been described by Bogert and Chambers[3] and the 7-amino by Bogert and Klaber[1] and Bogert and Kropff.[2] Zacharias[3] prepared a crude 8-amino-2-methyl-4-quinazolone, by reduction of the corresponding nitro compound, but failed to get the substance pure.

---

[3] THIS JOURNAL, 28, 208 (1906).

The 6-amino derivatives described in the following pages are the first definitely shown to belong to this series. It seems likely that the aminoquinazolines prepared by Griess[4] and by Niementowski[5] carry the amino group at position 6, although this remains to be proven. The same is true of the diaminoquinazoline of Niementowski,[6] where it is quite probable that the two amino groups are located at 6 and 8, although their position likewise has yet to be determined.

On account of the greater expense of the 2,5-diaminotoluene, most of our experiments were carried out with the 2,4-isomer, and the majority of the products are therefore 7-aminoquinazolines.

Practically all of the new products are crystalline solids of high melting or decomposing points. Some of the quinazolines are soluble in boiling water. Most of them are more or less soluble in alcohol and insoluble or difficultly soluble in ether. Those carrying the —CO.NH— $\rightleftarrows$ —C(OH) : N— grouping dissolve in cold caustic alkalies and are reprecipitated from these solutions on saturation with carbon dioxide, but this grouping is not affected by acylating agents or by phenylhydrazine.

With chloroform and alcoholic caustic alkali, both 6- and 7-aminoquinazolones give off a faint not unpleasant odor when heated.

By the diazo reaction, the amino group can be replaced by other groups or, by diazotizing and combining with suitable couplers, azo dyestuffs may be produced.

The acetaminoquinazolones can be directly nitrated or brominated.

In former papers from this laboratory[7] we have shown that by condensing acylanthranils with hydrazine hydrate, or with 3-aminoquinazolones, 3,3'-diquinazolonyls may be obtained. We have now found that Bz-amino-4-quinazolones can be similarly condensed with acylanthranils, and in this way have obtained a 3,7'-diquinazolonyl, where the union of the two heterocycles is an N–C instead of an N–N one:

In our study of the properties of 2-methyl-7-acetamino-3-amino-4-quinazolone, we were rather surprised to find that it failed to give the Bülow condensation[1] with diacetosuccinic ester.

Experimental.

I. Preparation of Anthranils.

4-Acetaminoacetanthranil,  $(4)CH_3CONH\,.\,C_6H_3\left\langle\begin{array}{l}CO(1)\\ |\\ N.COCH_3(2)\end{array}\right.$. — The 2,4-diaminotoluene was changed to the diacetaminotoluene by the action of acetic anhydride. The following was found to be the most rapid and satisfactory method of carrying out the acetylation:

Ten g. of the dry and finely pulverized diamine are added at once to about 20–25 g. pure acetic anhydride. An energetic reaction ensues, with considerable rise of temperature. As the reaction abates in violence, the rapidly thickening mass is stirred vigorously to insure complete contact with the anhydride. On cooling, the mass solidifies. The entire reaction is completed in a few minutes and without external heating. The product is washed thoroughly with water and then crystallized from the same, giving long, snowy, silky needles of the pure diacetaminotoluene.[2] From 30 g. pure diamine, we obtained 37.5–38.4 g. of the pure diacetyl derivative.

For most of our work, however, we used a crude commercial toluylenediamine, giving an acetylated product of darker color and in poorer yield. It was found unnecessary to purify this crude acetyl derivative, as the impurities were eliminated in the subsequent oxidation of the compound, and affected only the yield and not the purity of the oxidation product.

The 2,4-diacetaminotoluene was oxidized to the 2,4-diacetaminobenzoic acid by the action of potassium permanganate in neutral solution.[3] On the completion of the oxidation and concentration of the resulting solution of potassium diacetaminobenzoate, some unchanged diacetaminotoluene first separates and should be removed. On acidifying the filtrate, the acid precipitates in microcrystalline condition, sufficiently pure for the preparation of the acetanthranil. Starting with 20 g. of pure diacetaminotoluene, the yield of acid varied from 17.6–19.9 g. and half a gram of diacetaminotoluene was recovered unoxidized. With a like amount of the crude diacetaminotoluene, 2–3 g. remained unoxidized, and 15–16 g. of the acid were obtained.

In an attempt to nitrate this diacetaminobenzoic acid, it was treated with excess of fuming nitric acid at 35°. Most of the diacetamino acid dissolved, and on diluting the solution with water reprecipitated apparently unchanged, for when washed with water and recrystallized from alcohol, fine, colorless needles resulted, of approximately the same melting point (261° cor.) and composition (found: N, 12.0; theory, 11.86) as the original acid.

---

[1] *Ber.*, 39, 2621, 3372 (1907), *et al.*

[2] Koch, *Ann.*, 153, 132.

[3] Ullmann and Uzbachian, *Ber.*, 36, 1803 (1903).

Twenty to twenty-five g. acetic anhydride were heated to gentle boiling and 10 g. well-dried and finely pulverized diacetamino acid slowly stirred in, so that the solution remained fairly clear and gentle boiling continued. In this way, bumping is avoided. When the acid had all been added, the solution was concentrated to about half its original volume, and on cooling the mass solidified in rosettes of pale yellowish or colorless needles of the anthranil. Yield, somewhat over eight grams. Purified by crystallization from acetic anhydride, it forms colorless needles, m. p. 220° (cor.).

Found: N, 13.04. Calculated for $C_{11}H_{10}O_3N_2$: N, 12.90.

It is slightly tribo-electric. In presence of moisture, it is hydrated to the diacetamino acid. Heated with primary amines, it yields 7-acetamino-2-methyl-4-quinazolones.

2,5-Diacetaminobenzoic Acid, $(2,5)(CH_3CONH)_2C_6H_3.COOH$.—2,5-Diacetaminotoluene[1] was prepared by adding the diaminotoluene hydrochloride to a solution of fused sodium acetate in acetic anhydride, the temperature of the solution being maintained above the boiling point of acetic acid, then boiling the solution for a few minutes. When cold, the mixture was diluted with water and the precipitated acetyl derivative recrystallized from water, in which it is much more soluble than the 2,4-isomer. Yield, 21 g. acetyl derivative from 30 g. of the diamine hydrochloride.

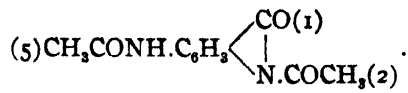
This acetyl derivative was oxidized with potassium permanganate in presence of magnesium sulphate. It is much more difficult to oxidize than the 2,4-isomer. From 10 g. of the diacetaminotoluene and 30 g. potassium permanganate (double the calculated amount), but 4 g. of the acid were obtained. A further increase in the amount of permanganate failed to increase the yield of acid. The acid precipitates usually in an amorphous state, but assumes a crystalline condition on standing. Treated with bone-black and recrystallized from alcohol, it forms minute, colorless crystals, melting with decomposition at 262° (cor.).

Found: N, 11.97. Calculated for $C_{11}H_{12}O_4N_2$: N, 11.86.

It is soluble in strong mineral acids and in aqueous solutions of caustic or carbonated alkalies, but is insoluble in dilute hydrochloric or in acetic acid. It dissolves also in nitrobenzene, aniline, or alcohol, but is not appreciably soluble in ether, carbon tetrachloride, ligroin or benzene.

---

[1] Nietzki, *Ber.*, 10, 1157 (1877); 12, 2237 (1879).



$$(5)\mathrm{CH_3CONH.C_6H_3}\left\langle\begin{array}{l}\mathrm{CO}(1)\\ |\\ \mathrm{N.COCH_3}(2)\end{array}\right.$$

5-Acetaminoacetanthranil, $(5)CH_3CONH.C_6H_3\langle CO(1) | N.COCH_3(2)\rangle$. — Five grams of the diacetamino acid were added to 10 g. hot acetic anhydride and the solution boiled down to one-third its original bulk. On cooling, the anthranil separated in coarse, yellowish-brown needles, which, recrystallized twice from acetic anhydride, still retained a faint yellowish-brown cast and melted at 253° (cor.). Yield, 3.5 g. anthranil from 5 g. acid.

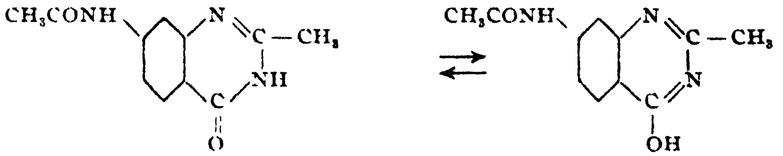
Found: N, 13.02. Calculated for $C_{11}H_{10}O_3N_2$: N, 12.90.

Like its isomer, this anthranil readily takes up moisture and reverts to the diacetamino acid. With primary amines, it yields 6-acetamino-2-methyl-4-quinazolones.

II. Quinazolones from 4-Acetaminoacetanthranil.

With the exception of the first compound, all the following quinazolines carrying the —CO.NH— $\rightleftarrows$ —C(OH) : N— group are, for the sake of brevity, denominated quinazolones and given the —CO.NH— formula.

7-Acetamino-2-methyl-4-quinazolone (*7-Acetamino-2-methyl-4-hydroxyquinazoline*),



Eight g 4-acetaminoacetanthranil were added to 50 cc. dilute ammonium hydroxide solution (10 cc. ammonium hydroxide solution of sp. gr. 0.9 to 40 cc. water) and the mixture heated a few minutes. The thick paste resulting was diluted with water to about 400 cc. and boiled for several minutes. Part dissolved and part separated (with more ammonia, a clear solution can be obtained, but the excess of ammonia must then be boiled off, or the separation of the product is not so complete). On cooling, the quinazolone separated form the solution in fine, short, silky, colorless needles, softening in the neighborhood of 342° and melting at 344° (cor.). Yield, 5.5 g.

Found: N, 19.53. Calculated for $C_{11}H_{11}O_2N_3$: N: H_2O, 19.35.

It is easily soluble in boiling water or in alcohol, slightly soluble in ethyl acetate, very difficultly soluble or insoluble in ether, carbon tetrachloride or toluene.

From water it crystallizes with water of crystallization: 1.0363 g. air-dried sample lost 0.15 g. on drying to constant weight at 100–10°.

Found: H_2O, 14.46. Calculated for $C_{11}H_{11}O_2N_3.2H_2O$: H_2O, 14.23.

7-Amino-2-methyl-4-quinazolone.—Five and one-half g. of the above acetyl derivative were boiled for about an hour with dilute potassium hydroxide solution (5 g. KOH to 50 cc. water), the solution cooled, diluted, filtered, and the filtrate saturated with carbon dioxide. The aminoquinazolone separated in fine, silky, colorless hairs, rapidly assuming a faint pinkish cast on standing. It can be further purified by recrystallization from dilute alcohol. From water it crystallizes with half a molecule of water of crystallization:

Found: H_2O, 4.8. Calculated for $(C_9H_9ON_3)_2\ H_2O$: H_2O, 4.9.

The anhydrous compound melts at 311° (cor.).

Found: C, 61.7 and 61.8; H, 5.1 and 5.2. Calculated for $C_9H_9ON_3$: C, 61.7; H, 5 1.

The substance is therefore identical with the 7-amino-2-methyl-4-quinazolone prepared by Bogert and Klaber[1] by reduction of the corresponding nitro compound.

It is tribo-electric, and gradually darkens on standing in the air. It is readily soluble in hot acetone, very slightly soluble in hot benzene, and apparently insoluble in ligroin. Boiled with alcoholic potassium hydroxide solution and chloroform, it emits an odor, presumably of an isonitrile, and yet of a rather pleasant banana-like character.

Bogert and Seil[2] found that when 5-nitro-2-methyl-3-amino-4-quinazolone was heated with phenylhydrazine, the 3-amino group was replaced by the phenylhydrazino group and the CO of the quinazolone reacted with a second molecule of the hydrazine, the result being a phenylhydrazinophenylhydrazone. A similar reaction did not occur when the above 7-amino-2-methyl-4-quinazolone and phenylhydrazine were heated together, alone or in alcoholic solution. No ammonia was evolved and the original quinazolone was recovered unaltered. It seems strange that the Bz-amino group failed to react, as an aromatic amino group can thus often be replaced directly by the phenylhydrazino group.

When the aminoquinazolone was boiled with formaldehyde and potassium cyanide, a reaction took place, but we failed to isolate any new products from the mixture. No change occurred when the aminoquinazolone was boiled with ethyl chloroacetate.

Azo dyestuffs can readily be produced from this amine by the usual diazotizing and coupling reactions.

Potassium Salt.—Square, colorless plates, easily soluble in cold water, but slightly soluble in alcohol.

Hydrochloride.— Prepared by the action of strong hydrochloric acid upon the free base or upon its ethyl acetate solution. Light brown, granular powder, decomposing on heating.

Chloroplatinate—Red, granular crystals.

Found: Pt, 25.6. Calculated for $(C_9H_{10}ON_3)_2PtCl_6$: Pt, 25.6.

---

[1] THIS JOURNAL, 30, 810 (1908).

[2] *Ibid.*, 28, 88 (1906).

Dinitro-7-acetamino-2-methyl-4-quinazolone. — The acetaminoquinazolone was added to a slight excess of fuming nitric acid at room temperature. It dissolved in the acid with a hissing sound and rise of temperature, and the solution finally set to a solid mass. Water was added and the temperature raised to boiling. During the boiling some decomposition was indicated by an escape of carbon dioxide. The solution on cooling deposited the nitro compound as a dark orange, sandy precipitate. After several recrystallizations from dilute acetic acid, it was obtained in orange, sandy crystals, melting with decomposition at about 302° (cor.). Yield, very poor.

Found. N, 22.9. Calculated for $C_{11}H_9O_6N_5$: N, 22.8

It is soluble in boiling water, very slightly soluble in boiling alcohol, in ether or in nitrobenzene. In aqueous caustic alkalies, it dissolves to a dark orange solution, from which it is precipitated slowly by saturation with carbon dioxide, more rapidly by acidification with acetic acid. The positions of the nitro groups were not determined, but it seems most likely that they are 6 and 8.

Bromo-7-acetamino-2-methyl-4-quinazolone. — The acetaminoquinazolone was suspended in dilute (50 per cent.) acetic acid and the mixture warmed Bromine was then added carefully to the warm solution. The reaction was vigorous, hydrobromic acid being evolved and the quinazolone dissolved. Soon thereafter the bromoquinazolone began crystallizing from the hot solution in minute needles. The solution was cooled, water added, the precipitate filtered out, washed, and recrystallized from dilute acetic acid or from a mixture of alcohol and acetic acid, in both of which it is rather difficultly soluble. It was thus obtained in minute needles, practically colorless, which began to darken at about 287° (cor.) and melted at 292° (cor.).

Found: N, 14.1; Br, 27.75. Calculated for $C_{11}H_{10}O_2N_3Br$: N, 14.2, Br, 27.03.

It is difficultly soluble in boiling alcohol. The use of a large excess of bromine in the above method of preparation gave the same product.

Bromo-7-amino-2-methyl-4-quinazolone. — The acetyl derivative just described was boiled for about an hour with ten per cent. potassium hydroxide solution, the solution cooled, diluted, filtered, and the filtrate saturated with carbon dioxide. The light yellow flocculent precipitate which separated was washed with water and purified by two crystallizations from alcohol. Light yellow flaky crystals were obtained, melting at 272–3° (cor.).

Found: N, 16.55. Calculated for $C_9H_8ON_3Br$: N, 16.53.

The substance is tribo-electric. It is moderately soluble in cold alcohol, easily in hot. It also dissolves in hot water, in warm nitrobenzene or isoamyl alcohol, but is apparently insoluble in ether, carbon tetrachloride or chloroform. The position of the bromine was not determined. Probably it is at 6.

7-Formamino-2-methyl-4-quinazolone, $HCONH.C_6H_3.CO.NH.C(CH_3) : N$.—7-Amino-2-methyl-4-quinazolone was boiled for four hours with excess of glacial formic acid, the excess of acid distilled off, the residual solution diluted, precipitated with sodium carbonate, and the precipitate crystallized from water. Colorless feathery crystals resulted, darkening at about 300°, softening in the neighborhood of 335°, and melting finally at 339–40° (cor.).

Found: N, 20.46. Calculated for $C_{10}H_9O_2N_3$: N, 20.69.

On standing a few days with ammoniacal silver nitrate solution to which a little sodium hydroxide has been added, it gives a silver mirror.

7-Propionamino-2-methyl-4-quinazolone, prepared in similar fashion, from the aminoquinazolone and propionic anhydride, crystallizes from water in long, white, silky needles, softening at about 317–20°, and melting at 326–7° (cor.).

Found: N, 18.48. Calculated for $C_{12}H_{13}O_2N_3$: N, 18.18.

It is tribo-electric and rather difficultly soluble in water or alcohol. In the latter solvent, it is much less soluble than the free aminoquinazolone. In hot, dilute organic acids, it is moderately soluble.

7-Hydroxy-2-methyl-4-quinazolone, $HO.C_6H_3.CO.NH.C(CH_3) : N$.—The 7-amino-2-methyl-4-quinazolone was dissolved in dilute hydrochloric acid and treated at 0° with the calculated amount of sodium nitrite in aqueous solution. Upon completion of the reaction, the mixture was diluted with water and boiled. Nitrogen was evolved freely and the color of the solution changed from yellow to orange. When the evolution of nitrogen ceased, the solution was allowed to cool. A small amount of flaky precipitate separated, but without removing this the mixture was neutralized with sodium carbonate. A voluminous yellow precipitate resulted. As we failed to get good crystals of this from any of the ordinary solvents, it was treated with moderately strong hydrochloric acid, which dissolved the greater part of it. The insoluble, dark orange portion was filtered out, and the filtrate neutralized with sodium carbonate. The light brown precipitate thus produced was again dissolved in hydrochloric acid, the solution filtered, and the filtrate reprecipitated with sodium carbonate. It was then dissolved in caustic alkali, yielding a red solution, reprecipitated with acetic acid, and dried. As thus purified, it formed a light brown powder, beginning to darken at about 345°, but not melting at that temperature.

Found: N, 16.28. Calculated for $C_9H_8O_2N_2$: N, 15.91.

It dissolves in hot alcohol or hot dilute acetic acid, but does not crystallize well from either solvent. It is soluble to a red solution in potassium hydroxide, and is reprecipitated from this solution by acetic acid but not by carbon dioxide. It is insoluble in ether, chloroform, carbon tetrachloride, benzene, toluene or acetone, but dissolves in hot isoamyl alcohol, aniline or nitrobenzene.

That portion of the original reaction product which was insoluble in the hydrochloric acid and dark orange in color, dissolved in potassium hydroxide solution with a red color, and when reprecipitated with hydrochloric acid came down in a gelatinous, colloidal condition which could not be further purified because of the small amount of material available.

7-Acetoxy-2-methyl-4-quinazolone, $CH_3COO.C_6H_3.CO.NH.C(CH_3) : N$.—On boiling the above 7-hydroxyquinazolone for an hour with excess of acetic anhydride, a reddish brown solution was obtained. This was cooled, diluted, and neutralized with sodium carbonate, giving a fine light brown precipitate which, on crystallization from alcohol, appeared in large pale brownish needles, softening at about 262° and melting at 266° (cor.).

Found:	C, 60 53;	H, 4.83;	N, 13.06.
Calculated for $C_{11}H_{10}O_3N_2$:	C, 60.55;	H, 4.60;	N, 12.84.

7-Cyano-2-methyl-4-quinazolone, $NC.C_6H_3.CO.NH.C(CH_3) : N$.—The 7-amino-2-methyl-4-quinazolone was diazotized and boiled with copper potassium cyanide solution. The precipitate was filtered out, washed with water, dried and extracted with carbon tetrachloride, to free it from metallic cyanides. On evaporating the carbon tetrachloride, a colorless crystalline mass remained, which was further purified by two crystallizations from alcohol, and then appeared in colorless feathery needles, melting at about 303–4° (cor.), and not volatile with steam.

Found: N, 22.0. Calculated for $C_{10}H_7ON_3$: N, 22.6.

The unsatisfactory character of this analytical result is due partly to the fact that the yield of product in the above reaction is very small and we did not have sufficient to run a good analysis. From 5 g. of the amino compound, the yield of pure cyano compound was only 0.1 g. This was particularly disappointing, as we had hoped to obtain sufficient to saponify to the corresponding acid, for the latter has already been described in a previous paper from this laboratory.[1]

7-Acetamino-2,3-dimethyl-4-quinazolone,

$CH_3CONH.C_6H_3.CO.N(CH_3).C(CH_3) : N$, was prepared from 4-acetamino acetanthranil in essentially the same manner as the monomethyl compound, using methylamine instead of ammonia. Recrystallized from alcohol, it forms colorless silky needles, melting at 284° (cor.).

---

[1] Bogert, Wiggin and Sinclair, THIS JOURNAL, 29, 87 (1907).

Found: N, 18.5. Calculated for $C_{12}H_{13}O_2N_3$: N, 18.2.

It is soluble in hot water or in alcohol, slightly soluble in acetone, insoluble in ether, carbon tetrachloride or ligroin.

7-Amino-2,3-dimethyl-4-quinazolone.—The above acetyl derivative was heated for about an hour with 10 per cent. potassium hydroxide solution in excess, the solution filtered hot, and the filtrate allowed to cool. The free base separated as the filtrate cooled in rosettes of fine colorless silky needles (or short heavy prisms, if the cooling occurred very slowly), which darkened on exposure to the air, and on recrystallization from water melted at 224° (cor.).

Found: N, 22.36. Calculated for $C_{10}H_{11}ON_3$: N, 22.22.

The substance is easily soluble in warm water, alcohol or benzene, slightly soluble in chloroform, insoluble in ether or ligroin. On attempting, by means of the diazo reaction, to replace the amino group by an OH, the yield of product was so small that the effort was abandoned.

Chloroplatinate.—Red crystals.

Found: Pt, 24.6. Calculated for $(C_{10}H_{11}ON_3)_2PtCl_6$: Pt, 24.7.

7-Acetamino-2-methyl-3-ethyl-4-quinazolone. — 4-Acetaminoacetanthranil was heated with an aqueous ethylamine solution. The anthranil dissolved and, on cooling, the quinazolone separated in colorless, glistening, pearly plates. Recrystallized from alcohol, it formed short colorless needles, melting at 254° (cor.).

Found: N, 17 07. Calculated for $C_{13}H_{15}O_2N_3$. N, 17.14.

It crystallizes from water in clusters of long, colorless, silky needles, slightly soluble in cold, readily in warm alcohol.

*7-Acetamino-2-methyl-3-*n*-propyl-4-quinazolone.* — 4-Acetaminoacetanthranil was added to the *n*-propylamine diluted with a little water, and the mixture heated. The anthranil dissolved and, on cooling, the quinazolone precipitated in colorless, silky needles. Recrystallized from water, rosettes of needles were obtained, melting at 206–7° (cor.).

Found: N, 16.46. Calculated for $C_{14}H_{17}O_2N_3$: N, 16.22.

*2,4-Diacetamino-*sec.*butylbenzamide*, $(2,4)(CH_3CONH)_2C_6H_3CONHC_4H_9$. —No condensation could be effected with the anthranil and a dilute aqueous solution of secondary butylamine (2-aminobutane), but when the anthranil was boiled with the pure amine, colorless needles separated from the solution on cooling. These needles were purified by repeated crystallization from dilute alcohol, giving finally a m. p. of 235° (cor.). Dried at 100–20°, the substance was analyzed with the following result:

Found: N, 14.61. Calculated for the quinazolone ($C_{15}H_{19}O_2N_3$): N, 15.38; for the intermediate amide ($C_{15}H_{21}O_3N_3$): N, 14.43.

The product is thus apparently the amide and not the expected quinazolone. It forms short, colorless needles. Boiled with water, these crystals dissolve, but do not separate again as the solution cools. Treated with potassium hydroxide solution, acetanthranilic acid results and not the quinazolone.

7-Acetamino-2-methyl-3-isoamyl-4-quinazolone.—When 4-acetaminoacetanthranil was heated with a dilute aqueous solution of isoamylamine, no quinazolone was obtained. The anthranil was therefore added directly to the pure undiluted amine and the mixture heated. The anthranil dissolved, but nothing separated from the solution on cooling. It was then diluted and heated, and on cooling the quinazolone separated as a white, flaky precipitate. Recrystallized repeatedly from dilute alcohol, it was obtained in rosettes of colorless, silky, feathery needles, melting at 288° (cor.), soluble in alcohol, difficultly soluble in cold water, moderately soluble in hot.

Found: N, 14.76. Calculated for $C_{16}H_{21}O_2N_3$: N, 14.63

7-Acetamino-2-methyl-3-phenyl-4-quinazolone was obtained by heating the anthranil and aniline together. Recrystallized from alcohol, it formed minute, colorless, pearly octahedra, melting at 276° (cor.).

Found: N, 14.24. Calculated for $C_{17}H_{15}O_2N_3$. N, 14.33.

It is apparently insoluble in ether, chloroform, acetone or water; very slightly soluble in hot carbon tetrachloride; but dissolves readily in hot alcohol or nitrobenzene.

*7-Acetamino-2-methyl-3-*p*-anisyl-4-quinazolone.*—1.09 g. of 4-acetaminoacetanthranil and 0.61 g. *p*-anisidine were intimately mixed and the mixture heated. At 55° it formed a thick paste, gradually growing more fluid up to 90° when the mass solidified The temperature was then raised to 100° and the salmon-colored mass, after a short heating at this temperature, allowed to cool. Crystallized from dilute alcohol, flesh-colored, glistening octahedra were obtained, melting at 273° (cor.), easily soluble in hot alcohol, apparently insoluble in water, ether or chloroform.

Found. N, 13.2. Calculated for $C_{18}H_{17}O_3N_3$: N, 13.0.

*7-Acetamino-2-methyl-3-*p*-phenetyl-4-quinazolone.*—0.7 g. *p*-phenetidine was dissolved in dilute alcohol, 1 g. 4-acetaminoacetanthranil added, and the temperature raised to boiling. No condensation took place. But when the two substances were heated together dry at 95°, in the same proportion, the mixture first liquefied, then solidified (at about 80°). The crude product on crystallization from dilute alcohol gave clusters of fine short needles, of a slight pinkish cast, and melting at 259° (cor.).

Found: C, 67.50; H, 5.88; N, 12.66. Calculated for $C_{19}H_{19}O_3N_3$: C, 67.66; H, 5.64; N, 12.46.

It is difficultly soluble in hot water or in carbon tetrachloride, insoluble in ether, but dissolves in boiling benzene, and is easily soluble in warm chloroform, ethyl or isoamyl alcohol. The structure of this compound recalls rather remotely that of phenacetine, but its physiological properties have not been studied.

4-Acetaminoacetanthranil and p-*Aminobenzonitrile.*—2.18 g. of the anthranil were heated with 1.18 g. of the nitrile. At 85° the mixture formed a thick paste, which became thinner as the temperature rose. At 140° the heating was interrupted and the melt allowed to cool. When the crude product was crystallized from dilute alcohol, rosettes of pale yellowish, downy needles were obtained, very strongly tribo-electric and softening at about 240°. Recrystallized until colorless, these needles melted at 258° (cor.) with decomposition.

Found: N, 13.36. Calculated for the quinazolone ($C_{18}H_{14}O_2N_4$): N, 17.61.

The product is evidently not the quinazolone. Dried three hours at 130–60° and again analyzed, the nitrogen percentage was found to be 13.41, *i. e.*, practically unchanged.

The substance is soluble in alcohol, insoluble in water. In dilute alcohol, it gives an opalescent solution. Boiled with dilute (10 per cent.) potassium hydroxide solution, it dissolves with copious evolution of ammonia, but no precipitate results when the solution is acidified with acetic or hydrochloric acid. Attempts to prepare an acetyl derivative were unsuccessful.

In another experiment, the constituents were heated to a somewhat higher temperature (170°), but the product showed the same melting point (258° cor.) and approximately the same nitrogen percentage (found, 12.96 per cent.).

7-Acetamino-2-methyl-3-α-naphthyl-4-quinazolone.—1.09 g. 4-acetamino acetanthranil and 0.715 g. α-naphthylamine were heated together. The mixture became pasty at about 50°, quite fluid at 80–100°, thickening again at 120°. The heating was carried to 150° and the melt then allowed to cool. When cold it was brittle and highly tribo-electric. Treated with cold chloroform, it dissolved and then light-colored flakes gradually separated. On warming, this precipitate increased. It was filtered from the warm solution, washed with ether and dried. The product is a pale gray powder, melting at 256° (cor.).

Found: N, 12.05. Calculated for $C_{21}H_{17}O_2N_3$: N, 12.24.

It appears to be less soluble in hot than in cold chloroform. It is soluble also in methyl or ethyl alcohol, or in glacial acetic acid, but insoluble in ether.

7-Acetamino-2-methyl-3-amino-4-quinazolone.—On mixing 4-acetamino-acetanthranil and hydrazine hydrate in equimolecular proportion and heating the mixture to boiling, the anthranil dissolved, and soon there separated from the boiling solution fine, colorless, glistening needles which, when recrystallized from 95 per cent. alcohol, carry a molecule of water of crystallization, the anhydrous base melting at 268° (cor.).

Found: H_2O, 7.31. Calculated for $C_{11}H_{12}O_2N_4.H_2O$: H_2O, 7.2
Found: N, 24.38. Calculated for $C_{11}H_{12}O_2N_4$: N, 24.14.

The water of crystallization is not easily driven out at 110°, but can be removed by drying at 125–30°. The anhydrous base is practically insoluble in ether, benzene, water or cold alcohol; difficultly soluble in chloroform; moderately soluble in hot, dilute alcohol; easily soluble in warm nitrobenzene.

When an equimolecular mixture of the above quinazolone and diacetosuccinic ester, dissolved in glacial acetic acid, was boiled for an hour, no condensation occurred. When a little acetic anhydride was added to the glacial acetic acid solution, the only effect was acetylation of the amino group. The two substances were therefore fused together without solvent. A brown paste resulted at about 210°, considerable acetic acid being evolved during the fusion. When cold, the mass was pulverized, and the tan-colored product crystallized thrice from alcohol, giving short, tan-colored needles, melting at 253–4° (cor.) which, on further purification, proved to be only the unchanged quinazolone. The reaction therefore involved only the breaking down of the diacetosuccinic ester and no condensation to a pyrrole derivative. We had expected, from the investigations of Bülow[1] and our own experience with —N — NH_2 quinazolones, to get the pyrrole compound.

Hydrochloride.—The aminoacetaminoquinazolone was suspended in ether and the solvent saturated with dry hydrogen chloride. The free base was thus changed to the hydrochloride and remained insoluble in the ether. It was filtered out, washed with ether, and dried *in vacuo* over potassium hydroxide.

Found: N, 19.65. Calculated for $2C_{11}H_{12}O_2N_4.3HCl$: N, 19.53.

Short, colorless needles, darkening somewhat at about 305°, and melting with vigorous decomposition at 312° (cor.).

When the aminoquinazolone was dissolved in 95 per cent. alcohol and the solution saturated with dry hydrogen chloride, no hydrochloride was formed, the unchanged quinazolone itself precipitating.

2,4-Diacetaminobenzohydrazide, $(2,4)(CH_3CONH)_2C_6H_3CONHNH_2$.—In the interaction of the acetaminoacetanthranil and hydrazine hydrate (in 50 per cent. aqueous solution), if the anthranil is added to the hydrazine hydrate solution without heating, it remains in suspension for a few seconds, then heat is evolved and finally a snowy pasty mass is formed made of fine short needles. If water be now added and the mixture boiled, the aminoacetaminoquinazolone described above is formed.

---

[1] *Ber.*, 39, 2621, 3372 (1906), etc.

If, on the other hand, these first crystals be filtered out, recrystallized from alcohol, and dried at 80°, the hydrazide is the product.

Found: N, 22.43. Calculated for $C_{11}H_{14}O_3N_4$: N, 22.4.

Dried six hours at 120–40°, no loss of weight occurred and no important change in the nitrogen percentage (found, 22.55 per cent. nitrogen). The crystals melt at the same point as the 7-acetamino-2-methyl-3-amino-4-quinazolone, probably passing into this by loss of water at higher temperatures.

3,7-Diacetamino-2-methyl-4-quinazolone, prepared from the aminoacetaminoquinazolone by the action of acetic anhydride, crystallizes from water with water of crystallization. These hydrated crystals melt down at 100°. From alcohol, it crystallizes in minute, colorless crystals, melting at 304° (cor.).

Found: N, 20.34 and 20.44. Calculated for $C_{13}H_{14}O_3N_4$: N, 20.44.

Excess of acetic anhydride causes no further acetylation.

3,7-Diamino-2-methyl-4-quinazolone. — 7-Acetamino-2-methyl-3-amino-4-quinazolone was boiled for half an hour with dilute (10 per cent.) potassium hydroxide solution. On cooling, colorless, silky needles were deposited in clusters in such amount that the whole mass solidified. These crystals were washed with water and recrystallized from dilute alcohol, melting then at 238° (cor.).

Found: N, 29.7. Calculated for $C_9H_{10}ON_4$: N, 29.5

7-Acetamino-2-methyl-3-anilino-4-quinazolone,

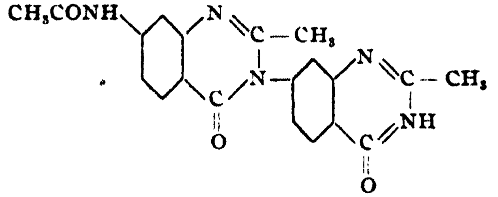
$CH_3CONH.C_6H_3.CO.N(NHC_6H_5).C(CH_3):N$. — 4-Acetaminoacetanthranil was added to an equimolecular amount of phenylhydrazine in alcoholic solution and the mixture heated to boiling. A clear yellow solution resulted which gradually changed to dark red on continuing the heating. After a half hour's boiling, the solution was concentrated and allowed to cool. Nodules of fine yellow needles were deposited. After several recrystallizations from alcohol, they appeared as colorless, feathery needles, softening at about 208°, and melting at 214° (cor.).

Found: N, 18.4. Calculated for $C_{17}H_{16}O_2N_4$: N, 18.2.

The substance is soluble in hot water, benzene, chloroform, acetone, ethyl or isoamyl alcohol, or in nitrobenzene, less readily in ether or in carbon tetrachloride.

When the anthranil was added to a slight excess of pure and undiluted phenylhydrazine and the mixture gently warmed, the anthranil dissolved and the reaction proceeded with violent ebullition even when the source of external heating was immediately removed at the beginning of the reaction. It is likely that deeper-seated changes accompanied this reaction, as we failed to isolate any of the above anilino derivative among the products.

7-Acetamino-2-methyl-3 : 7′-[2′-methyl-4′-quinazolone]-4-quinazolone,



7-Amino-2-methyl-4-quinazolone and 4-acetaminoacetanthranil, in equimolecular proportion, were intimately mixed and the mixture heated gradually to 250°. The melt on cooling formed a brown, porous, brittle mass, giving a yellow powder when pulverized. This powder was dissolved in alcohol, the solution treated with bone-black twice, and the filtrate then concentrated. Short, thick, light yellow needles crystallized out, darkening at about 330° and melting at 335° (cor.).

Found. C, 63.86; H, 4.86; N, 18.61. Calculated for $C_{20}H_{17}O_3N_5$. C, 64.00; H, 4.53; N, 18.67.

The compound dissolves in boiling water, in alcohol or in nitrobenzene. It is very slightly soluble in carbon tetrachloride, benzene, ligroin or ether, but somewhat soluble in acetone. It dissolves also in potassium hydroxide solutions and is reprecipitated therefrom by saturation with carbon dioxide. The alcoholic solution of the substance shows a greenish fluorescence.

III. Quinazolones from 5-Acetaminoacetanthranil.

6-Acetamino-2-methyl-4-quinazolone, prepared from the 5-acetamino acetanthranil and ammonia, is much less readily soluble in alcohol than the 7-acetamino isomer. It crystallizes from this solvent in clusters of small, coarse, colorless needles or prisms, melting at 350° (cor.).

Found: N, 19.33. Calculated for $C_{1}H_{11}O_2N_3$. N, 19.35.

6-Amino-2-methyl-4-quinazolone.—The acetyl derivative was boiled with excess of 10 per cent. potassium hydroxide solution, and the solution then precipitated by carbon dioxide. The precipitate crystallized from water in rosettes of long, colorless, highly refracting needles, which began to darken in the neighborhood of 300°, softened somewhat at about 304°, and melted finally at 314–5° (cor.).

Found: N, 23.92. Calculated for $C_9H_9ON_3$: N, 24.0.

At 70–80°, the crystals lose their luster, although they do not carry any water of crystallization. The compound tends to darken on standing. It is insoluble or difficultly soluble in ether, ligroin, chloroform or benzene, but dissolves in ethyl or isoamyl alcohol, acetone or nitrobenzene.

6-Acetamino-2,3-dimethyl-4-quinazolone. — 5-Acetaminoacetanthranil was added to a dilute aqueous solution of methylamine and the mixture heated. The anthranil first dissolved and then the quinazolone separated from the hot solution in colorless, silky needles, soluble in alcohol, and melting at 278° (cor.).

Found: N, 18.22. Calculated for $C_{12}H_{13}O_2N_3$: N, 18.18.

6-Acetamino-2-methyl-3-ethyl-4-quinazolone was prepared similarly, using ethylamine instead of methylamine. When the anthranil and ethylamine were heated together (the latter being used in aqueous solution), a clear solution was obtained, from which nothing separated on further heating or on cooling. A small amount of potassium hydroxide was added, the solution again boiled, and on long standing the quinazolone finely separated in long, colorless, silky needles which, after recrystallization from water, melted at 229° (cor.).

Found: N, 17.43. Calculated for $C_{13}H_{15}O_2N_3$: N, 17.14.

The crystals are highly refracting, and dissolve in hot water or in alcohol.

*6-Acetamino-2-methyl-3-*n*-propyl-4-quinazolone*, from the anthranil and *n*-propylamine, crystallizes from water in long, colorless, silky needles, melting at 181° (cor.).

Found: N, 16.45. Calculated for $C_{14}H_{17}O_2N_3$: N, 16.22.

6-Acetamino-2-methyl-3-phenyl-4-quinazolone.—The anthranil and pure aniline were heated together at 110°, and the product purified by repeated crystallization from dilute alcohol. It forms brownish plates, melting at 255° (cor.), very difficultly soluble in boiling water, readily in hot alcohol.

Found: N, 14.43. Calculated for $C_{17}H_{15}O_2N_3$: N, 14.33.

6-Acetamino-2-methyl-3-amino-4-quinazolone.—The anthranil was added to a dilute aqueous hydrazine hydrate solution and the mixture heated to boiling. The anthranil dissolved and, on cooling, the quinazolone crystallized out in rosettes of colorless, silky needles, which were washed with water and recrystallized from it, when they melted at 262–3° (cor.). The crystals are soluble in hot water or in alcohol.

Found: N, 24.29. Calculated for $C_{11}H_{12}O_2N_4$: N, 24.14.

ORGANIC LABORATORY, HAVEMEYER HALL,
COLUMBIA UNIVERSITY, June, 1910.

ETHYL TANNATE.

BY R. J. MANNING.

Received June, 1910.

Of the naturally occurring tannins gallotannic acid, obtained from gallnuts and many other sources, is the most important and best known. Strecker[1] claims that gallotannic acid is a glucoside of gallic acid as it yielded gallic acid and glucose on hydrolysis. Schiff[2] synthesized digallic acid from gallic acid by means of phosphorus oxychloride and claims that digallic acid and gallotannic acid are isomers. If this were so, gallotannic acid would have a formula $C_{14}H_{10}O_9$ and on hydrolysis would yield no glucose. On account of the difficulty in purifying the tannin, determinations of its composition vary with different experimenters. I have prepared a crystalline ester and through it have obtained satisfactory analyses giving the composition of gallotannic acid and considerable information about it.

---

[1] *Ann.*, 90, 340.

[2] *Ibid.*, 170, 49.

Description of the Gallotannic Acid Used.

The material used in these experiments was obtained through Lyman Bros., Toronto, from the German firm of Schering, and came in the form of light whitish brown flakes; extracted with ether in a Soxhlet, all dissolved, leaving a slight brown stain on the shell, soluble in boiling water. It was purified by the method described by Walden:[1] 100 grams of the commercial tannin were dissolved in 250 grams of amyl alcohol (which must contain a little water) and 350 grams of ether were added; no precipitate appeared. The tannin was then thrown down by gasoline, filtered and dried in a vacuum desiccator over sulphuric acid. So purified, it formed a whitish, rather heavy powder.

The crude sample of tannin contained a trace of gallic acid detected by the potassium cyanide method;[2] the purified product was free from this if excess of gasoline were not added during purification, and in every respect, except solubility, behaved like gallotannic acid as described in Allen's "Commercial Organic Analysis."[3]

Hydrolysis.—A dilute aqueous solution, after boiling for half an hour, reduced Fehling's solution (glucose) and gave a distinct red with potassium cyanide (Young's test for gallic acid); the same result is obtained by boiling for a moment with dilute hydrochloric acid. After long boiling with calcium carbonate while a current of air passed through the solution, the blue coloration changing to red with acids (which is characteristic of gallic acid) was observed.

Behavior with Reagents.—*Arsenic acid* in 5 per cent. alcoholic solution, warmed with its own volume of a 10 per cent. solution of the tannin, solidified to an insoluble jelly, which on standing in the air dried up to a garnet colored mass. *Ammonium molybdate* and *potassium ferricyanide*, reddish colorations; *lime water*, white precipitate quickly turning blue; *ferric chloride*, blue-black precipitate, soluble in much water; *lead acetate or nitrate*, white precipitate in not too dilute solutions; *silver nitrate*, silver mirror on warming; *copper sulphate*, greenish blue gelatinous precipitate turning black on warming; *potassium permanganate* in alkaline solution, red-brown precipitate, dissolving on warming to a yellow-brown solution which becomes wine-red in the air; dilute *sulphuric acid* and dilute *hydrochloric acid*, and *concentrated salt* solutions form precipitates in moderately concentrated solutions of the tannin, which dissolve again on adding water.

[1] *Ber.*, 31, 3167 (1898).

[2] S. Young, *Chem. News*, 48, 31.

[3] Vol. III, Part I, pages 35–38 (1900).

Solubility.--My preparation was soluble in water, glycerol, ethyl acetate, and acetone; slightly soluble in anhydrous amyl alcohol, ether or ethyl alcohol; very slightly soluble in carbon disulphide, benzene and gasoline. It is quite insoluble in chloroform (the gallotannic acid and chloroform were shaken together and filtered, but the filtrate gave no coloration whatever with ferric chloride).

Allen[1] says that gallotannic acid is soluble in six parts of cold water; my preparation was much more soluble. In an experiment in which the tannin and water were shaken together in a thermostat at 0°, many successive portions of tannin kept dissolving until the liquid was a thick sirup, and further addition of the solid balled together and dissolved with extreme slowness. In the end the perfectly clear brownish sirup contained less than one and a half grams of water to one of tannin. At 32° the saturated sirup was still thicker, and contained more than two grams of tannin to one of water.

The solubility of tannin in ether, amyl alcohol, and ethyl acetate, is greatly increased by the addition of a trace of water, as shown by the following data:

One gram of	Dissolved at 15°
Ethyl acetate (Kahlbaum)............	...... 0.2 g. tannin
" " with 5 per cent. water by volume	.... 2.5 " "
Amyl alcohol normal (Kahlbaum).......	.... 0.1 " "
" " with 5 per cent. water by volume ..	.... 0.84 " "

The solubility of mannose, glucose, galactose, cane sugar and of the glucosides, saponin, salicin, and amygdalin in amyl alcohol, acetone, and in ethyl acetate, is also much increased by the addition of a trace of water but not so markedly as in the case of tannin. The solubility of the alkaloids, strychnine and brucine, in ethyl acetate and in acetone, on the other hand, is not markedly increased by the addition of water.

In these solubility determinations the method of analysis for gallotannic acid was that described by F. Jean,[2] involving titration with iodine in alkaline solution.

Analysis of Gallotannic Acid.

To insure perfect dryness the tannin was heated in a hot air bath at 110° for two hours.

(*a*) The elementary analysis gave the following results:

---

[1] *Commercial Organic Analysis*, 3rd Ed., Vol. III, Part I, page 34.

[2] *Chem. Centr.*, 1900, I, 1107.

Calculated for $C_{41}H_{32}O_{20}$. C, 52.35; H, 3.40.
Found: C, 52.4, 52.25; H, 3.45, 3.49.

(*b*) To estimate the glucose in tannin, the following procedure was adopted: 0.2 to 0.5 gram of the tannin was boiled with 200 cc. water and 25 cc. of 10 per cent. hydrochloric acid for an hour. As gallic acid has a marked reducing action on Fehling's solution, it was removed by extraction with ether, and as glucose itself is somewhat soluble in water-saturated ether, the extraction was carried on quantitatively and a correction applied as follows:

From 0.1 to 0.25 gram glucose was mixed with 0.5 to 1.2 grams ethyl gallate and the mixture dissolved in 200 cc. water and 25 cc. of 10 per cent. hydrochloric acid. After boiling the solution for an hour, it was made up to 100 cc. and extracted six times by shaking up for ten minutes each time with 50 cc. of ether. After the sixth extraction, all the gallic acid formed by the hydrolysis of the ether except a slight trace had been removed. The following percentages of the original glucose were found by analysis in the aqueous layer:

Glucose	78 9	79 0	78 8	78. 6 per cent

Hence the boiled solution of tannin was extracted six times with ether, the free hydrochloric acid neutralized with sodium carbonate, the glucose estimated and the results multiplied by 100/79.

The analysis gave glucose 19 0, 18 79 per cent Calculated on the assumption that one formula weight of the tannin on hydrolysis gives one formula weight of glucose: 19.1 per cent

(*c*) Formula weight determinations from the boiling point of solutions:

Water as solvent.	813	843	922	1025	1500
Acetone as solvent	1672	2023	1500	1450	
Water as solvent (from freezing point)	1957	1942	1769	1956	1972

Calculated for $C_{41}H_{32}O_{20}$. 940

Preparation of the Ethyl Ester of Gallotannic Acid.

50 grams of the tannin were dissolved in 250 cc. of Kahlbaum's 99.8 per cent. ethyl alcohol. After introducing the light brown solution into a 500 cc. flat-bottomed flask, hydrogen chloride gas, dried by passing through 18 inches of pumice stone moistened with sulphuric acid, was bubbled through for at least two and a half hours. During the operation the temperature of the liquid rose to about 60°. By cooling the solution during the passage of the gas through it, the yield was diminished, while applying heat to the flask did not noticeably increase the amount of the ester formed.

The dark brown sirup left after the passage of the hydrogen chloride gas was evaporated in a large porcelain evaporating dish until quite thick, and Kahlbaum's lime-free barium carbonate added in excess. The sticky mass was extracted three times with anhydrous ether, the resulting greenish brown ethereal liquid allowed to evaporate, and the residue heated for some hours in a water bath. A dark greenish brown powder remained.

The crude ethyl tannate so obtained was purified by extraction with chloroform in a Soxhlet for two days. This leaves behind the coloring matter and unaltered tannin but dissolves any ethyl gallate as well as the ethyl tannate; hence the necessity of using tannin as free as possible from gallic acid. During the extraction the ethyl tannate separated out of the chloroform in the form of pale yellow spherical nodules of about 2 mm. in diameter. The yield was about 40 per cent. of the tannin used.

In the hope of obtaining a better yield, 50 cc. of benzene[1] were added to the dark brown solution through which the hydrochloric acid gas had been passed, the whole well shaken and the benzene distilled off. After three successive treatments with benzene, the liquid left in the distilling flask was evaporated and treated with barium carbonate and ether as before. This method gave no better yield and was therefore not used again.

Description of the Ethyl Tannate.

On splitting open these nodules, they were seen to consist of a mass of light yellow shining crystals radiating from a common center. Their melting point was 157° (ethyl gallate melts at 141°).[2] They were readily soluble in ether, alcohol and water; slightly soluble in chloroform; insoluble in gasoline and in carbon bisulphide. Their aqueous solution resembled a solution of tannin in its reactions with ammonium molybdate, lead nitrate or acetate, silver nitrate, copper sulphate, and potassium permanganate. With potassium cyanide the aqueous solution of ethyl tannate always gave a slight red color indicating the presence of traces of gallic acid or its ester.

Analysis of the Nodules.

(*a*) *Elementary Analysis.*—The substance was mixed with a little carefully dried red lead and ignited in a porcelain boat.

The analysis gave:	C, 52.3	52.4	52.35:	H, 5.25	5.11	5.25
Calculated for $C_{51}H_{62}O_{31}$:	52.30			5.30		

(*b*) *Loss of Water on Heating.*—To estimate the percentage of water, the nodules were heated in an air bath to 125–135° for two hours. On first heating they became rather sticky, but did not melt completely, and on continued heating became drier again but showed a tendency to turn brown and to sublime. Hence care had to be taken not to allow the temperature to rise over 135°.

The analysis gave: 7.6, 7.5, 7.8 water; calculated for $C_{51}H_{52}O_{26}.5H_2O$: 7.69 per cent.

---

[1] *J. Chem. Soc.*, 88, 852 (1905).

[2] Etti, *Ber.*, 11, 1882.

(*c*) *Ethoxyl Determination.*—The method used was that of Zeisel as described in Meyer and Tingle's "Estimation of Organic Radicles," pp. 34–48. In some of my determinations the precipitate of silver iodide was brownish instead of yellow. The results with these colored precipitates varied widely, being too large, and hence were rejected. It was found afterward, however, that if the brown silver iodide precipitates in these high results were boiled for five minutes with 100 cc. of 15 per cent. nitric acid, filtered and weighed, the precipitates regained their normal color and the new results agreed with those not rejected. This treatment with nitric acid does not perceptibly affect the pure silver iodide.

OC_2H_5 found: 19.24, 19.32, 19.39, 19.55, 19.55 per cent.; calculated for $C_{41}H_{27}O_{21}(OC_2H_5)_5.5H_2O$[1]: 19.23 per cent.

(*d*) *Hydrolysis of the Ester and Estimation of the Glucose.*—2 grams of the ester were boiled with 100 cc. water for two hours with a return condenser and then 25 cc. distilled off. This distillate gave no trace of alcohol when tested by the iodoform method.[1] If, however, previous to the distillation, 10 cc. of dilute hydrochloric acid or of dilute caustic potash were added to the distilling flask, the distillate then gave, especially in the latter case, a distinct deposit of iodoform.

The freshly prepared solution of ethyl tannate reduced Fehling's solution slightly; but the solution which had been boiled with acid or with caustic potash reduced Fehling's solution readily and gave a marked potassium cyanide test for gallic acid. The products of the hydrolysis are therefore ethyl alcohol, glucose, and gallic acid.

The glucose was estimated by the same method as was used for the estimation of glucose in the gallotannic acid and the same correction was applied.

The analysis gave: 15.37, 15.42, 15 51, 15.13 per cent glucose. Calculated on the assumption that one formula weight ($C_{51}H_{62}O_{31}$) of the ester on hydrolysis gives one formula weight of glucose: 15.38 per cent.

(*e*) *Estimation of the Gallic Acid.*—0.2 to 0.3 gram of the ethyl tannate was hydrolyzed by boiling with dilute hydrochloric acid as in the estimation of the glucose. The boiled solution was then diluted to 250 cc. and the gallic acid estimated by the iodine titration method of Jean.[2]

Gallic acid found: 72.56, 72.66, 72.8. Calculated on the assumption that one formula weight ($C_{51}H_{62}O_{31}$) of the ester on hydrolysis gives five formula weights of gallic acid: 72.64 per cent.

(*f*) *Formula-weight Determinations from Boiling Point of Solutions.*—

Acetone as solvent: 255, 280, 257.
Ethyl acetate as solvent: 362, 275, 300.
Chloroform as solvent: 1335, 1000, 1200, 1467.
Water as solvent (from freezing point): 301, 309.
Calculated for $C_{51}H_{62}O_{31}$: 1170

---

[1] *Z. anal. Chem.*, 9, 492.

[2] *Chem. Centr.*, 1900, I, 1107.

Comparing these results, it is seen that those given by the chloroform solution are several times greater than those given by the other solutions. The lower numbers might be explained by assuming that in all the solvents but chloroform there is a dissociation into anhydrous ester and water. To test this, 0.5 to 1.0 gram of the ester was dissolved in 50 cc. acetone and the solution dehydrated carefully by introducing 10 grams anhydrous calcium chloride. After filtering and washing the calcium chloride carefully with acetone, the filtrate was diluted up to 100 cc. and its boiling point determined, giving the following results:

Formula weight found· 950, 1050. Calculated for $C_{51}H_{32}O_{26}$: 1080.

Moreover, on evaporating this solution to dryness, an amorphous, dark brown, sticky mass was left, instead of the crystalline substance before obtained.

A Higher Hydrate of the Ester of Gallotannic Acid.

On the evaporation of solutions of ethyl tannate in ether, chloroform, alcohol, acetone, and ethyl acetate, only minute crystals were obtained. To get large crystals, a cold (15°) saturated aqueous solution of ethyl tannate, obtained without heat, was allowed to evaporate in a round-bottomed evaporating dish by being placed in the sunlight. Even at that temperature a partial decomposition of the ester into ethyl gallate and glucose took place. The ethyl gallate, being less soluble, crystallized out first as a top ring of pale yellow, steep rhombic crystals around the sides of the evaporating dish. At the bottom of the vessel, on almost complete evaporation, were found large, light brown crystals, many between one and two centimeters in length, with a sticky fluid containing the glucose.

An aqueous solution of these crystals behaved like a solution of the lower hydrate of ethyl tannate. They melted at 132°[1] and effloresced readily over sulphuric acid and slowly in the air. They lost their water of crystallization on being heated at 125–135° like the lower hydrate.

Analysis gave: 20.5, 20.7, 21.0 per cent. water. Calculated for $C_{51}H_{52}O_{26}.15H_2O$: 20 per cent.

Synthesis of Ethyl Tannate from Ethyl Gallate and Glucose.

20 grams ethyl gallate prepared according to Schiff's method[2] were ground up with 5–6 grams glucose and mixed to a thin paste with phosphorus oxychloride. After heating this paste in a water bath for two hours, during which time great quantities of hydrochloric acid were given off, a dark sticky mass remained. This was further dried by heating at 120° for a couple of hours, extracted with anhydrous ether, the ether solution evaporated, and the residue again extracted with chloroform in a Soxhlet for twenty-four hours. At the end of that period a light

---

[1] Hydrated ethyl gallate melts at 90°.

[2] Schiff, *Ann. Chem.*, 163, 215; 170, 72.

colored mass had settled out of the chloroform. By the fractional crystallization of its aqueous solution as previously described, the higher hydrate of the ethyl ester of gallotannic acid was obtained. This gave all the reagent tests for tannin, for glucose, and ethoxyl groups. It melted at 132°. The maximum yield I obtained was only about 5% of the theoretical.

Summary.

1. Two crystalline derivatives of tannin have been obtained. They are ethyl esters of gallotannic acid differing in the amount of water of crystallization. The previous analyses of gallotannic acid varied because crystalline derivatives were not known and therefore pure material was very difficult to obtain.

2. These esters were synthesized from alcohol and gallotannic acid and one of them was also synthesized from ethyl gallate and glucose.

3. Various analyses show that the formulas for these esters are $C_{41}H_{27}O_{21}(OC_2H_5)_5.5H_2O$ and $C_{41}H_{27}O_{21}(OC_2H_5)_5.15H_2O$, and that they are glucosides of gallic acid in which one formula weight of glucose and five formula weights of gallic acid are represented in one formula weight of the ester. This gives the formula $C_{41}H_{32}O_{26}$ for gallotannic acid.

4. Dissociation of the hydrated ester into water and anhydrous ester would account for the low formula-weight determinations in acetone, etc.

This work was done under the direction of Professor W. Lash Miller.

UNIVERSITY OF TORONTO

ACTION OF AMINES ON PHTHALIC ACID. VII.[1]

By J. Bishop Tingle and S. J. Bates

Received August 4, 1910

The work described in the earlier papers by the senior author and his colleagues has shown that the phthalamidic acids combine with amines to form salts, $RNHCOC_6H_4CO_2NH_3R'$. Secondary or tertiary amines, if they are not too negative, convert these salts into imides, $C_6H_4{<}\substack{CO\\CO}{>}NR$ or $C_6H_4{<}\substack{CO\\CO}{>}NR'$, whereas primary amines give rise to one or more of the following products: the amidic acid $R'NHCO C_6H_4CO_2H$, the amides $RNHCOC_6H_4CONHR$ or $C_6H_4(CONHR')_2$, and the imides formulated above. In the case of the secondary phthalamidic acids, $RNR'COC_6H_4CO_2H$, where R and R' may represent similar or dissimilar groups, the amine $R''NH_2$ behaves somewhat differently; it may cause hydrolysis of the original amidic acid to phthalic acid, or the group R″ may replace R or R′ in the amidic acid, giving $R''NHCOC_6H_4CO_2H$. This last acid may then eliminate water and form the imide  $C_6H_4<\genfrac{}{}{0pt}{}{CO}{CO}>NR''$. The amidic acids of the aliphatic series[1] do not exhibit a similar series of reactions and consequently the formation of substituted imides, under the influence of amines, could only be ascribed to the influence of "the inherent nature of the benzene nucleus."

---

[1] The previous papers bearing on this subject have appeared as follows: Bishop Tingle and Cram, *Am. Chem. J.*, **37**, 596 (1907); Bishop Tingle and Lovelace, *Ibid.*, **38**, 642 (1907); Bishop Tingle and Rolker, THIS JOURNAL, **30**, 1882 (1908); Bishop Tingle and Brenton, *Ibid.*, **31**, 1157 (1909); Bishop Tingle and Bates, *Ibid.*, **31**, 1233 (1909); Bishop Tingle and Brenton, *Ibid.*, **32**, 113 (1910).

In the case of the phthalamidic acids the particular course which the reaction takes, or the preponderating organic product, if more than one is formed, is determined essentially by the nature of the groups R, R′, R″ which are linked to the nitrogen atoms of the amine or amidic group.

In the present paper we describe the results which we have obtained in the course of an investigation of phthalamidic acids containing one or more chlorine atoms or nitro groups in the benzene nucleus. In this connection we have investigated a number of amidic acids derived from 3,6-dichloro-, tetrachloro-, 3-nitro- and 4-nitrophthalic acids.

We have isolated *di-m-toluidine* and *di-p-chloroaniline 3,6-dichlorophthalates* and have materially improved Graebe's method for the preparation of 3,6-dichlorophthalophenylamidic acid, $C_6H_5NHCOC_6H_2Cl_2CO_2H$, and of its anil. Our products appear to be superior in purity to those described hitherto.

Unlike other members of this series, 3,6-dichlorophthalophenylamidic acid does not appear to be dehydrated by the action of amines in solution, but it is very readily transformed into the anil  $Cl_2C_6H_2<\genfrac{}{}{0pt}{}{CO}{CO}>NC_6H_5$, by the action of 50 per cent. alcohol. It furnishes, therefore, another example of the marked dehydrating power of even dilute alcohol. This phenomenon was discussed in an earlier paper by Bishop Tingle and Rolker.[2]

Entirely similar transformation results were observed with *tetrachlorophthalophenylamidic acid*, $C_6H_5NHCOC_6Cl_4CO_2H$. This acid is prepared most conveniently from tetrachlorophthalic anhydride and aniline, in benzene solution, but it may also be obtained by hydrolysis of the phenylimide. Its *sodium* and *potassium salts* form colloidal solutions in water; when these liquids are shaken, well-marked lathers are produced.

o-Toluidine and tetrachlorophthalic acid or its anhydride give what is, apparently, *tetrachlorophthalo-o-tolylamidic acid*, $CH_3C_6H_4NHCOC_6Cl_4CO_2H$; it is deposited in lustrous, white crystals, melting at 218–20°.

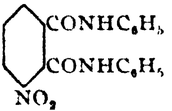
For comparison with the above phenylamidic acid we prepared *tetrachlorophthalo-β-naphthylamidic acid*, $C_{10}H_7NHCOC_6Cl_4CO_2H$, and the corresponding *β-naphthylimide*,  $C_6Cl_4<\genfrac{}{}{0pt}{}{CO}{CO}>NC_{10}H_7$. Both of these compounds are white, crystalline substances, melting at 287°, *i. e.*, the melting point of the imide. The β-naphthylamidic acid resembles the phenyl derivative in general properties, but it is somewhat less stable and is hydrolyzed by alkalies to its constituents with relative ease. Its transformation into the β-naphthylimide does not appear to be influenced by the presence of amines.

---

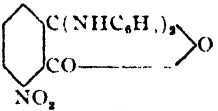
[1] Bishop Tingle and Bates, *loc. cit.*

[2] THIS JOURNAL, 30, 1884 (1908).

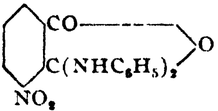
3-Nitrophthalophenylamidic acid, $C_6H_5NHCOC_6H_3(NO_2)CO_2H$, was prepared from the phenylimide.[1] When heated at about 100°, with alcohol (50%), it is changed slowly to a 3-nitrophthalodianilide, which is also formed, under similar conditions, in the presence of amines such as aniline, quinoline or *p*-toluidine. Our dianilide melted at 233–4° and is evidently isomeric with that of Chambers,[2] which melts at 211–2°. Chambers did not determine the structure of his compound, which was prepared from 3-nitrophthalyl chloride, but he pointed out that, according to theory, there should be three dianilides of 3-nitrophthalic acid, *viz.*



I.



II.



III.

On account of its method of formation and of its higher melting point, our compound is probably the symmetrical derivative (I).

In this connection it is interesting to point out the effect of the nitro group in determining the production of the *dianilide* as the only product of the reaction. In the case of the compounds studied hitherto, the chief product has always been an imide, $C_6H_mX_n<\genfrac{}{}{0pt}{}{CO}{CO}>NR$ (X = H or Cl), a dianilide, if formed at all, being obtained only in very small quantity.

4-Nitrophthalophenylamidic acid, $C_6H_5NHCOC_6H_3(NO_2)CO_2H$, was prepared from the phenylimide obtained by Graebe and Buenzod,[3] or, more conveniently, by the action of aniline on 4-nitrophthalic anhydride. For the hydrolysis of the phenylimide Bogert[4] used baryta water; we find that an aqueous solution of potassium hydroxide is much more desirable. Our acid melted at 192°, not 181° as stated by Bogert, and, contrary to his experience, it dissolved without difficulty in a cold, aqueous solution of sodium carbonate. Our specimens of the phenylimide melted at 200–1°; Bogert[5] found 194°.

It is, perhaps, worth mentioning that the amidic acids, with which the senior author has worked during the past few years, frequently melt at temperatures about 15–20° lower than the melting points of the corresponding substituted imides, they then solidify and remelt at a higher temperature. It is found, however, that preparations which behave in this manner are almost always slightly impure. After further treatment they show the same melting point as the substituted imide and this temperature is always a degree or two higher than the second melting point mentioned above. It is, perhaps, hardly necessary to remark that, in every experiment which we have described, precautions have been taken in order to demonstrate that the final methods of purification which were adopted did not themselves convert the acids into their imides.

[5] *Ibid.*, 23, 757.

When heated on a boiling water bath, during 5 hours, with alcohol (50 per cent.), with and without the addition of quinoline, 4-nitrophthalophenylamidic acid is transformed, in part, into the phenylimide, the remaining acid being recovered unchanged. Under similar conditions, with alcohol (50 per cent.) and aniline, the same products are obtained, together with a small quantity of a *compound*, melting at 199–200°. In view of the results observed with the 3-nitro acid (see above) and from the fact that the new compound is not attacked by boiling with aqueous solutions of potassium hydroxide, or of hydrochloric acid, we conclude that the substance in question is probably *4-nitrophthalodianilide*, $O_2NC_6H_3(CONHC_6H_5)_2$.

A comparison of the results of the transformation experiments with 3-nitrophthalophenylamidic acid and those of the 4-nitro acid show that the approximation of negative groups [$CO_2H : CO_2H : NO_2 = 1 : 2 : 3$] inhibits the formation of the phenylimide and greatly favors that of the dianilide. The opposite result is obtained when the nitro group is in the 4-position. It is, of course, easy to ascribe this inhibition of the imide formation to "steric hindrance," but we prefer to regard it as being due to a specific influence of the nitro group. The chief ground for this attitude is the fact that the 3,6-dichloro- and the tetrachlorophthalophenylamidic acids form phenylimides readily, although they show a specific insensibility to the transforming influence of amines.

4-Nitrophthalo-β-naphthylamidic acid, $C_{10}H_7NHCOC_6H_3(NO_2)CO_2H$, is prepared by mixing acetone or benzene solutions of β-naphthylamine and 4-nitrophthalic anhydride. After purification the acid is deposited in light yellow crystals, melting at 202–4°.

Camphorphenylamidic acid, $C_6H_5NHCOC_8H_{14}CO_2H$, was prepared by the method of Auwers and Schleicher,[1] from aniline and camphoric anhydride. *Camphor-β-naphthylamidic acid*, $C_{10}H_7NHCOC_8H_{14}CO_2H$, was obtained in a similar manner from β-naphthylamine. It is crystalline and melts at 220–1°. Neither of these acids was changed by prolonged heating at the temperature of a boiling water bath, in presence of alcohol (50 per cent.), or of various amines.

---

[1] *Ann.*, 309, 341.

In our earlier paper[1] we called attention to the readiness with which amidic acids of the phthalic series formed imides, $R<{CO \atop CO}>NX$ (and other compounds), as compared with the stability in this respect of the analogous acids of the aliphatic series. Expressed in another way, the question is one of the relative stability of the substituted ammonium salts of the acids of the two series. After discussing the matter briefly, we reached the conclusion that the instability of the ammonium phthalamidates can be due only "to the inherent properties of the benzene nucleus," whatever this may mean.

Our object in preparing camphorphenyl- and β-naphthylamidic acids was to obtain further light on this point. They are the most readily available derivatives of the alicyclic series and, as stated above, their behavior is essentially similar to that of the corresponding aliphatic compounds. Consequently our previous conclusion, regarding the effect of the benzene nucleus, is still valid, but it may be supplemented by the statement that the accumulation and approximation of negative groups in the phthalic acid nucleus favors the formation of dianilides, $C_6XY(CONHC_6H_5)_2$, rather than that of imides, $C_6XY<{CO \atop CO}>NR$.

Experimental.

1. DERIVATIVES OF 3,6-DICHLOROPHTHALIC ACID.—The following salts have been prepared. *Di-m-toluidine 3,6-dichlorophthalate*, $Cl_2C_6H_2(CO_2NH_3C_6H_4CH_3)_2$, is obtained as a light colored precipitate by mixing the acid and amine in concentrated, alcoholic solution. It is deposited, after recrystallization from water or alcohol, in light yellow crystals, melting at 176°. Found: N, 6.68; calculated, 6.28 per cent. *Di-p-chloroaniline 3,6-dichlorophthalate*, $Cl_2C_6H_2(CO_2NH_3C_6H_4Cl)_2$, is prepared in a similar manner from *p*-chloroaniline and 3,6-dichlorophthalic acid, in benzene solution. Light yellow crystals from water or alcohol, melting at 215°. Found: N, 5.90; calculated, 5.70 per cent.

Only tarry products were obtained by heating 3,6-dichlorophthalic acid with aniline or acetanilide, under various conditions of temperature, with and without solvents.

3,6-Dichlorophthalic anhydride was most easily prepared by heating the acid, at 40°, in a current of dry air, until water ceased to be evolved. The purification of the product is somewhat tedious. We found it best to dissolve the material in benzene and add a little gasoline. After a few hours a resinous deposit is formed on the sides of the container. The clear liquid is decanted and a little more gasoline added and the process repeated until no more resin is precipitated. To the clear liquid three or four volumes of gasoline are now added, whereupon the anhydride will be precipitated as a white powder. In order to purify it completely it may be necessary to dissolve it in a little benzene, at the ordinary temperature, and repeat the treatment with gasoline.

---

[1] THIS JOURNAL, 31, 1235.

Preparation of 3,6-dichlorophthalanil and of 3,6-dichlorophthalophenylamidic acid.—We made numerous attempts to prepare these compounds by Graebe's method,[1] which consists in heating aniline 3,6-dichlorophthalate. We varied the conditions rather widely, but at the best the yield of crude product was very poor and a great deal of it was lost because it was necessary to recrystallize it several times from acetic acid and to boil it with bone-black in order to obtain it in a condition of approximate purity. The small quantity of material which we obtained ultimately was hydrolyzed by means of an aqueous solution of potassium hydroxide. After acidification with hydrochloric acid a brownish precipitate was deposited; it was identified as 3,6-dichlorophthalophenylamidic acid by means of a mixed melting point.

Having found that Graebe's method was entirely unsuited for the preparation of the amidic acid, except in minute quantities, we devised the following process by which the acid may be obtained in a quantitative yield. Aniline (2 mols.) is added to 3,6-dichlorophthalic anhydride (1 mol.), dissolved in benzene. Water and potassium hydroxide (1 mol.) are then added and the mixture is boiled for some time and well stirred. After cooling, the benzene, which contains the excess of the aniline, is removed and the aqueous solution is acidified by means of hydrochloric acid. The resulting precipitate is light brown; this color appears to be due to the presence of a little impurity which is derived from the anhydride and which lowers the melting point of the amidic acid considerably. In order to remove this colored substance it was necessary to dissolve the crude acid in an aqueous solution of sodium hydrogen carbonate; this solution was boiled with bone-black, the acid reprecipitated and recrystallized twice from alcohol and twice from a mixture of benzene and gasoline. The 3,6-dichlorophthalophenylamidic acid, $C_6H_5NHCOC_6H_2Cl_2CO_2H$, which was ultimately obtained, was a light brown powder, melting at 165°. It dissolves readily in benzene, acetone, ether, alcohol, ethyl acetate and in a cold, aqueous solution of sodium carbonate. Found: Cl, 22.99; calculated, 22.90 per cent.

Transformations of 3,6-Dichlorophthalophenylamidic Acid.—The acid was not changed by dissolving it in benzene and heating the solution on a boiling water bath. The addition of aniline, quinoline, or β-naphthylamine produced no effect.

With 50 per cent. alcohol, instead of benzene, a part of the acid is transformed into the anil. The heating was continued during 35 minutes. The presence of aniline, quinoline, or β-naphthylamine does not appear to influence either the velocity or extent of this dehydration. These facts are discussed in the theoretical part of the present paper; they are of considerable interest in connection with the earlier work of Bishop Tingle and Rolker.[1]

---

[1] *Ber.*, **33**, 2019 (1900).

We have found that 3,6-dichlorophthalanil,  $Cl_2C_6H_2<\substack{CO \\ CO}>NC_6H_5$, is most conveniently prepared, in the manner described above, by heating the amidic acid with alcohol. The product melts at 201°. Graebe's material, obtained by fusing the aniline salt, was evidently impure. It is stated to melt at 191°.

EXPERIMENTS WITH TETRACHLOROPHTHALIC ACID. *o-Toluidine and Tetrachlorophthalic Acid.*—*o*-Toluidine (2 mol.) and the acid or anhydride were mixed in acetone solution. The precipitate which forms immediately was purified by solution in water or ethyl acetate, from either of which it is deposited in lustrous white crystals. It melts at 218–20° and is probably tetrachlorophthalo-*o*-tolylamidic acid, $CH_3C_6H_4NHCOC_6Cl_4CO_2H$. Found: N, 3.95; calculated, 3.56 per cent.

Preparation of Tetrachlorophthalophenylimide and of Tetrachlorophthalophenylamidic Acid.—The phenylimide was prepared by Graebe and Buenzod's method, which consists in the fusion of aniline tetrachlorophthalate.[2] The yield is quite poor and it is difficult to purify the product.

Tetrachlorophthalophenylamidic acid, $C_6H_5NHCOC_6Cl_4CO_2H$, may be obtained by boiling the anil, during 2–3 hours, with a rather concentrated aqueous solution of potassium hydroxide, but it is prepared much more easily by adding aniline to tetrachlorophthalic anhydride, both in benzene solution. The precipitate which forms immediately is collected and is purified by dissolving it in a warm, aqueous solution of sodium carbonate and subsequently adding hydrochloric acid. It is readily soluble in acetone, ether, or ethyl acetate and is deposited from alcohol in white crystals, melting at 266°, *i. e.*, at the same temperature as the anil. Specimens which have been insufficiently purified melt about 230°, then become solid and finally remelt a little below 266°. Found: N, 3.76; calculated, 3.69 per cent.

In aqueous solution the acid reddens litmus paper immediately and it dissolves without difficulty in warm, aqueous solutions of alkali hydroxides, but cold solutions attack it only slowly because its *sodium* and *potassium salts* are colloidal and soapy and readily form lathers. When a warm aqueous solution of either of these salts is cooled it becomes turbid, then jelly-like and finally, if the liquid is sufficiently concentrated, a tarry or resinous precipitate is formed.

[1] *Loc. cit.*

[2] *Ber.*, 32, 1994.

Transformations of Tetrachlorophthalophenylamidic Acid.—The acid was recovered unchanged after boiling during 35 minutes in benzene solution. The addition of aniline was without effect. In 50 per cent. alcohol, on a boiling water bath, a part of the acid is transformed into the anil. The reaction does not appear to be influenced by the presence of aniline, or of β-naphthylamine.

On account of their identical melting points, as mentioned above, some trouble was at first encountered in distinguishing between tetrachlorophthalophenylamidic acid and the phenylimide; this difficulty is increased by the fact that the acid does not dissolve easily in a cold, aqueous solution of potassium hydroxide. The most ready methods of identification were the solubility of the acid in a boiling, aqueous solution of sodium carbonate and the fact that the aqueous solution of the acid reddens litmus paper. Tetrachlorophthalophenylamidic acid changes slowly to the phenylimide at the ordinary temperature, consequently the material employed for the transformation experiments described above was carefully purified by means of sodium carbonate solution immediately before use.

Tetrachlorophthalo-β-naphthylamidic Acid.—This acid, $C_{10}H_7NHCOC_6Cl_4CO_2H$, is prepared from β-naphthylamine and tetrachlorophthalic anhydride, in a simliar manner to the phenyl derivative. The *sodium* and *potassium salts* dissolve with difficulty in water, at the ordinary temperature and the resulting solutions are colloidal, consequently it is somewhat troublesome to separate the amidic acid from unchanged β-naphthylamine. The best plan we found was to add dilute hydrochloric acid to a boiling aqueous solution of the sodium salt, collect the precipitated acid and boil it with a large quantity of water; after drying it is treated with a mixture of toluene and glacial acetic acid; from this it deposits in white crystals, melting at 287°, which is the m. p. of the β-naphthylimide. It dissolves readily in ethyl acetate, acetone and in 95 per cent. alcohol, is less soluble in ether, chloroform and in 50 per cent. alcohol and is practically insoluble in benzene. Found: N, 3.23; calculated, 3.26 per cent.

The acid changes slowly, at the ordinary temperature, to the β-naphthylimide. Concentrated, aqueous potassium hydroxide solution hydrolyzes it slowly to β-naphthylamine and tetrachlorophthalic acid, both of which were fully identified.

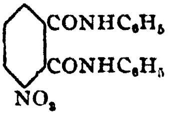
Highly purified tetrachlorophthalo-β-naphthylamidic acid is transformed into the β-naphthylimide when heated with alcohol of 95 or 50 per cent. The change was not complete during the time of our experiments, about 35 minutes, and the reaction does not appear to be influenced by the addition of aniline or β-naphthylamine to the alcoholic solution.

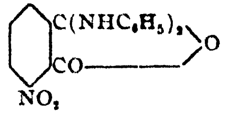
Tetrachlorophthalo-β-naphthalo-β-naphthylimide, $C_6Cl_4 < \begin{matrix}CO\\CO\end{matrix} > NC_{10}H_7$, is prepared by heating the acid at 260–70°, during 10 minutes. It is soluble in acetone, ethyl acetate, or alcohol and is deposited in white crystals, melting at 287°. The compound does not dissolve in an aqueous solution of sodium carbonate, but by the action of a warm, aqueous solution of potassium hydroxide it is hydrolyzed slowly to potassium tetrachlorophthalo-β-naphthylamidate, which, of course, goes into solution.

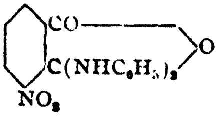
DERIVATIVES OF 3-NITROPHTHALIC ACID.—3-Nitrophthalophenylamidic acid, $C_6H_5NHCOC_6H_3(NO_2)CO_2H$, was prepared by the hydrolysis of the phenylimide. We found that this was readily accomplished by warming with an aqueous solution of potassium hydroxide, in place of the barium hydroxide employed by Bogert.[1] After several recrystallizations from ethyl acetate our material melted at 181° and, contrary to the statement of Bogert,[2] dissolved readily in an aqueous solution of sodium carbonate, at the ordinary temperature.

Transformation of 3-Nitrophthalophenylamidic Acid.—At the temperature of a boiling water bath, during 35 minutes, the acid is not changed in presence of alcohol (50 per cent.), or of quinoline, but on adding aniline to the alcohol a little 3-nitrophthalodianilide is produced and the yield of this compound is quantitative if the heating is prolonged during 5 hours. With *p*-toluidine or alcohol (50 per cent.), during 5 hours' heating, the acid also gives a small quantity of the same dianilide. This *dianilide* was obtained in crystals, melting at 233–4°. It is readily soluble in alcohol, chloroform, ether, acetone, or ethyl acetate, but dissolves with difficulty in benzene, or toluene. The compound is not attacked by a boiling, aqueous solution of potassium hydroxide, nor by hydrochloric acid. Found: C, 66.76; H, 4.66. Calculated: C, 66.48; H, 4.15 per cent.

Our 3-nitrophthalodianilide appears to be isomeric with one prepared by Chambers[3] from 3-nitrophthalyl chloride. It is uncertain which of the three possible structures







are to be assigned to the two compounds in question, but we think that ours is probably the symmetrical derivative.

3-Nitrophthalic Anhydride and β-Naphthylamine.—When these substances are mixed in an organic solvent, a compound is precipitated which appears to be *3-nitrophthalo-β-naphthylamidic acid*, $C_{10}H_7NHCOC_6H_3(NO_2)CO_2H$. Its purification is attended with considerable difficulty on account of the progressive formation of an oily material. We obtained light yellow crystals from a mixture of acetone, benzene and chloroform; they melted at 201–2° and dissolved easily in alcohol, ethyl acetate, acetone, or ether, less readily in chloroform. That the compound is an acid is shown by the fact that it is soluble in an aqueous solution of sodium carbonate and is reprecipitated on acidification with hydrochloric acid. The quantity of purified material ultimately available was too small to permit of analysis.

---

[1] THIS JOURNAL, 23, 740.

[2] *Loc. cit.*

[3] THIS JOURNAL, 25, 611.

DERIVATIVES OF 4-NITROPHTHALIC ACID.—4-Nitrophthalophenylamidic acid, $C_6H_5NHCOC_6H_3(NO_2)CO_2H$, was obtained from the phenylimide, which was prepared by Graebe and Buenzod's method.[1] This consists in heating aniline 4-nitrophthalate. The resulting anil, after purification, was dissolved in a warm, aqueous solution of potassium hydroxide, the heating continued during about 5 minutes and the amidic acid precipitated by means of dilute hydrochloric acid. The acid was then crystallized several times from ethyl acetate, in order to separate it from tarry matter which is always produced during the fusion of the aniline 4-nitrophthalate.

The phenylamidic acid may also be obtained by mixing benzene solutions of aniline and 4-nitrophthalic anhydride. The product obtained in this manner is less difficult to purify than that prepared from the anil. The acid was dissolved in a cold, aqueous solution of sodium carbonate, reprecipitated by means of dilute hydrochloric acid and recrystallized several times from ethyl acetate. Our acid melted at 192°. The method of preparation given above is much more convenient than that described by Bogert.[1] He hydrolyzed the anil by the use of barium hydroxide, added sulphuric acid and extracted the amidic acid by means of alcohol. His product melted at 181°, and did "not appear to decompose carbonates." Our material dissolved in a cold, aqueous solution of sodium carbonate after 10–15 minutes. Bogert gives 194° as the m. p. of 4-nitrophthalophenylimide.[2] Our preparation melted at 200–1°.

We refer, in the first part of this paper, to a peculiarity shown by the acids of this series in regard to their melting points.

Transformation of 4-Nitrophthalophenylamidic Acid.—At the temperature of a boiling water bath, after 5 hours, in presence of alcohol (50 per cent.), a part of the acid was recovered unchanged, the remainder being converted into the phenylimide. A similar result was obtained by adding quinoline to the solution. After 6 hours' heating, under similar conditions, with a mixture of alcohol (50 per cent.) and aniline, the products consisted of unchanged acid, phenylimide and a *compound,* melting at 199–200°. It was not attacked by boiling with aqueous solutions of potassium hydroxide, or hydrochloric acid; boiling with alcoholic solutions of the same reagents produced only a slight effect. These results lead to the conclusion that the substance is probably *4-nitrophthalodianilide,* $O_2NC_6H_3(CONHC_6H_5)_2$, which does not appear to have been described hitherto. The material available was insufficient for an analysis.

---

[1] *Loc. cit.*

[2] *Ibid.*, p. 757.

Preparation of 4-Nitrophthalo-β-naphthylamidic Acid.—This acid, $C_{10}H_7NHCOC_6H_3(NO_2)CO_2H$, was prepared by adding β-naphthylamine to 4-nitrophthalic anhydride, both substances being dissolved in acetone, or benzene. The precipitate which is formed is collected, dried, dissolved in an aqueous solution of potassium hydroxide, the liquid acidified with hydrochloric acid and the precipitated solid recrystallized several times from a mixture of acetone and benzene. In this manner we obtained the acid in light yellow crystals, melting at 202–4°. It dissolves in a cold, aqueous solution of sodium carbonate and is reprecipitated by hydrochloric acid. The acid is readily soluble in acetone, ethyl acetate, alcohol, or ether, less readily in chloroform and practically insoluble in benzene. Found: N, 8.21, calculated, 8.33 per cent.

DERIVATIVES OF CAMPHORIC ACID.—Camphorphenylamidic acid, $C_6H_5NHCOC_8H_{14}CO_2H$, was prepared without difficulty by the method of Auwers and Schleicher;[1] it consists in boiling camphoric anhydride, aniline and chloroform during 3 hours. The product was recrystallized from alcohol.

Camphor-β-naphthylamidic acid, $C_{10}H_7NHCOC_8H_{14}CO_2H$, was prepared in a similar manner to the phenyl derivative, except that the heating was continued during 5 hours. The chloroform was then evaporated, the residue dissolved in a warm, aqueous solution of sodium bicarbonate and the amidic acid precipitated from the clear solution by means of hydrochloric acid. After solution in alcohol the compound was obtained in white crystals, melting at 220–1°. Found: N, 4.39; calculated, 4.30 per cent.

The acid dissolves readily in acetone, alcohol, ethyl acetate, chloroform, or ether; it is slightly soluble in benzene and in hot water. In solution the acid reddens blue litmus paper and it dissolves in a warm, aqueous solution of sodium carbonate. The *sodium* and *potassium salts* are somewhat colloidal and soapy.

Neither camphorphenyl- nor β-naphthylamidic acids could be transformed into the imides at the temperature of a boiling water bath. The experiments were made in alcoholic solution (50 per cent.), the heating continuing during 35 minutes in the case of the phenyl compound and

---

[1] *Ann.*, 309, 341.

6 hours in that of the β-naphthyl derivative. The addition of aniline or quinoline to the alcoholic solution of the phenylamidic acid and of β-naphthylamine to that of the β-naphthylamidic acid produced no effect. It is clear, therefore, that these two acids resemble the aliphatic amidic acids and differ from those of the aromatic series.

Summary.

1. We have prepared a number of phthalamidic acids of the type $RNHCOC_6XCO_2H$, where R = phenyl or β-naphthyl and X represents H_2Cl_2, Cl_4 or H_3NO_2.
2. The behavior of these acids when heated with alcohol alone and also with alcohol and amines has been studied.
3. The accumulation and approximation of negative groups in the phthalic acid nucleus favors the formation of diamides, $C_6X(CONHR)_2$, rather than that of imides,  $C_6X<\genfrac{}{}{0pt}{}{CO}{CO}>NR$.
4. Camphoramidic acids, $RNHCOC_8H_{14}CO_2H$, ($R = C_6H_5$ or β-naphthyl) resemble the corresponding aliphatic acids and not those of the aromatic series. They are stable under the conditions employed.
5. A number of new compounds are described, and improved methods have been worked out for the preparation and purification of certain substances which had been obtained previously by other chemists.

The investigation is being continued in various directions.

THE BASIC PROPERTIES OF OXYGEN: COMPOUNDS WITH BROMINE AND IODINE.

By D. McIntosh.

Received August 5, 1910.

Two addition compounds of ether and bromine are known. One, which we may call the tribromide (m. p. 22°)[1] consists of three, and the other, the dibromide (m. p. —40°)[2], of two atoms of bromine to a molecule of ether.

The constitution of the dibromide may be explained in several ways, assuming the oxygen to be quadrivalent and the bromine uni- or trivalent. The tribromide, however, can be conveniently expressed only by doubling the formula and writing it $C_4H_{10}O = Br - Br = Br - Br = Br - Br = OH_{10}C_4$; and as nothing is known against this mode of representing the dibromide, either in regard to its molecular weight or its reactions, its formula, too, may be doubled, $(C_4H_{10}O = Br - Br = Br - Br = OH_{10}C_4)$.

---

[1] Schützenberger, *Ann.*, 167, 86 (1873).

[2] *Trans. Chem. Soc.* (London) 87, 784 (1905).

In a recent paper Chelintzev and Kepovalov[1] criticize these formulas and attempt to show that the dibromide has the constitution $C_4H_{10}O\langle^{Br}_{Br}$. As I have tried to determine the molecular weights of these and similar compounds, a brief account of the work may be useful; and while it has been found impossible to decide on the correct formulas it can at least be shown that Chelintzev and Kepovalov misinterpret the results of their experiments.

These investigators prepare what they believe to be the dibromide ether complex by adding absolute ether to pure bromine. After the reaction is complete, the excess of ether is removed by heating to 30° under reduced pressure. They obtain an oily orange-red liquid, etc.

Under such conditions the dibromide is not formed but a mixture of substitution products colored by bromine is produced as repeated analyses have shown. The dibromide can be prepared only with the greatest care at a low temperature. Then it may be obtained with less than $^1/_{20}$ per cent. hydrobromic acid. Above its melting point (—40°) substitution takes place, so that a mixture of bromine and ether may contain a large amount of acid.

In parallel columns are placed the properties given to the compound by Chelintzev and his collaborator and those of the pure dibromide.

Chelintzev and Kepovalov	McIntosh
Orange-red liquid.	Bromine colored liquid.
Soluble in benzine, benzene and carbon disulphide on warming, precipitated on cooling.	Decomposed
Soluble in chloroform.	Largely decomposed.
Partly soluble in carbon tetrachloride.	" "
Soluble in ethyl alcohol and ethyl acetate with heat evolution.	" "
Changed slowly by KOH solution.	Instantly decomposed.
Acid fumes evolved in strong sulphuric acid.	" "
Little affected by sodium acid sulphite solution.	" "
Slowly acts on potassium iodide solution.	Instant decomposition with liberation of iodine
Heat of formation 9130 cal.	Under 2000 cal.

These investigators find the molecular weight of their compound in acetic acid by the cryoscopic method to be about 240. The dibromide, however, is decomposed by this solvent and its molecular weight cannot be determined.

Freezing-point measurements of this substance were made with chloroform (m. p. —63°) as solvent. The compound was partly decomposed, and the freezing-point lowerings, although a little less than the sum of the ether and bromine depressions determined separately, could not be used to fix its molecular weight.

---

[1] *Ber.*, 42, 1531 (1909).

An attempt was made to determine the molecular weight of these bromides by Ramsay and Shields' method. The figures for the tribromide[1] may be given:

FORMULA TAKEN FOR CALCULATION $C_4H_{10}OBr_3$.

T.	$\gamma(MV)^{2/3}$.
25.9	1229.5
29.6	1223.0
37.2	1201.2
45.0	1175.3

When plotted these members lie approximately in a straight line. Between 25° and 45° $\frac{d\gamma(MV)^{2/3}}{dT} = 2.85$ while for normal compounds the value is 2.12. Clearly the compound is largely dissociated. The dibromide separates into two layers 10° above its melting point. It, too, is largely dissociated.

These results show that the ordinary methods of molecular weight determinations are not applicable to these oxonium compounds, and that the formulas must remain in doubt until other methods are devised.

While examining the action of bromine and chlorine on the alcohols, ketones, etc., in 1905, a large amount of time was spent in attempting to produce analogous compounds with iodine. Quite recently Waentig[2] has made some experiments on this point and believes that he has obtained addition products at low temperatures.

When a solution of iodine in alcohol or acetone is cooled to —80° or —90° the iodine may separate and be mistaken for a compound, but when carefully dried at a low temperature analyses show the product to be iodine contaminated with a little of the organic solvent. With ethyl acetate mixed crystals of the solvent and iodine may be obtained.

Bromine and chlorine when dissolved in organic substances containing oxygen give a noticeable heat evolution; iodine a slight heat absorption.

If iodine gives compounds analogous to those formed by the other halogens, the reaction between iodine and ether may be represented by the equation

$$\overset{\text{A.}}{C_4H_{10}O + I_2} \rightleftarrows \overset{\text{B.}}{C_4H_{10}OI_2}$$

or $K = B/A$, where K is the equilibrium constant, and B and A the concentrations of the substances involved.

---

[1] The tribromide always contains several per cent. hydrobromic acid.

[2] *Z. physik. Chem.*, 68, 1513 (1909).

From van't Hoff's equation

$$\log K_2 - \log K_1 = \frac{q}{2}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

Where K_1 and K_2 are the equilibrium constants at the temperatures T_1 and T_2, T_2 being the higher, and q the heat of formation of A. Since q is positive[1] K_2 must be larger than K_1 or less of the compound is produced at a low temperature than at a higher one. It seems probable, then, that these compounds cannot be produced in a reasonably pure state by cooling their solutions to a low temperature.

Rearrangements of Unsaturated Acids 6 Illustrations of True Rearrangements of Non-reversible Type 7. Rearrangements with Reaction 8 Review of the Field of Molecular Rearrangements

1. Types of Chemical Reaction.

In the study of molecular rearrangements of carbon compounds, two types of chemical reactions are noted; the reversible and non-reversible.[3] Tautomerism furnishes many examples of molecular rearrangements of the reversible type. Wislicenus showed, in the case of formylphenylacetic ester,[4] that in certain solvents an equilibrium between the two isomeric forms is established, which equilibrium is dependent upon temperature, concentration, and the nature of the solvent. Molecular rearrangements of the non-reversible type are illustrated by the change of Δ^2 unsaturated acids into their Δ^1 isomers by boiling with alkalis.

A further study of reversible and non-reversible molecular rearrangements shows that certain rearrangements occur when atoms are added to or substracted from the original molecule, while in many other cases the rearrangement consists only in the readjustment of the atoms already present in the molecule. Molecular rearrangements of the former class will be termed rearrangements with reaction while those of the latter class will be called true rearrangements or rearrangements without reaction. Tautomeric changes illustrate true rearrangements of the reversible type, while the change of Δ^2 unsaturated acids to their Δ^1 isomers furnish illustrations of non-reversible rearrangements of this class. The historic rearrangement of pinacone to pinacolin by the elimination of water illustrates a rearrangement with reaction. The following discussion will deal mainly with true rearrangements of the non-reversible type.

2. Formation and Stability of Compounds that Rearrange.

It has often been suggested by chemists that molecular rearrangements occur in the direction to produce a more stable substance. Before this idea can be developed it is necessary to consider carefully the conditions under which compounds rearrange, as well as the nature of the compounds. Nernst[1] states: "The fact that reaction velocity in chemical systems is usually extraordinarily small, no matter how far removed from the point of equilibrium, is of the very greatest importance for our knowledge of chemical compounds. Probably nine-tenths, or rather ninety-nine one hundredths, of all organic compounds would never have seen the light of day if they had proceeded to their stable conditions with greater velocity. The many polymeric hydrocarbons of the formula C_nH_n could not exist at the same time if they all tended to go at once to the system of greatest stability corresponding to the formula C_nH_n. In the sense of the preceding, *organic chemistry is peculiarly the region of unstable compounds*, and these either go over to a more stable form very slowly in a measurable time or else not at all. In most cases heat only accelerates a reaction—whether a decomposition or a union—which would take place spontaneously, though, to be sure, perhaps only during the lapse of, say, a thousand years."

Baeyer, in his work upon terephthalic and phthalic acids, furnishes the experimental part to Nernst's discussion. Terephthalic acid upon reduction in the cold with sodium amalgam, in the presence of carbon dioxide to remove the hydroxyl ion, gives $\Delta^{2,5}$-dihydroterephthalic acid. This acid rearranges to the $\Delta^{1,5}$ isomer upon warming with water. The $\Delta^{1,5}$ acid, when boiled in the presence of hydroxyl ions, gives the $\Delta^{1,4}$-dihydroterephthalic acid. Baeyer concluded that the $\Delta^{2,5}$-dihydro acid is the most unstable, while the $\Delta^{1,4}$ isomer is the most stable. Using a more vigorous reducing agent, namely sodium amalgam in the absence of carbon dioxide gas, he obtained no $\Delta^{2,5}$-dihydroterephthalic acid, but more stable products. On the other hand, the reduction of phthalic acid at a higher temperature by sodium amalgam in the absence of carbon dioxide gives the most stable tetrahydrophthalic acid. No unstable intermediate dihydro or more unstable isomeric tetrahydro acids could be formed under these conditions, so that molecular rearrangements are not possible, because the product first formed by the reduction is the most stable. Thus the conditions under which compounds must be formed which undergo true molecular rearrangements of the non-reversible type, become evident, namely that the reagents used at the time of formation as well as the speed of the reaction must be such that unstable compounds are produced.

---

[1] Nernst, Theoretical Chemistry. Translation of revised 4th German edition, 672.

3. Catalysis of Speed of True Rearrangements of the Non-reversible Type.

According to Nernst the unstable compounds, considered above, may be going over to a more stable state very slowly in a measurable time or else not at all. It is evident that true rearrangements of the non-reversible type occur in unstable compounds which go, spontaneously, to a more stable state. In the case of the rearrangement of $\Delta^{2,5}$-dihydroterephthalic acid to the $\Delta^{1,5}$ isomer, simply heating with water caused the reaction to be complete in a short time. In many other cases heat is the only thing necessary to complete the rearrangement in a short time. The $\Delta^{1,5}$-dihydroterephthalic acid rearranged to the $\Delta^{1,4}$ isomer when boiled with hydroxyl ions. Thus it appears that the reagents used in true rearrangements of the non-reversible type are catalysts to the speed of the rearrangement and in their presence reactions which might take thousands of years are completed in a few minutes. Goldschmidt and Reinders[1] have proved this to be the case for the change of diazoaminobenzene into aminoazobenzene. A thorough study of the catalytic influence of the reagents added to hasten true rearrangements of the non-reversible type will be made in the near future.

4. A Correlation of True Molecular Rearrangements of Acids and Bases, Belonging to the Non-reversible Type, With the Free Energy of Ionization.

Under 2 it was shown that the reaction velocity and stability were of fundamental importance in the study of rearrangements of this type, so that some measure of these factors must be found. Reaction velocity is readily determined by the amount of the substance changed in a given time, but a measure of stability is not so readily obtained. The term stability is frequently used in a vague way. It has an exact meaning only when the conditions are specified, as will be seen in the following: The above quotation from Nernst makes it evident that when a reaction takes place *spontaneously* (or may so take place if sufficient time is given) the initial substance is unstable with respect to the final and hence there is a decrease in free energy during the change. As stated above, in true rearrangements of the non-reversible type, the initial substance is slowly changing into its isomer even in the absence of a catalyzer. Thus the initial substance in such a rearrangement must be unstable with respect to the final substance. Yet, as stated in the quotation from Nernst, the final substance may be unstable with respect to other substances as, for example, to the elements carbon, hydrogen, and oxygen. Hence in the previous discussion stability toward rearrangements is meant whenever the term is used.

---

[1] *Ber.*, 29, 1369, 1899 (1896).

In seeking a criterion of stability in true rearrangements of the non-reversible type, the logarithm of the ionization constant of acids and bases has been chosen. From the second law of thermodynamics, the expression, $A = RTlnK$, is obtained, in which

A is the free energy of ionization,
R is the gas constant,
T is the absolute temperature, and
K is the ionization constant.

The free energy of ionization of acids and bases is "the change in free energy" as expressed by the reaction $HA \rightleftarrows H^+ + A^-$ for acids and $ROH \rightleftarrows R^+ + OH^-$ for bases when the initial and final substances are at unit concentration. Therefore, the above expression gives a measure of the free energy of ionization in terms of the ionization constant and shows that the free energy of ionization is directly proportional to the natural logarithm of the ionization constant. Since that acid is most stable toward ionization which possesses the smallest amount of free energy of ionization, it is evident that when one acid has a smaller ionization constant than another the change in the free energy of ionization is smaller and its stability with respect to ionization is greater. Therefore to determine the relative stabilities of two acids in terms of the free energy of ionization, we need only to compare the logarithms of their ionization constants.

In the following table examples of true rearrangements of the non-reversible type are given. The Briggsian logarithm of the ionization constant of each acid or base that undergoes the rearrangement is given in column 6, and that of the isomer resulting from the rearrangement is given in column 7. From this table it is evident that the free energy of ionization of the initial substance is greater than that of the final substance and that during the rearrangement there has been a decrease in free energy. The final substance is, therefore, more stable toward ionization than the initial substance. As stated above, the final substance in a rearrangement of this type must be the more stable toward rearrangement, so that that acid or base is most stable toward rearrangement which is also most stable toward ionization as Table I shows. Hence, *the final (stable) substance in a series of true rearrangements of the non-reversible type has a smaller ionization constant (or free energy of ionization) and the logarithm of the ionization constant may therefore be taken as a criterion of stability in these rearrangements.*

The meaning of the classes referred to in Table I will be explained in the final section of this article.

5. Rearrangements of Unsaturated Acids.

The most thorough test of the principle that true rearrangements of acids or bases of the non-reversible type take place in the direction to decrease the free energy of ionization is that given by the unsaturated acids. Rearrangements of such acids are so common that Thiele's partial valence theory was advanced for the explanation of the reason that $\Delta^{1,3}$ unsaturated acids gave Δ^2 unsaturated acids upon reduction. Further in the literature on unsaturated acids it is constantly noted that Δ^2 unsaturated acids rearrange to the Δ^1 isomer, etc.

Fichter and Pfister[1] first called attention to the fact that the Δ^2 unsaturated acids of the aliphatic series give a greater ionization constant than any of their isomers. The following figures and data will show this principle to be generally true in both open-chain and ring unsaturated acids. In the figures, the ordinates give the Briggsian logarithms of the affinity constants while the abscissas give the positions of the unsaturation in the acids, given in the table following the figures. The logarithm of the affinity constant is used rather than the algebraic value, since the free energy of ionization is proportional to a logarithmic function of the affinity constant and, also, since a comparison of the relative stabilities of the acids toward ionization is desired.

The principle of Fichter and Pfister appears to be general and not a single exception to it is known, while the data given in Table II show that it has been tested for twenty acids. In the case of Δ^1-tetrahydrophthalic acids an apparent exception to this rule is found, which disappears if we start the nomenclature with the other carboxyl so that the Δ^1 and Δ^2* positions are interchanged. The position of the double union then corresponds to that given in the other 18 acids. As Table I shows, these acids all rearrange in the direction to decrease the free energy of ionization so that it may be stated as a general rule *that whenever the unsaturation is Δ^2 with respect to a given carboxyl group true rearrangements of the non-reversible type are possible.*

Thiele and others have found that $\Delta^{1,3}$ unsaturated acids upon reduction give the Δ^2 acids, which, according to the above paragraph, are the most unstable toward ionization of any of their isomers, and rearrangements would be predicted and have been observed quite generally. Nernst states that such unstable isomers are formed under conditions where the speed of reaction at the time of formation is very slight. The above discussion of the reduction of the terephthalic acid showed that when precaution was taken to maintain conditions of slow speed of reaction and to use weak reducing agents the $\Delta^{2,5}$ unsaturated acid resulted.

This acid has both double unions Δ^2 to carboxyl groups. It should have the greatest amount of free energy of ionization according to the principle of Fichter and Pfister and should undergo rearrangements, which agrees with the experimental facts as shown above. *Hence it is evident that the compounds from which Thiele deduced his theory of partial valence, as well as other acids which obey the same rule, must be compounds which are formed with weak reducing agents involving small energy changes and where the speed of reaction is small so that compounds result which are very unstable toward ionization, and therefore toward rearrangement.*

6. Illustrations of True Rearrangements of Non-reversible Type.

The following table is a list of some of the more important true rearrangements of the non-reversible type. Many other illustrations of the rearrangements of Δ^2 unsaturated acids to their Δ^1 isomers are known for which no measurements of the ionization constants have been made. Yet in the light of the above discussion it is safe to conclude that they take place in the direction to decrease the free energy of ionization.

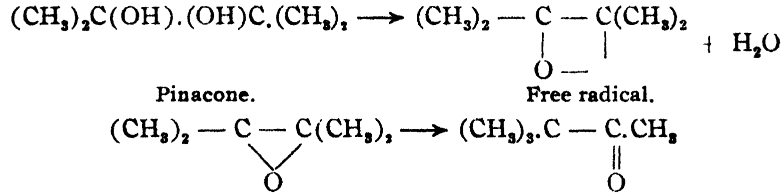
7. Rearrangements with Reaction.

In Table IV a few examples of molecular rearrangements with reaction are given. The numbers in the first column of the table refer to the classes of Table V. With rearrangements of this type, it is much more difficult to distinguish any regular behavior. If such rearrangements are grouped according to the kind of reaction by which they are formed, some uniformity is obtained. Thus rearrangements taking place simultaneously with dehydration appear to be due to the fact that a free radical cannot exist for a measurable time or that a possible intermediate ring compound is too unstable toward rearrangement to exist. This is illustrated by the pinacone-pinacolin change:



$$(CH_3)_2C(OH).(OH)C.(CH_3)_2 \longrightarrow (CH_3)_2-\underset{|}{C}-\underset{|}{C}(CH_3)_2 + H_2O$$

Pinacone. Free radical.

$$(CH_3)_2-C-C(CH_3)_2 \longrightarrow (CH_3)_3.C-\underset{\|}{C}.CH_3$$

Unstable ring compound. Pinacolin.

In the case of the reduction of the unsaturated acids, the speed of the reaction and the strength of the reducing agent control the rearrangement. For example, if $\Delta^{1,3}$-dihydrobenzoic acid is reduced in the cold by sodium amalgam, the Δ^2-tetrahydro acid results, and there has been a shifting of the double union either from the Δ^1 or Δ^3 position to the Δ^2 position. If this same reaction is performed with the same reagents at a higher temperature the Δ^1-tetrahydrobenzoic acid results and there has been no shifting of either double union. A review of Fig. 1 and Tables I and II shows that the acid having two double unions within the molecule possesses more free energy of ionization than any of its dihydro reduction products. Further, the figure shows that the Δ^2 unsaturated acid has the greatest amount of free energy of ionization of any of its isomers. Hence, when Δ^2-tetrahydrobenzoic acid was formed by the reduction of $\Delta^{1,3}$-dihydrobenzoic acid, the decrease in the free energy of ionization was a minimum and a double union was shifted. With the same reagents, at a higher temperature, *i. e.*, where the speed of reaction was greater, reduction of the $\Delta^{1,3}$-dihydrobenzoic acid gave the Δ^1-tetrahydrobenzoic acid. The data for Fig. 1 show that the difference in the free energy of ionization of the $\Delta^{1,3}$ acid and its Δ^1-dihydro reduction product is much greater than in the case above where the Δ^2-dihydro reduction product was formed. Further, the formula for these acids show that there has been no shifting of the double union in the latter reduction. Therefore, *when the reduction of unsaturated acids containing more than one double union takes place so that the decrease in the free energy of ionization is a minimum, compounds form simultaneously*

TABLE IV

Class.	Rearrangements with reaction Before.	 After.	Reaction
1	Pinacone	Pinacolin	Dehydration

with a rearrangement and these compounds, in turn, will undergo rearrangement.

This class of rearrangements furnishes many fine illustrations of Ostwald's *law of successive reactions.*[1]

8. Review of the Field of Molecular Rearrangements.

The conclusions, given in the preceding paragraphs, are based on a general review of the field of molecular rearrangements. In this review, the need of a classification of the mass of material included under the term molecular rearrangement has been very evident. Not only should such reactions be classified as reversible and non-reversible rearrangements of the types discussed above, but the behavior of the different radicals should be thoroughly studied.

Classes of Known Rearrangements.

Table V has been developed to show the present state of the problem of rearrangement. In the first vertical column a partial list of the elements and radicals has been given. In the first horizontal row is given the elements between which the rearrangement occurs, while the second horizontal row gives their position in the compound, that is, whether in the ring or side chain. The third horizontal row gives the class to which each rearrangement of a given group is assigned. In the first horizontal row the letter stands for the atomic symbol of the element and the arrow shows the direction of the rearrangement. In the second row Op stands for open chain, R for closed chain or ring, Op ⟶ R for open or side chain to closed chain, and R ⟶ Op from closed to open or side chain. Thus to read the behavior of the alkyl group for class I, it is evident that the alkyl group will rearrange from carbon to carbon in the open chain; or for class 8, it is evident that the alkyl group may rearrange from carbon in the ring to oxygen in the side chain. Those rearrangements which are theoretically impossible because of the law of constant valence are designated by the sign x, while those impossible for the trivalent but possible for the pentavalent nitrogen are designated by the sign v.

To show the present state of knowledge of the phenomenon of rearrangements, the following system of marking is employed in the vertical columns beneath the classes:

o designates occasional occurrence,
c designates common occurrence, and
r designates rare occurrence.

Doubtless the above scheme is incomplete so far as the known cases are concerned, but it must be borne in mind that such a table when completed will demand many years of careful reading, especially in a field where systemization has not been attempted.

	Hydrogen	Tautomerism—Amide	Imidol type
29	Hydrogen	Tautomerism—Amide	Imidol type

This table, in conjunction with Tables III and IV, shows that hydrogen, the double union (which in general is the same thing as the shifting of hydrogen) and the alkyl group are more generally rearranged than the other elements or radicals. Further, rearrangements occur much more frequently between nitrogen and carbon, the shifting occurring from sidechain nitrogen to ring carbon. The alkyl, acyl, aromatic acid radical, hydroxyl, amine, alkylamine, arylamine, nitroso, nitro, halogen and sulphonic radicals undergo this rearrangement (members of class 19). In general, however, the oxyalkyl, oxyaryl, and alkyl, aryl, nitro, nitroso, and haloamine groups do not rearrange as a whole, but rather the alkyl, aryl, nitro, nitroso and halogens shift from the oxygen or nitrogen to carbon.

The classes given in the tables, refer to this scheme of classification, and Table VI gives illustrations of rearrangements of different elements and radicals belonging to these classes.

Summary.

1. Molecular rearrangements of carbon compounds are of the reversible and non-reversible types of chemical reactions.

2. Molecular rearrangements of carbon compounds must be further classified according as the rearrangement is simply a readjustment of the atoms already present in the molecule (true rearrangements) or as the rearrangement is due to atoms having been added to or taken away from the original molecules (rearrangements with reaction).

3. Compounds which rearrange are formed under conditions where the speed of formation is a minimum so as to produce substances very unstable toward arrangements.

4. The reagents present when a compound undergoes true rearrangement of the non-reversible type are catalytic to the speed of the rearrangement.

5. True rearrangements of the non-reversible type take place in the direction to produce substances more stable toward rearrangement.

6. True rearrangements of acids and bases belonging to the non-reversible type take place in the direction to produce acids and bases more stable toward ionization (*i. e.*, having less free energy of ionization) and therefore the logarithm of the ionization constant may be used as a criterion of stability in these rearrangements.

7. An organic acid, which possesses a double union Δ^2 to its carboxyl group, has a greater free energy of ionization than any of its isomers and may, therefore, readily undergo rearrangements to produce isomers more stable toward ionization and rearrangement.

8. Δ^2 Unsaturated acids are formed from $\Delta^{1,3}$ unsaturated acids under the conditions where the speed of formation is a minimum, the de-

crease in the free energy of ionization is a minimum, and the stability toward rearrangement is a minimum.

9. Many rearrangements with reaction are due to the fact that a free radical cannot exist, and after certain atoms or groups have been eliminated the very unstable radical resulting undergoes a readjustment of the atoms present so as to maintain the quadrivalent nature of carbon and produce a substance more stable toward rearrangement.

10. A schematic review of the field of molecular rearrangements of carbon compounds is given by Table V, and Table VI gives illustrations of the classes of rearrangements designated in Table V.

The author wishes to thank Dr. W. A. Noyes, of the University of Illinois, for his kind suggestions and criticisms of this paper and also Dr. W. C. Bray, of Massachusetts Institute of Technology, for his kind suggestions regarding Section 4.

[Contribution from the Bureau of Chemistry, U. S. Dept. of Agriculture.]

THE INVERSION OF CANE SUGAR BY INVERTASE. VII. THE EFFECT OF ALCOHOL ON INVERTASE.

By C. S. Hudson and H. S. Paine.

Received July 11, 1910.

Purpose of the Investigation.

A knowledge of the action of alcohol on invertase is of practical importance for two reasons: first, alcohol is naturally present during the fermentation of cane sugar by yeast and the invertase of the yeast is thus normally in the presence of weak alcohol; and, second, alcohol is often used, though generally with little success, to prepare the enzyme in a solid form by precipitation from an aqueous extract of yeast. In order to learn what influence alcohol of different strengths has on invertase, the following investigation was made. The results show that the influence is exceedingly great and that it consists in three distinct actions, namely, an inactivation, a permanent destruction, and a precipitation of the enzyme. These actions will be described in the order named.

The Inactivation of Invertase by Alcohol.—The activity of purified invertase in inverting cane sugar dissolved in various strengths of ethyl alcohol was measured at 30° by the usual method. Care was taken to have sufficient acetic acid in the solutions to insure that the maximum activity of the enzyme was attained, and the solutions were made alkaline at the end of the experiment to stop the enzymatic action and complete the mutarotation. The alcohol used was Squibb's or Baker's absolute alcohol and the concentrations are expressed as volume per cent. The activities are recorded in Table I as the velocity coefficients of the inversion, using minutes and decimal lagarithms and multiplying by

10,000 to avoid decimals. The results are also expressed graphically in Fig. 1.

It is apparent that alcohol has a strong inactivating action on invertase even when the alcohol is dilute. The destruction of invertase by alcohol does not take place below about 20 per cent., as will be shown under the following caption, but the activity of the enzyme is markedly lowered by even a few per cent. of alcohol. The figure shows that the relation between alcoholic strength and activity is not proportionality but may be represented as a logarithmic or hyperbolic function. On account of the fact that rapid destruction of the enzyme takes place in solutions above 30 per cent. alcoholic strength it is not possible to measure the activity of invertase in this region by the usual method; the theory of the modified procedure which has accordingly been used to measure the activity in 50 and 70 per cent. alcohol is given on page 1355 and the values which were found are included in the table and figure.

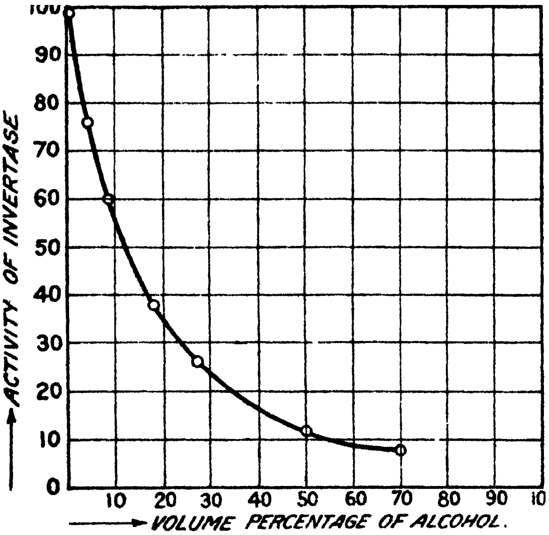

Fig. 1.—The influence of alcohol on the activity of invertase.

The inactivation of invertase by alcohol was noticed by O'Sullivan and Thompson,[1] and they state that the inactivation by alcohol is "in direct proportion with the amount present. Five per cent. alcohol decreases the speed of the reaction by about one-half." The results here given are somewhat different in detail from those quoted, because we have measured the inactivation for higher strengths of alcohol than were used by the previous investigators. It will be noticed that our results also show almost a linear relation between activity and alcohol strength for weak alcoholic solutions.

TABLE I.—ACTIVITY OF PURIFIED INVERTASE IN AQUEOUS ALCOHOL.

(Temperature 30°. Concentrations: Aqueous alcohol containing cane sugar 0.2 normal, and acetic acid 0.02 normal; 100 cc. of this mixture were added to 10 cc. of purified invertase solution.)

Concentration of alcohol (volume per cent.).	Activity invertase K_1 (10,000).	Percentage activity.
0.0	80.0	100
4.3	61.0	76
9.1	48.0	60
18.2	30.0	38
27.3	21.0	26
50.0	8.8	11
70.0	6.4	8

The Destruction of Invertase by Alcohol.—The measurements of the destruction of invertase by alcohol were made by the method previously used in studying the destruction of the enzyme by acids and alkalies.[1] The rate of the destruction follows the course of unimolecular reactions, as is shown by the following experiment. The value of the velocity coefficient of the unimolecular formula, k_2, remains constant within the errors of experiment during the course of the destruction.

TABLE II.—UNIMOLECULAR ORDER OF THE DESTRUCTION OF INVERTASE BY ALCOHOL.

(Temperature 30°. Alcohol 20 per cent. by volume. Maximum activities were measured.)

Time. Minutes.	Activity of invertase [k_2 (10,000)].	Velocity coefficient (k_2).
0	8.98	.....
15	8.11	0.00295
30	7.33	0.00294
45	6.54	0.00306
75	5.41	0.00293
105	4.66	0.00271
165	4.13	0.00204
	Average,	0 00277

The rates of destruction of invertase which were found in various strengths of alcohol are recorded in Table III, the values of k_2 being expressed in minutes and decimal logarithms and multiplied by 1,000 to avoid decimals. The results are also shown graphically in Fig. 2.

The rate of destruction changes most peculiarly with the strengths of the alcohol, reaching a pronounced maximum at about 50 per cent. Presumably the protective action of strong alcohol is due to its precipitating the invertase, or some other substance whose precipitation protects the

---

TABLE III.—RATES OF DESTRUCTION OF INVERTASE BY ALCOHOL.

Concentration of alcohol (volume per cent.).	Rate of destruction [$k_2 \times (1{,}000)$].	Concentration of alcohol (volume per cent.).	Rate of destruction [$k_2 \times (1{,}000)$]
0	0	50	850
10	0	55	570
20	3	60	240
30	44	70	74
40	260	80	7
45	487	90	2

invertase, as a visible precipitation begins at or near the strength of 50 per cent., at which the maximum of the curve falls and the protective action begins. If the curve to the left of the maximum is alone regarded as the curve of the destruction in solution, it is noticed that it is very similar to the curve for the destruction of the enzyme by acids and alkalies.[1] It appears, therefore, that the destruction by alcohol in homogeneous solution is due to a decomposition of the invertase similar to the hydrolytic decompositions that are presumably the cause of the destruction by acids and alkalies. The practical application of the results on alcoholic precipitation is given on page 1356.

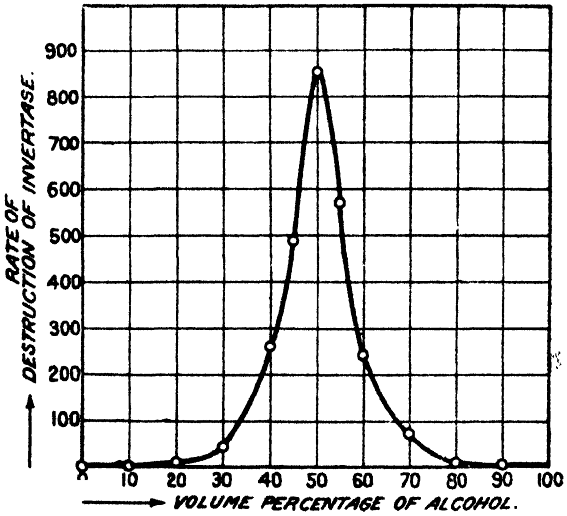

Fig. 2.—The destruction of invertase by alcohol.

The Action of Cane Sugar in Preventing the Destruction of Invertase.—In order to learn whether cane sugar protects invertase from destruction by alcohol, the rate of destruction in a 0.2 normal solution of cane sugar in 50 per cent. alcohol was measured at 30° by the method already described. A correction was applied for the rotation of the sugar in the samples as they were removed to test their activities. The method of preparing the mixture of cane sugar, aqueous alcohol, invertase, and acetic acid is shown in the description of the experiment recorded in Table V; the results on the rate of destruction are given in Table IV:

---

[1] THIS JOURNAL, 32, 779.

TABLE IV.—RATE OF DESTRUCTION OF INVERTASE IN 50 PER CENT. ALCOHOL CONTAINING 6 PER CENT. OF CANE SUGAR.

Time Minutes.	Activity of sample (k_1).	Velocity coefficient (k_3)
0	0.00049	...
30	0.00024	0.010
60	0.00016	0.008
	Average,	0.009

The rate of destruction is far less than that shown for 50 per cent. alcohol in Table III, namely 0.850. The cause of this difference can lie only in the fact that cane sugar was not present in the latter experiments. Several other experiments have given results agreeing with these in showing that cane sugar exerts a very strong influence in protecting invertase from destruction by alcohol. O'Sullivan and Tompson[1] have shown that cane sugar protects invertase from destruction by hot water, and it is well known among distillers that diastase is not so easily destroyed by hot water, if maltose is in the solution; it is then an analogous fact that cane sugar protects invertase from the action of alcohol. The most plausible explanation is that these sugars combine with the enzyme, and the resulting compound is not so easily attacked by alcohol or hot water.

Theory of t[illegible] Rate of Inversion of Cane Sugar during the Destruction of the Invertase.

The rate of inversion of cane sugar by invertase in dilute solution follows the unimolecular order, and it has just been shown that the rate of destruction by alcohol does the same. If invertase is added to a solution of cane sugar in aqueous alcohol of a strength which destroys the enzyme, there occur two simultaneous reactions, the inversion of the cane sugar and the destruction of the invertase. The theory of these dependent or coupled reactions is as follows: At constant temperature start with a solution containing A gram molecules of cane sugar per liter and I units of invertase. After the lapse of t minutes let there be in the solution i units of invertase and $(A - x)$ gram molecules of cane sugar. The rate of destruction of the invertase is

$$-di/dt = k_2 i, \tag{1}$$

in which k_2 is the velocity coefficient of the destructive reaction. The integral of Equation 1 under the condition that $i = I$ when $t = O$ is

$$i = Ie^{-k_2 t}. \tag{2}$$

---

[1] *J. Chem. Soc.*, 57, 900 (1890).

The rate of inversion of the cane sugar is

$$dx/dt = k_1\,(A - x)\,i/I = k_1\,(A - x)\,e^{-k_2t}, \tag{3}$$

where k_1 is the velocity coefficient of the inversion when I units of invertase are present. The integral of Equation 3 under the condition that $x = O$ when $t = O$ is

$$\log A/A - x = k_1/k_2\,(1 - e^{-k_2t}). \tag{4}$$

Equation 4 has been used in finding the velocity of inversion of cane sugar by invertase (k_1) in 50 per cent. alcohol. A mixture of 600 cc. of 0.2 normal cane sugar solution in 55 per cent. alcohol (which was also 0.02 normal with respect to acetic acid) with 60 cc. of dialyzed invertase solution was kept at 30° and the progress of the inversion measured polarimetrically from time to time, the samples being made alkaline before each reading of the rotation. In Table V the rate of this incomplete inversion of cane sugar by invertase in 50 per cent. alcohol is recorded. The quantity of cane sugar present (A) is expressed in degrees, $A = 48.1\,(1.267)^1 = 61.6$, and the quantity of cane sugar present at any time t is $A - x = r + 48.7\,(0.267)$, where r is the reading of the solution. The value of k_2 is taken from Table IV as 0.009.

TABLE V.—COURSE OF THE INCOMPLETE INVERSION OF CANE SUGAR BY INVERTASE IN 50 PER CENT. ALCOHOL

Time Minutes	Rotation (°)	$k_1 = \frac{k_2}{1 - 10^{-k_2t}} \log \frac{A}{A - x}$
0	48.7	
15	44.8	0.00094
30	42.3	0.00091
45	40.9	0.00087
60	39.9	0.000[illegible]
90	38.5	0.00083
120	37.7	0.00083
240	36.0	0.00086
360	35.6	0.00094
	Average,	0.00088

The values of k_1 in the last column, as calculated from Equation IV, are sufficiently constant to show that the reaction follows the laws that were assumed in the theory, within the limits of the present experimentation. It was found that the activity of the invertase when no alcohol was present was $k_1 = 0.0080$. If this rate in pure water is taken as 100, the rate in 50 per cent. alcohol is then 11. Similar experiments have shown that in 70 per cent. alcohol the rate of inversion, on the basis of 100, is 8. These values for the activity in 50 and 70 per cent. alcohol are included in Table I.

The Precipitation of Invertase by Alcohol.—Alcohol precipitates inver-

[1] The Clerget factor at 30°; see *J. Ind. Eng. Chem.*, 2, 144 (1910).

tase,* and it is in this way possible to prepare a solid enzyme, though nothing regarding its purity can be predicated at present. It is a fact, however, that such solid invertase preparations are usually of low enzymatic activity. The reason for this is apparent from the results of this investigation, for unless the alcoholic precipitation is performed in very strong alcoholic solution, the invertase is rapidly destroyed by the alcohol. There are three ways by which this destruction can be lessened: one is to use strong alcohol in large proportion, another is to work at low temperatures, and the third is to have cane sugar present in the solution to protect the invertase from destruction. In order to test the first method, 50 cc. of invertase liquor which had been dialyzed until it contained only 1 per cent. of total solids was mixed with 500 cc. of 95 per cent. alcohol at 25°, and after half an hour the coagulated precipitate was filtered off, washed with alcohol, then with ether, and dried over sulphuric acid in a desiccator. The mass, which resembled horn in superficial appearance, was dissolved in 50 cc. of water, and its inverting activity was found to be 78 per cent. of that of the original sample. The second method of precipitation, at low temperature (0°), gave a small recovery and is not to be recommended.

In order to test the protective action of cane sugar, 25 grams of it were dissolved in 50 cc. of dialyzed invertase and 95 per cent. alcohol added until the strength of the mixture became 70 per cent. alcohol. The precipitate was filtered off, washed with ether, and dried in a desiccator. On redissolving, it showed 94 per cent. of the original activity and a second experiment gave a recovery of 96 per cent. These experiments demonstrate that it is possible to precipitate invertase with alcohol without any important loss of activity provided the enzyme is protected by cane sugar. Other sugars may have this protective action also, but this point has not yet been investigated.

Summary.

O'Sullivan and Tompson's observation that alcohol reduces the activity of invertase is confirmed, and the relation between alcoholic strength and inactivation is shown to be graphically a rounded curve (Fig. 1). Alcohol is found to destroy invertase, and the relation between alcoholic strength and rate of destruction is very peculiar, as it shows a high maximum at about 50 per cent. alcohol. The destruction follows the course of unimolecular reactions; it is not noticeable below 20 per cent. alcohol at 30°, is almost instantaneous at 50 per cent., and decreases to nearly zero at 80 per cent. (Fig. 2). If the alcohol contains cane sugar, the destruction is much slower; thus, 6 per cent. cane sugar reduces the rate of destruction in 50 per cent. alcohol from 0.850 to 0.009, or to about 1 per cent. of its original value. A mathematical theory of the progress of the inversion of cane sugar by invertase in alcoholic solution of sufficient

strength to slowly destroy the enzyme has been worked out and its conclusions are found to agree with the results of the experiments. In this way it has been possible to measure the activity of invertase in 50 and 70 per cent. alcohol, where the destruction plays an important role. Invertase can be precipitated by alcohol without much destruction, provided the strength of alcohol in the final solution is high, approximately 90 per cent. By this method of precipitation, working at room temperature, a solid preparation was obtained which had 78 per cent. of the activity of the original solution. . If cane sugar is present, invertase can be precipitated with no important destruction by even 70 per cent. alcohol; this method of precipitation gave a recovery of 94 and 96 per cent. of the original activity.

[FROM THE STORRS AGRICULTURAL EXPERIMENT STATION.]

THE CATALASE OF MOLDS.

BY ARTHUR W. DOX.

Received June 22, 1910.

An enzyme which accelerates the decomposition of hydrogen peroxide with the liberation of oxygen in a molecular form seems to be almost universally present in living tissues. Its presence in animal organs, in blood, and in milk has been widely investigated. In the vegetable kingdom its occurrence in green plants and in certain fungi is well known.

Many of the basidiomycetes, as well as the yeasts and bacteria, have been found by numerous investigators to contain catalase. The molds, however, have received but little attention with reference to their catalase content. Bach and Chodat[1] found catalase in *Sterigmatocystis nigra*, and Pringsheim[2] noted its presence in the press juice of fifteen out of the seventeen species of mold examined by him. No other investigators seem to have given any attention to the catalase of this important group of fungi.

Catalase is quite distinct from the oxidizing enzymes known as oxidase and peroxidase, though both of these are probably dependent for their oxidizing power upon the presence of some peroxide, either in the plant itself or added in the form of hydrogen peroxide. In the case of the oxidizing enzymes, the oxygen seems to be liberated in a nascent or active form, which readily acts upon oxidizable substances, such as leuco bases, guaiaconic acid, phenolphthalin, etc., and the reaction at once made apparent by the color of the product of oxidation.

Although the molds investigated by the writer showed only slight evidence of oxidase or peroxidase, catalase was generally present in greater concentration. Many of these fungi produce colored spores or secrete a colored substance into the medium, making the color reactions for oxidizing enzymes rather difficult of demonstration. With guaiaconic acid little or no production of color was noticed, though hydroquinone seemed to be acted upon somewhat more readily. Catalase was first observed in the desiccated mycelium which furnished the basis of the studies of other enzymes by the writer.[1]

Experimental.

Most of these experiments were conducted with *Penicillium camemberti*, the well-known mold which ripens Camembert cheese. The organism was grown in pure culture upon a synthetic fluid containing *d*-glucose and inorganic salts. One hundred cc. of the medium were placed in each of a series of 300 cc. Erlenmeyer flasks. The flasks were closed with a cotton plug, then sterilized in an autoclave and inoculated with spores of *P. camemberti*. Determinations were made on successive days, a fresh culture being used each time. To distinguish between intra- and extracellular enzymes, both the mycelium and the filtered medium were tested. The mycelium was ground to a fine paste, suspended in 100 cc. water and 10 cc. taken for the determination. The same proportion of the medium (10 cc.) was taken for the extracellular determinations.

The form of apparatus used for measuring the gas liberated was an ordinary Schiff nitrometer. This was connected by means of a rubber tube with a small glass cylinder containing the enzyme solution and a small dish of hydrogen peroxide (5 cc.) floating on the solution. By shaking the cylinder the enzyme and peroxide are brought in contact, and the gas liberated displaces the water in the nitrometer. This method of measuring directly the volume of gas liberated in a given time was found more satisfactory in this case than Sentner's method of titrating the excess of peroxide with potassium permanganate. Owing to the presence of sugar and perhaps other reducing substances in the medium, the blank that had to be deducted when Sentner's method was used was so high as to introduce considerable error.

The peroxide used was the commercial preparation known as "Dioxygen." One cubic centimeter reduced 22.4 cc. of decinormal permanganate solution, showing that the strength was 3.81 per cent. by weight or 12.5 volume per cent.

In addition to the enzyme determinations, the nitrogen in an aliquot portion of the mycelium was determined, also the optical rotation of the medium, in order to compare the enzymatic activity with the stage of development of the fungus and the supply of nutriment remaining in the medium. The results for *P. camemberti* are tabulated below. The gas volumes are expressed at 0° and 760 mm. pressure.

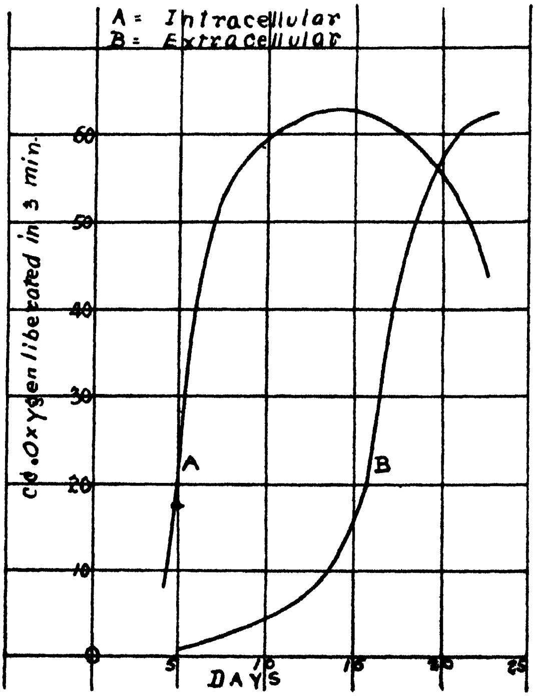
As soon as the mold made its appearance on the surface of the culture medium, the mycelium was found to contain a very active catalase. The increase on succeeding days does not represent a percentage increase, but is due rather to the greater amount of mold as shown by the appearance of the culture as well as by the nitrogen determinations. After about fifteen days, when the culture is mature, the intracellular enzyme gradually decreases. This change is accompanied by a loss of nitrogen from the mycelium and a gradual decrease of turbidity of the fungus cells. In fact, after the culture is a month old the mycelium can be disintegrated by simply shaking the flask. The decrease in intracellular catalase is not to be regarded, therefore, as an actual loss in activity of the enzyme, but rather as the change from the intra- to the extracellular form.

The enzyme in the medium or extracellular enzyme increased steadily during the entire time that the cultures were under observation. This increase continued after the enzyme in the mycelium had begun to decrease and the carbohydrate was completely exhausted from the medium. The medium was always perfectly clear after filtering off the mold. Its activity was not appreciably impaired when it was freed from the mycelium and preserved two weeks with toluene. But on heating the liquid to boiling its activity was completely destroyed.

The relation between intra- and extracellular catalase can best be shown graphically. As the amount of oxygen approaches the theoretical yield, however, the differences in enzyme activity from day to day, as shown by the figures recorded, are much less striking than is actually the case. Unless this is borne in mind the following curve, where the amount of oxygen liberated is plotted against the time during which the culture has grown, is apt to be somewhat misleading. The curve in the main shows the relation between age of culture and enzyme activity, except that the summit is unduly flattened.



Both the intra- and extracellular catalase are somewhat diffusible through parchment and collodion membranes. In performing the test with the endo enzyme, the cellular débris was not completely removed, and there is a possibility that during the course of the experiments, some of this enzyme may have changed to the extracellular form and passed through the membrane as such. Conclusive experiments as to the diffusibility of the intracellular enzyme can best be made with the so-called press-juice, the means of preparing which were not at the writer's command.

In order to determine how widely catalase is distributed in this group of fungi, cultures of a number of species were made, and the catalase in the medium determined at the end of two months. The molds were grown in test tubes on 10 cc. of the fluid medium. The liquid was filtered, and 5 cc. diluted with 10 cc. water were tested with 2 cc. of peroxide.

Species.	Cc. oxygen in 3 min.

ostianus	4.5
ochraceus	3.9
oryzae	2.4
candidus	1.2
wentii	0.6
niger	0.0

In this experiment the formation of extracellular catalase took place much less rapidly on account of the greater depth of the culture medium as compared with the mold-covered surface. In no case was the sugar completely used up, for the filtrate invariably gave a heavy precipitate of cuprous oxide on boiling with Fehling's solution. The above table shows, however, that nearly all of the species examined secrete a catalase into the medium. Nevertheless there are striking differences in the amount produced by the various species. These variations can hardly be attributed to differences in the vigor of the cultures, for all of the species grew well upon this medium and formed a dense mycelium with normal fruiting bodies.

From the experiments described in this paper it is evident that molds contain the enzyme catalase, first in the intracellular form, then gradually allow it to escape into the medium as an extracellular enzyme. Just how this change is effected is not definitely known as yet, but it seems probable that some of the fungus cells undergo disintegration, or at least a loss of vitality, by which an opportunity is afforded the enzymes for diffusion or mechanical release into the medium.

NOTE.

The Instability of Alloxan.—The notes by Professor Wheeler and Professor Bogert on the instability of alloxan in the June number of the JOURNAL recall an experience of my own with the same substance. On attempting some years ago to open a small glass-stoppered bottle containing alloxan I found the stopper so firmly fixed that it was impossible to remove it by any of the methods usually employed in such cases. I then proceeded to scratch a mark on the neck by means of a file, when the bottle exploded with a loud report, but with no damage other than scattering glass and the contents of the bottle over a considerable area of the working table and floor of the laboratory. My conclusion at the time was that the explosion was caused by an accumulation of gases resulting from the slow decomposition of the alloxan in a bottle with a tightly fitting stopper. EDWARD C. FRANKLIN.

NEW BOOK.

Notions fondamentales de chimie organique. By CH. MOUREU, professeur à l'École supérieure de Pharmacie de l'Université de Paris, troisième édition, revue et mise au courant des derniers travaux. Paris. Gauthier-Villars. 1910. 354 pp.

The new edition of this excellent introduction to the study of organic chemistry follows along the same general lines as its predecessors.[1] The subject matter of the second edition has been revised and considerable new material added, to bring the book as nearly as possible up to date. This is evident in the space accorded to catalytic processes and to the developments of the Grignard reaction, and in the inclusion of the results of recent investigations on osmotic pressure and molecular refraction, as well as such newer classes of compounds as the ketenes, ozonides, and the like. A full index constitutes a very welcome addition. The book can be cordially commended. MARSTON TAYLOR BOGERT.

EQUILIBRIUM IN THE SYSTEM: POTASSIUM IODIDE, IODINE AND AQUEOUS ALCOHOL.

BY CHARLES L. PARSONS AND H. P. CORLISS.

Received September 14, 1910.

The question of the existence or non-existence of polyiodides of potassium and the various physical and chemical constants of a solution of iodine in potassium iodide has been for years an interesting problem and is still a subject of investigation. Two previous researches upon the subject have been conducted in this laboratory which accomplished little more than to develop the intricacies of the problem and the various precautions necessary to eliminate errors of manipulation and analysis. The question was first attacked in water solution and second in pure alcohol. In both of these the concentration of the solutions became so great near the invariant point (1 liquid and 2 solid phases at the constant temperature 25°) that, at the time, duplication of results could not be depended upon. In pure alcohol, at least, equilibrium in the strongest solutions was reached with extreme slowness and it has since been discovered that filtration through glass wool which was used at the time was inadequate to separate the solid from the liquid phase. As the liquid in these solutions reaches a specific gravity above 3, is absolutely opaque and somewhat viscous, only the most careful filtration can insure the removal of the small solid particles held in suspension which no optical examination will expose.

Since the addition of water to alcohol greatly diminishes the solubility of iodine in the solvent and the addition of alcohol to water likewise affects the solubility of potassium iodide, it was reasoned that by using aqueous alcohol as the solvent, solution of much lower concentrations would be produced at the saturation point and many difficulties thereby eliminated. That this reasoning was incorrect is readily seen from the results that follow, for the degree of saturation when both iodine and potassium iodide are present in the solid phase differs little whether the solvent be water, alcohol or a mixture of the two. Accuracy of analysis was at last attained, however, as results will show, and there is no good reason why the curve can not be traced as well and with equal accuracy in aqueous or alcoholic solution. The problem divides itself into two distinct parts: (*a*) Do polyiodides of potassium exist as solid phases? and (*b*) Do polyiodides exist in solution? The phase rule enables us to give a positive answer to the first part of the problem but unfortunately it has its limitations, and the second query must still remain open to dispute.

Composition of Solid Phases.

As usually happens the literature contains claims for the existence of solid polyiodides of potassium and also evidence of the non-existence at least of the tri-iodide. Johnson[1] states that he succeeded in obtaining lustrous dark blue crystals by evaporating concentrated solutions of iodine in both aqueous and alcoholic potassium iodide, which analysis showed him to be the tri-iodide. As all the mixed crystals obtained from these strong solutions have much the same appearance and can not be separated from the mother liquor, his conclusions are not to be relied upon, especially as analysis is no criterion whatever of the formula of a substance unless its identity as a single compound is proven by other means. The more recent work of Abegg and Hamburger[2] upon solutions of iodine in aqueous potassium iodide is extensive, and they conclude that no polyiodide of potassium exists of less complexity than KI_7. A difference of opinion may be held as to whether the solid phase they analyzed as near to KI_7 was in reality homogeneous. Foote and Chalker[3] give results which, if correct, prove the existence of KI_3 and KI_7. They are in direct opposition to our own and both can not be right. We must leave the judgment to others. We can only suggest that possibly equilibrium was not attained, that the analyses of the solutions supposed to be constant are not in sufficient agreement to prove constancy of composition and that in these concentrated solutions the potassium iodide content of the solid phase, after pressing between filter paper, is alone no real criterion of its true composition. Furthermore, we are unable to plot their results on any semblance to a solubility curve.

In order to study this question a mixture of pure alcohol and pure water containing 60.04 per cent. of alcohol was prepared and saturated with both iodine and potassium iodide in the presence of varying amounts of the other. In order to make doubly certain any results obtained a solution containing 40.03 per cent. of alcohol was treated likewise. The alcohol was carefully freed from aldehydes and ketones. The potassium iodide was J. T. Baker's "special" and was found to be free from iodate and otherwise pure as claimed. The iodine, with the exception of a few of the last experiments, was distilled from water containing potassium iodide, drained, resublimed in dry air and kept for weeks over sulphuric acid before use. In the exceptions noted, our stock being exhausted, a pure resublimed iodine was used and it was proven to have no impurity affecting results by addition to bottles which had already arrived at equilibrium. The potassium iodide was powdered and dried at 180°.

In order to determine the solubility curves and corresponding solid phases for the system various mixtures were prepared and placed in 100 cc. hard glass bottles, the glass stoppers of which had been carefully ground. The bottles were then rotated in a large thermostat carefully regulated at 25°. The rotating was started December 1, 1909, and the bottles were removed from time to time for analysis and for the addition of more potassium iodide or of iodine as the case might require should examination show that the solid phase had all disappeared.

Equilibrium was reached most quickly in the more concentrated solutions, which was directly contrary to previous experience in pure alcohol. Many of the bottles had not reached equilibrium on March 1st after three months rotation. Practically all were at equilibrium by April 1st, but No. 12 and No. 35 where pure iodine alone was present in solution still showed slight gains on June 1st over analyses made some two weeks previously. They were, however, very near to saturation.

For removing portions of the liquid for analysis a special filter was made, consisting of a glass tube enlarged at the end to hold a platinum disk. This tube was fitted by a ground glass joint to a small pipette and a fine asbestos felt was prepared on the disc, which was washed with alcohol and dried. By drawing through this felt the liquid was absolutely separated from any solid present and the slight diminution in pressure necessary to fill the pipette caused no loss of iodine that could be detected. Many analyses made in duplicate showed that this method could be depended upon to give results varying less than 0.1 per cent. among themselves even in the most concentrated solutions. The liquid so withdrawn was weighed in a glass-stoppered weighing bottle, diluted to 100 cc. with alcohol and aliquot parts taken for analysis. The iodine was determined by titration with an approximately tenth normal thiosulphate solution, carefully standardized against arsenious oxide and pure iodine. The potassium iodide was estimated by careful evaporation in platinum and direct weighing, care being taken to drive off the last traces of iodine by redissolving the residue in water and again evaporating to complete dryness. When equilibrium was reached, as shown by duplicate analyses made many days apart, a portion of the solid phase was removed in a small platinum cup, quickly placed in a weighing bottle and analyzed in like manner. No special attempt to free the solid from mother liquor was made otherwise than to decant off the liquid from the cup before removal from the bottle. Having analyzed the liquid and solid the specific gravity of the liquid was determined in a small Sprengel pycnometer.

The following data are given from which the curves are plotted:

TABLE I.—THE MUTUAL SOLUBILITY OF IODINE AND POTASSIUM IODIDE IN 60 PER CENT. ALCOHOL.

Comments on the above table and its graphical representation in Fig. 1 are almost unnecessary. The analyses given are the final ones after equilibrium had been proven. Their accuracy may be judged from the seven analyses given of the most concentrated liquid at the invariant point No. 20. At this point the liquid was shown to be in equilibrium with iodine, with potassium iodide and with two mixtures of iodine and potassium iodide. It was first found to be in equilibrium with two solid phases, which could from the nature of the curve be only iodine and potassium iodide. For the sake of further demonstration the liquid was separated from the solid, pure iodine added and further rotated in the thermostat without change in composition. Potassium iodide was now added and it was later found to be still in equilibrium with this new mixture. It was again separated from the solid and rotated in contact with pure potassium iodide but no change in composition took place. As only two solid phases can co-exist at the invariant point, no polyiodide can be present. It might also be well to call attention to the highest concentration and the interesting fact that a mixture of twenty grams

[1] Final analysis June 1, saturation point may not have been quite reached.

[2] Analysis April 12th.

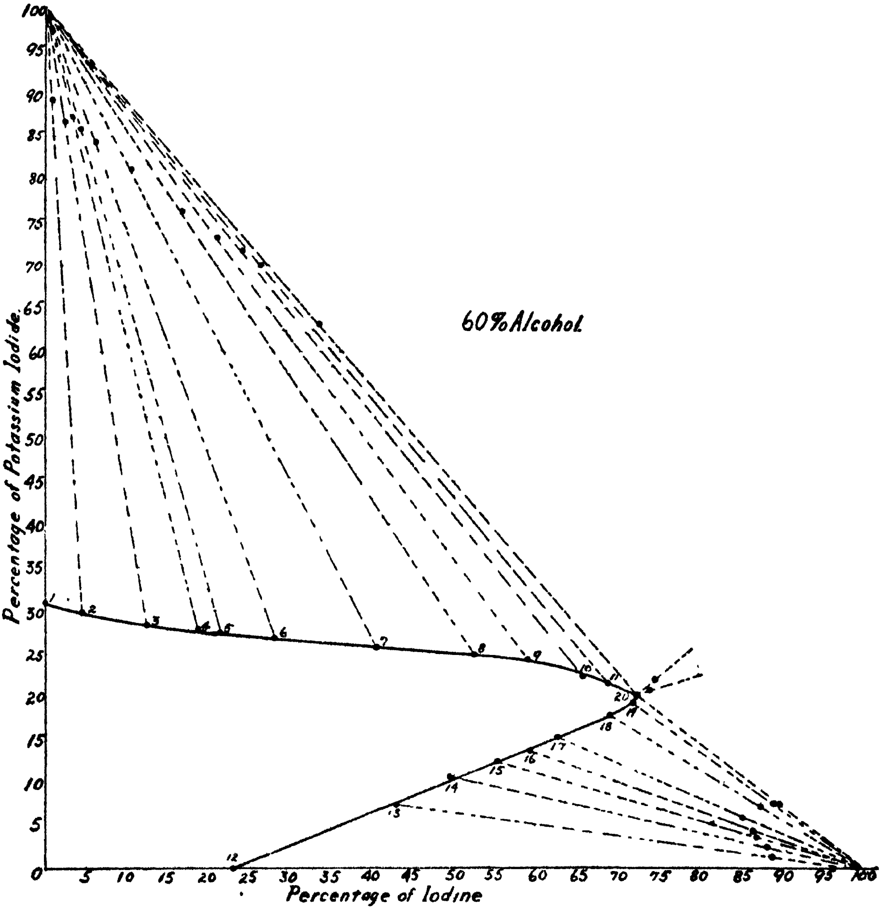

Fig. 1.

of potassium iodide and 72.5 grams of iodine can be kept in solution by 7.5 grams of 60 per cent. alcohol at 25°. Also the mutual solubility of potassium iodide and iodine increases in proportion to the amount of the other present, although the *percentage* composition of the potassium iodide decreases. At the invariant point the liquid phase contains nearly two and one-half mols of iodine for each mol of iodide.

In Fig. 1 are shown the two solubility curves meeting at the invariant point 20. The numbered points represent the composition of the liquid phases and the unnumbered points the solid phases together with adhering mother liquor in equilibrium with them. The extension of the lines joining these points shows the actual composition of the solid phases present.

As before stated, the solubility curves for solution in 40 per cent. alcohol were also determined and their perfect analogy to the 60 per cent. curve are interesting and confirmatory.

The data follow. Again point 35, pure iodine in aqueous alcohol,

[1] Final analysis June 1st. Saturation point may not have been quite reached.

[2] After addition of KI and further rotation.

reached equilibrium with extreme slowness and may not be quite saturated after six months' rotation. Point 34 was also shown to be in equilibrium with two different mixtures of two solid phases, but no attempt was made to put it in contact with pure iodine or pure iodide, as the proof was already complete.

The data in Table II are graphically represented on the two solubility curves in Fig. 2, which is drawn on the same principle as Fig. 1.

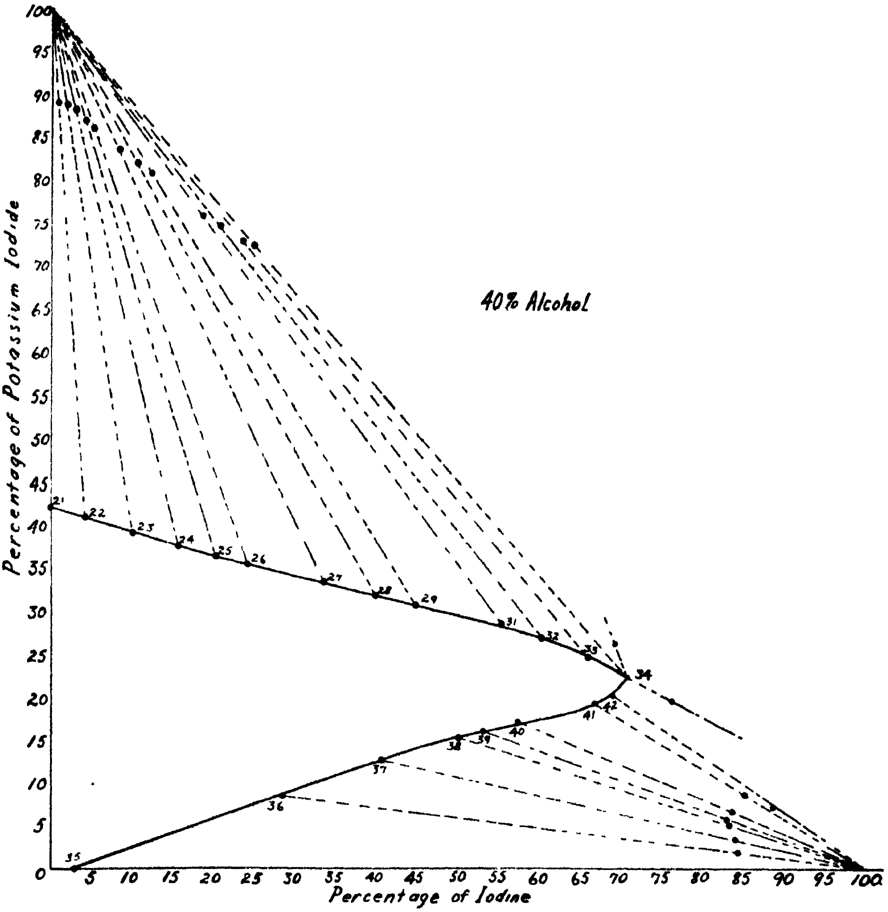

Fig. 2.

Composition of Liquid Phase.

While the non-existence of solid polyiodides of potassium is no proof that they may not exist in solution, it is at least strange that they can not be separated therefrom. Especially is this true when all the evidence in favor of their existence shows that in all solutions of potassium iodide saturated with iodine about one-half of the iodine present must be so combined and that in concentrated solutions the amount of iodine present and unaccounted for as KI_3 is much greater than this proportion. It is not the purpose of this paper to enter into an extended discussion of the problem. From the viewpoint of the dissociation theory, applied to *dilute* solutions, the ground is already well covered in literature, but as the solutions pass above 0.1 normal all formulas obtained begin to lose their force and at higher concentrations do not agree at all with observed facts. While the assumptions made apply well to dilute solutions, they do not show that other assumptions may not explain the conditions equally well, and they all have to discard the mass law as inapplicable as the concentrations increase.

Dossius and Weith[1] early pointed out that strong solutions of iodine in aqueous potassium iodide precipitate iodine on dilution, which is contrary to the mass law if the iodine is present as tri-iodide. LeBlanc and Noyes[2] explain the rise of the freezing point and the decrease in the conductivity when iodine is dissolved in aqueous potassium iodide by assuming the formation of polyiodides. Jakowkin[3] by experiments on the distribution of iodine between aqueous potassium iodide and carbon disulphide developed a mass law constant for dilute solutions indicating that potassium tri-iodide was present and was the only polyiodide present in any amount. His conclusions were based on the relative solubility of iodine in pure water and in carbon disulphide, assuming the potassium iodide present to have no simple solvent effect on the iodine. Dawson,[4] Burgess and Chapman[5] and Laurie[6] have also studied the matter from a similar standpoint and from considerations of transference and electromotive force. In dilute solutions they are in fair agreement. One of us[7] has already pointed out that the conclusions of Jakowkin, upon which most of the subsequent work is either grounded or to which the results obtained are compared, are untenable if dissolved potassium iodide itself has a simple solvent action for iodine such as added alcohol or acetic acid would possess. Furthermore, it was shown that these solutions of iodine in aqueous potassium iodide were perfectly analogous in their osmotic and conductance properties to such ternary mixtures as camphor in aqueous acetic acid and, osmotically at least, to all ternary mixtures where one of the dissolved substances was rendered less soluble by dilution of the mixture with that component which separated out first

on freezing. Indeed it was definitely pointed out that Miller[1] had thermodynamically shown that in all such binary solvents the freezing point must of necessity rise on addition of the third component. Accordingly, the assumption of complexes was not necessary to qualitatively explain the facts. Many published instances were cited of such ternary mixtures where the same reasoning as is applied to the demonstration of the polyiodides would lead to incomprehensible complexes. Bray and McKay,[2] on the assumption that the decrease in conductivity on dissolving iodine in dilute aqueous potassium iodide is due solely to the formation of KI_3, arrive at results in excellent agreement with those of Burgess and Chapman which they believe prove the existence of this polyiodide. They have also attempted to account for the abnormalities in concentrated solutions and find that the deviations from the mass law are not very serious below 0.1 normal potassium iodide but still are not negligible even below this concentration. While admitting the character and force of their arguments, especially when viewed from their standpoint, it should not be forgotten that similar reasoning would probably lead to poly-camphor compounds of acetic acid and other equally improbable complexes wherever the conductivity is diminished by adding a solute to a binary solvent. Furthermore, these results, and the results of the other authorities mentioned are applicable, without other assumption, only to that very limited portion of the solubility curve, which is less than tenth-normal. This is the only portion of the curve where the actual iodine solubility is equivalent in mols to one-half the iodide present and quantitatively meets the theory of Jakowkin. It appears to the authors of this paper that the phenomena accompanying mixtures of potassium iodide, iodine and water (or alcohol) are much more analogous to those known to apply to some ternary alloy mixtures than they are to the properties of known complexes such as some of the double cyanides.

In the paper by one of us[3] already cited it was shown that while known complexes such as potassium silver cyanide, potassium ferrocyanide, etc., pass through a membrane as such without decomposition, such was not the case with hypothetical potassium tri-iodide, which was shown to behave similarly to certain double salts like the alums that are supposed to exist as simple molecules in solution. Exception having been taken to these experiments on the basis that the solutions used were too concentrated, containing more iodine than any conception previously advanced could account for, and also that a membrane was an unknown quantity in dialysis, it was decided to attack the matter again, using sufficiently dilute solutions to carry conviction to all and agar-agar jelly in place of a membrane. Agar-agar was chosen because it has been shown to offer little, if any, resistance to electrolytes while allowing true diffusion phenomena to take place unaffected by convection currents. The experimental work was conducted, under the supervision of one of us, by Mr. George A. Perley, to whom our acknowledgments are due.

[2] *J. Am. Chem. Soc.*, 32, 914.

[3] *J. Physic. Chem.*, 11, 659 (1907).

Cylinders closed at one end were made of 3 per cent. agar jelly, using 0.1 normal potassium iodide as solvent. They resembled tall beakers, having walls approximately eleven millimeters thick. They were kept immersed in 0.1 normal potassium iodide until needed. When in use these cylinders were placed in 400 cc. Jena beakers containing 200 cc. 0.1 normal potassium iodide and were then filled nearly full with the iodine-saturated potassium iodide solution employed in the particular experiment and the whole placed in a thermostat at 25°. All the solutions had previously been brought to this temperature, the level of the liquids within and without the cylinder was kept the same and both liquids were mechanically stirred by plungers throughout the experiment.

According to Jakowkin's researches and the theory of those who believe in the presence of polyiodides, a solution of potassium iodide saturated with iodine must have one-half of the potassium iodide converted into tri-iodide and contain also a small, almost neglible amount of iodine dissolved as such in the water present.

In the first experiment tried the outer solution was 0.1 normal potassium iodide and the inner solution was 0.16 molar potassium iodide saturated with iodine.

According to Jakowkin the following conditions should exist and the potassium iodide should, of course, diffuse from higher to lower concentration or from left to right.

Outer solution.	Inner solution.
	0.08 molar KI
0.1 molar KI	0.08 molar KI_3
	0.0013 molar I_2

If there is no complex present, the following conditions should exist and potassium iodide should diffuse from right to left.

Outer solution.	Inner solution
0.1 molar KI	0.16 molar KI
	0.0813 molar I_2

At stated periods the outer liquid was removed for analysis and replaced by a fresh portion of 200 cc. each. The first portion was taken off just as the iodine diffused to the outer wall. This took almost exactly two hours and was easily judged by the eye. It will be seen at once that the potassium iodide passed outward and that a notable portion had passed through ahead of any iodine as was to be expected from its smaller molecular weight. The following results were obtained:

Analysis of outer solution after diffusion showing a total gain in outer solution for each 200 cc. and each period:

Period.	Time.	M. mols I_2.	M. mols KI.
1	2	trace	0.876
2	12	2.951	5.26
3	12	2.355	5.75
4	12	1.475	5.46

As a check, the same experiment was performed using simply the 0.1 molar and 0.16 molar potassium iodide solutions without added iodine. Considering the fact that different cylinders of agar-agar were used and that no attempt was made to accurately adjust the height of the liquid to the same diffusing surface as before the results are quite comparative.

GAIN OF KI IN OUTER SOLUTION.

Period.	Time.	M. mols KI.
1	2	1.84
2	12	6.501
3	12	5.64
4	12	5.45

In a second experiment it was decided to use 0.1 molar potassium iodide as the outer solution and a 0.1 molar potassium iodide inner solution saturated with iodine.

According to Jakowkin the following conditions would exist and the solution should therefore pass from left to right:

Outer solution.	Inner solution.
0.1 molar KI	0.05 molar KI 0.05 molar KI_3 0.0013 molar I_2

If no complex exists, then

Outer solution.	Inner solution.
0.1 molar KI	0.10 molar KI 0.0513 molar I_2

Here again the results of experiments are against the conception of any complex being present as the following show:

ANALYSIS OF OUTER SOLUTIONS OF 200 CC. EACH SHOWING TOTAL GAIN.

No.	Time.	M. mols I.	M. mols KI.
1	12	0.889	none
2	13	1.58	none

Analyses of the two portions of outer solution used showed them to be unchanged in their potassium iodide concentration.

In the above analyses the free iodine was titrated with thiosulphate and the total iodine was determined in a separate portion, being set free by ferrous chloride and sulphuric acid and distilled into a solution of potassium iodide, using an apparatus consisting entirely of glass. Many check analyses were run showing the agar to be without effect on the analytical results. Also the experiments were repeated with results entirely in accord with those cited.

We believe the above results strongly indicate that no polyiodide exists to any notable extent in these solutions and that we have here simply a case of "solution in a dissolved solid,"[1] a solid which above 82° has been shown by Abegg and Hamburger[2] to be itself a remarkable solvent for iodine. We have already pointed out that its behavior in regard to rise in freezing point, decrease in conductivity and distribution phenomena, upon which all claims to complexes in solution are based, have interesting analogies to many ternary mixtures where no such combination would be claimed. The idea of simple solution in a binary solvent has the added advantage that it explains the phenomena of the concentrated solutions equally well with those which are more dilute.

Summary.

No polyiodides of potassium exist as solid phases at 25°.

Potassium iodide and iodine, placed together in aqueous solution, apparently diffuse independently of any chemical combination with each other. Judging from this standpoint alone no polyiodide of potassium is present in solution.

NEW HAMPSHIRE COLLEGE,
DURHAM, N. H.

DIFFUSION PHENOMENA OF THE ALUMS.

BY CHARLES L. PARSONS AND W. W. EVANS.

Received September 14, 1910.

In connection with the diffusion experiments on solutions of iodine in potassium iodide described in the preceding paper and those on known complexes reported in a previous paper by one of us,[3] it seemed desirable to make preparatory trials on crystal complexes which were known or supposed to exist as a mixture of simpler molecules when dissolved. For this purpose ordinary alum was chosen and the work proved so interesting that the experiments were extended to other alums and were performed at 0° and 25°. This paper is written for the purpose of putting these data on record for the different alums studied. Its conclusions are simply confirmatory of previous work.

---

[1] To explain what is meant by solution in a dissolved solid it may be pointed out that so far as analogy goes the only difference between dissolving potassium iodide in water and water in alcohol is that one is a solid and the other a liquid at the temperature at which most of our ordinary ideas are conceived. Sugar is not soluble in alcohol until water is added, but it is doubtful if any one would claim that the solubility of sugar in aqueous alcohol is due to the formation of sugar hydrates. It is simply because sugar is soluble in water and if one worked at —1° it would be a solid we were adding which, after dissolving, in its turn dissolved the sugar. In like manner working at 15° solid acetic acid dissolving in water acts as a solvent for camphor and the latter gives analogous conditions as to *rise* in freezing point and *decrease* in conductivity to those that exist when iodine, itself practically insoluble in water, is brought easily into solution when dissolved potassium iodide is present.

[2] *Z. anorg. Chem.*, 50, 403 (1906).

[3] Parsons, *J. Physic. Chem.*, 11, 659 (1907).

The alums while crystallizing as complex molecules have long been known to exist as simple sulphates when dissolved. Some early diffusion experiments by Graham[1] were the first to show that the two sulphates of which ordinary alum is composed can be separated by diffusion. This was later confirmed by Marignac,[2] who came to the conclusion that double salts like the alums are found only at the moment of crystallization. Later Rudorff, using goldbeater's skin as a separating membrane,[3] reached much the same conclusion. Gerlach[4] points out that certain slight volume changes that took place when he mixed solutions of the constituents of the alums indicated the combination of these constituents but his arguments are not convincing when the evidence to the contrary is considered. Besides the above authorities, who argued from a diffusion standpoint, a number of investigations have been undertaken on the cryoscopic and conductivity constants of the alums, of which the research by Jones and Mackay[5] is perhaps the most complete. They likewise reach the conclusion that the alums exist for the main part only in the solid condition, although they found some evidence that as the solutions grew more concentrated there may have been some association in solution.

In our experiments a known amount of solution was placed either in parchment tubing, which is permeable to the simple constituents of the alums, or in cylinders of agar-agar jelly. These were then placed in beakers containing a measured amount of water and both inner and outer solutions constantly stirred in a thermostat for the periods of time stated below.

The solutions were analyzed by well-known methods and carefully checked. The method used to determine chromium while using well-known principles we did not find described elsewhere. A measured amount of the chromium solution was diluted to about 150 cc. with water, and about 1 gram sodium peroxide was added, the solution was heated and allowed to boil for about ten minutes, then cooled somewhat and diluted to about 400 cc. Then the solution was acidified with 5 cc. of sulphuric acid (1 : 1), 2 grams of potassium iodide were added and the liberated iodine was titrated in the usual manner with a standard solution of sodium thiosulphate. In every case good duplicates could be obtained.

Diffusion of Ammonium Chrome Alum.

The outside solution in each case was 200 cc. water. The experiment was conducted at 25°, each portion being run for three hours. The inside solution contained in 50 cc. the alum equivalent to 3.268 grams $Cr_2(SO_4)_3$ and 1.100 grams $(NH_4)_2SO_4$, the ratio of mols of each being 1 : 1. Parchment tubing was used.

COMPOSITION OF DIFFUSATE.

Period.	M. mols $(NH_4)_2SO_4$.	M. mols $Cr_2(SO_4)_3$.	$\frac{(NH_4)_2SO_4}{Cr_2(SO_4)_3}$.
1	5.6	1.228	4.48
2	2.4	1.200	2.00
3	1.2	0.848	1.41
4	0.36	0.6928	0.520
Inside solution after completion of experiment.	0.038	0.416	0.091

From the above it can be seen that there is an almost complete separation of the constituents of the alum into its components.

Diffusion of Potassium Chrome Alum.

The inside solution contained in 50 cc. the alum equivalent to 1.459 grams potassium sulphate and 3.278 grams chromium sulphate, the molar ratio being 1 : 1. The experiment was run as in the previous case, the periods being three hours each and the outside liquid consisting of 200 cc. of water at 25°.

COMPOSITION OF DIFFUSATE.

Period.	M. mols K_2SO_4.	M mols $Cr_2(SO_4)_3$.	$\frac{K_2SO_4}{Cr_2(SO_4)_3}$.
1	5.68	1.40	4.06
2	2.25	1.20	1.87
3	0.803	0.864	0.929
4	0.271	0.746	0.363
Solution in membrane after completion of experiment.	0.0688	1.012	0.068

It can be seen that the same separation takes place as in the previous case.

Diffusion of Potassium Aluminium Alum.

Inside solution contained in 50 cc. alum equivalent to 1.455 grams potassium sulphate and 2.856 grams aluminium sulphate, molar ratio 1 : 1. Details the same as in previous cases.

COMPOSITION OF DIFFUSATE.

Period.	M. mols K_2SO_4.	M. mols $Al_2(SO_4)_3$.	$\frac{K_2SO_4}{Al_2(SO_4)_3}$.
1	5.71	1.28	4.46
2	2.05	0.958	2.14
3	0.775	0.855	0.906
4	0.247	0.606	0.408
Solution in membrane after completion of experiment.	0.1049	0.1145	0.916

Diffusion of Ammonium Aluminium Alum.

Inside solution contained in 50 cc. the alum equivalent to 1.1014 grams ammonium sulphate and 2.852 grams aluminium sulphate, molar ratio 1 : 1. Details same as in previous cases.

COMPOSITION OF DIFFUSATE

Period.	M mols $(NH_4)_2SO_4$.	M. mols $Al_2(SO_4)_3$	$\frac{(NH_4)_2SO_4}{Al_2(SO_4)_3}$.
1	5.6	3.52	1.59
2	1.85	0.696	2.80
3	0.70	0.571	1.22
4	0.50	0.875	0.58
Solution in membrane after completion of experiment.			
	0.35	0.355	0.98

There was probably some error which entered in the first period, as can be seen from the ratio.

Diffusion of Ferric Ammonium Alum.

The inside solution was made up so that 50 cc. contained the alum equivalent to 1.103 grams ammonium sulphate and 3.334 grams ferric sulphate, molar ratio being 1 : 1. Details same as in previous cases.

COMPOSITION OF DIFFUSATE.

Period	M mols $(NH_4)_2SO_4$	M mols $Fe_2(SO_4)_3$	$\frac{(NH_4)_2SO_4}{Fe_2(SO_4)_3}$.
1	5.12	2.93	1.74
2	3.24	2.54	1.27
3	0.560	1.78	0.315
4	0.160	0.622	0.257
Solution in membrane after conclusion of experiment			
	0.160	0.570	0.287

It was found that in this case there was a tendency on the part of the iron toward hydrolysis, heightened by the removal of the ammonium sulphate. This interfered with the diffusion through the membrane and therefore this separation is not so perfect as in the case of the other alums. However, as can be seen from the above, there is no doubt that separation takes place.

Diffusion at Low Temperature.

Experiments were also conducted in a mixture of snow and water, the temperature being close to 0°, to see what effect a decrease in temperature would have upon the results. In other respects the work was carried on as before.

Diffusion of Ammonium Chrome Alum.

Inside solution same as before, 50 cc. containing the alum equivalent to 1.100 grams ammonium sulphate and 3.268 grams chromium sulphate, molar ratio 1 : 1. The temperature was kept constant by the use of a snow water mixture. Time of each period three hours. Parchment tubing used.

COMPOSITION OF DIFFUSATE.

Period.	M. mols $(NH_4)_2SO_4$.	M. mols $Cr_2(SO_4)_3$.	$\frac{(NH_4)_2SO_4}{Cr_2(SO_4)_3}$.
1	3.60	0.552	6.52
2	2.20	0.520	4.44
3	1.24	0.453	2.74
4	0.88	0.426	2.06
Solution left in membrane after close of experiment.			
	0.187	1.83	0.0122

Diffusion of Potassium Chrome Alum.

Inside solution as before, 50 cc. containing an amount of the alum equivalent to 1.459 grams potassium sulphate and 3.278 grams chromium sulphate, molar ratio 1:1. Details as above.

COMPOSITION OF DIFFUSATE.

Period.	M mols K_2SO_4.	M. mols $Cr_2(SO_4)_3$.	$\frac{K_2SO_4}{Cr_2(SO_4)_3}$.
1	3.80	0.880	4.32
2	2.50	0.506	4 94
3	0.736	0.466	1.59
4	0.665	0.440	1 50
Solution in membrane after conclusion of experiment.			
	0.0143	2 075	0.007

From the above work it can be seen that there is a separation at 0° as well as at 25°. The molecules at this temperature move more slowly as one would expect; consequently the separation of the two is not so rapid as at higher temperatures, but it is more complete.

Diffusion through Agar Jelly.

Graham has shown[1] in working with agar-agar jelly that mixtures of salts diffuse readily from aqueous solutions and that the diffusion constants do not change with rise of temperature but the amount of diffused salt regularly increases. He found that the rate of diffusion is practically the same for different concentrations of the jelly.

For our experiments a cylinder of the jelly closed at one end was made from a 3 per cent. solution, having walls about 11 mm. thick. The alum solution was placed inside and allowed to diffuse out into 150 cc. of water. The temperature was kept at 25° throughout the experiments. Each portion was run for a period of 24 hours and the portions analyzed.

Diffusion of Ammonium Chrome Alum.

The solutions used were the same as in the previous work. Periods 24 hours each.

---

	0.70	0.138	0 507

The results of these experiments with agar-agar show in the same way as with parchment that the constituents of the alums diffuse independently.

Conclusions.

When alums are dissolved in water they are decomposed into the simple sulphates, which can be separated from each other by diffusion. The chrome alums separate more readily than the aluminium alums. This is in entire accord with previous researches.

THE SOLUBILITY OF BARIUM NITRATE AND BARIUM HYDROXIDE IN THE PRESENCE OF EACH OTHER.

By C. L. Parsons and H. P. Corson.

Received September 14, 1910.

The work of Cameron and Robinson upon the system lime, nitric acid and water[1] proves the existence of a basic nitrate of calcium having a composition represented by $2CaO.N_2O_5.3\frac{1}{2}H_2O$. Their work suggested the possibility of the existence of similar compounds of barium, but in a careful search of the literature we were unable to find any record of such work upon barium. Hence the present investigation was undertaken.

A specially prepared barium nitrate obtained for this research was carefully tested for impurities. The salt was found to be very pure, no foreign substance being detected except a small amount of carbonate. A saturated solution of the nitrate was prepared and made slightly, yet distinctly, acid with nitric acid and boiled to remove carbon dioxide.

The barium hydroxide obtained for the work was found to be quite pure except for the presence of carbonate, which was eliminated by filtering a hot concentrated solution with careful exclusion of the carbon dioxide of the air. Upon cooling this solution, crystals of pure hydroxide separated out. This solid was dipped out with adhering solution and added to the solutions of nitrate.

---

[1] *J. Physic. Chem.*, **2**, 273 (1907).

Bottles were made up in regular steps of concentration from pure water to a saturated solution of barium nitrate, using freshly boiled distilled water for dilution. Barium hydroxide was then added until sufficient solid persisted. One bottle also had excess of solid nitrate added and two were made alkaline with barium hydroxide, but short of saturation, and excess of solid nitrate added. The bottles were sealed and constantly rotated in a water thermostat maintained at 25° until equilibrium was reached. The bottles were not opened for four months, although equilibrium was undoubtedly complete much earlier, since no reaction occurred and subsequent analysis of all bottles showed no change.

Previous experiment had shown that the gravimetric estimation of barium could be made more accurately in these pure salt solutions by weighing barium nitrate than by the usual sulphate method. Consequently the *total* barium oxide present was determined by this method. Portions of the solutions amounting to about 5 cc. were drawn off and weighed in a weighing bottle, transferred to a platinum dish, acidified with nitric acid and evaporated in an air bath at 100°. After the solution had come down to dryness, the temperature was increased to 115° to remove the last traces of free acid and moisture. The samples were then cooled and weighed as barium nitrate.

Barium oxide present as *hydroxide* was determined volumetrically by titrating a weighed portion of the solution with tenth normal nitric acid, using phenolphthalein as indicator.

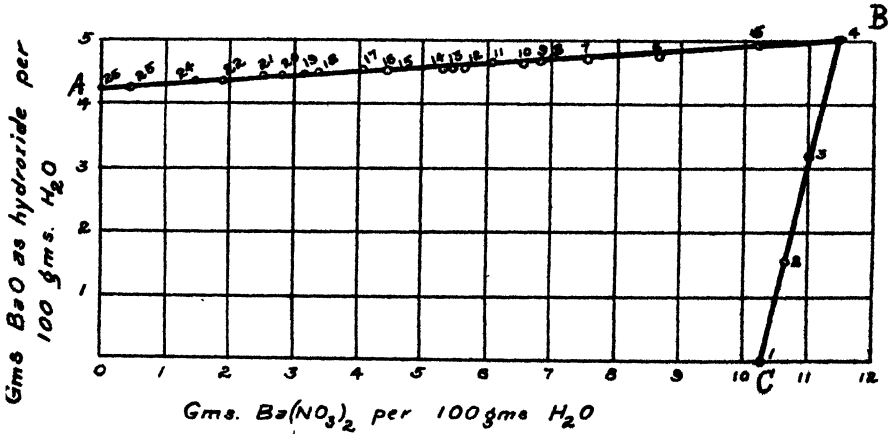

Fig. 1.

The data obtained are given in Table I, which shows (Nos. 4–26) the solubility of barium hydroxide in solutions of barium nitrate of various concentrations and (Nos. 1–4) the solubility of barium nitrate in solutions of barium hydroxide. No. 4 represents the composition at the invariant point where both solids are present in excess.

The results are expressed graphically in Fig. 1.

From an inspection of this chart, it will be seen that there are two distinct branches, AB and BC, to the isotherm. As this is a three-component system, along each of these two branches there can be only one solid phase in equilibrium with the solution.

TABLE I.

25	1.0538	4.29	0.43
26	1.0512	4.29	none

Several of the solids in contact with the solutions were analyzed. Along branch BC of the curve (Fig. 1) the solids were dipped from the solutions with a platinum spoon, no attempt being made to free them from mother liquor save by decantation. They were analyzed in exactly the same manner as the liquids, namely, titration of a weighed portion with nitric acid, then evaporation and weighing as nitrate.

The solids along branch AB of the curve (Fig. 1) were pure hydroxide and when pressed between filter paper contained so small a quantity of N_2O_5 that it was not practical to determine the exact amount. Table II gives the percentage composition of all the solutions, together with some of the corresponding residues.

TABLE II.

No.	Solutions.			Residues with adhering solution.

24	4.92	0.58	94.50	.....	.....	.....
25	4.32	0.17	95.51	.....	.....	.....
26	4.10	none	95.90	.....	.....	.....

Along the other branch, BC of the curve, the composition of the solid, evidently the nitrate, was proved by plotting the results of analyses on a triangular diagram.[1] When plotted in this manner the lines connecting the points representing liquids with other points representing their corresponding solids meet in a point which as scaled off on the diagram has the composition BaO 58.7, N_2O_5 41.3. This solid, then, is represented by the formula $BaO.N_2O_5$. The analysis of the solid in bottle No. 4, which lies at the intersection of the two branches of the isotherm, shows, of course, that it consists of both $Ba(OH)_2.8H_2O$ and $Ba(NO_3)_2$. Examination of the residues by the microscope is entirely in agreement with the conclusions arrived at by analysis.

---

[1] Schreinemakers, *Z. physik. Chem.*, 11, 81 (1893); Bancroft, *J. Physic. Chem.*, 6, 181 (1902).

Conclusions.

The solubility of barium hydroxide in solutions of barium nitrate increases as the concentration of the latter increases. This fact is interesting, for in most cases a common ion tends to decrease the solubility of substances in solution in a common solvent.

The solid in equilibrium with any solution along curve AB, Fig. 1, is $Ba(OH)_2.8H_2O$, and along curve BC, is $Ba(NO_3)_2$.

Consequently, we conclude that basic nitrates of barium do not exist at 25°.

NEW HAMPSHIRE COLLEGE,
DURHAM, N. H.

THE SOLUBILITY OF STRONTIUM NITRATE AND STRONTIUM HYDROXIDE IN THE PRESENCE OF EACH OTHER.

BY C. L. PARSONS AND C. L. PERKINS.

Received September 14, 1910.

In connection with the work described in the preceding paper on the solubility of barium nitrate in solutions of barium hydroxide it was decided to make a similar study of the strontium compounds and for the same reason. No basic nitrates of strontium have been described in the literature, but there was no certainty that a search along equilibrium lines might not reveal them.

A specially pure lot of strontium nitrate was prepared by separating the barium from a salt purchased as pure and containing no other contamination. Strontium hydroxide was prepared from pure strontium oxide by dissolving it in boiling water and filtering hot. Upon cooling the solution strontium hydroxide crystallized out and was preserved under the mother liquor. It was protected from the formation of carbonate by a sodium hydroxide seal.

A saturated solution of the nitrate was prepared and boiled with a slight excess of nitric acid to assure the absence of all carbonates. From this a series of solutions was made by diluting with freshly boiled, distilled water in varying amounts and adding the solid hydroxide until a solid phase persisted in sufficient quantity for analysis. One bottle also had excess of solid nitrate added and two bottles similarly prepared were made to contain hydroxide short of saturation. The solutions were placed in tightly stoppered bottles, the glass stoppers of which had been carefully ground, and rotated in a thermostat kept at 25° for more than a month before any analyses were made. Subsequent trials proved that equilibrium had already been attained.

Previous experimentation having shown that the methods used for barium in the research already referred to were applicable here, they were, accordingly, used. Definite portions of the solution were drawn off, weighed, acidified with nitric acid, evaporated to complete dryness and the total strontium nitrate weighed as such. The hydroxide present was determined by titrating a separate portion with tenth normal nitric acid.

The data obtained are given in Table I, which (Nos. 1–22) shows the solubility of strontium hydroxide in solutions of strontium nitrate of various concentration; also (Nos. 24–25) the solubility of strontium nitrate in varying solutions of strontium hydroxide. No. 2 indicates the conditions that exist at the invariant point when the solution is saturated with both substances.

Table I.

Bottle No.	Sp. gr. 25/25.	SrO as $Sr(OH)_2$ in 100 grams H_2O.	$Sr(NO_3)_2$ in 100 grams H_2O.
1	1.481	0.0	79.27
2	1.506	1.76	81.06
3	1.490	1.71	74.27
4	1.450	1.55	66.88
5	1.419	1.51	63.71
6	1.403	1.47	60.37
7	1.381	1.41	56.30
8	1.359	1.34	52.90
9	1.327	1.27	46.97
10	1.317	1.20	44.03
11	1.291	1.14	40.83
12	1.267	1.11	37.81

16	1.178	0.95	23.83
17	1.148	0.91	17.96
18	1.126	0.87	16.21
19	1.108	0.84	12.78
20	1.079	0.81	8.96
21	1.059	0.79	6.29
22	1.033	0.78	4.45
24	1.492	0.38	79.47
25	1.494	0.78	80.83

The results are expressed graphically in Fig. 1.

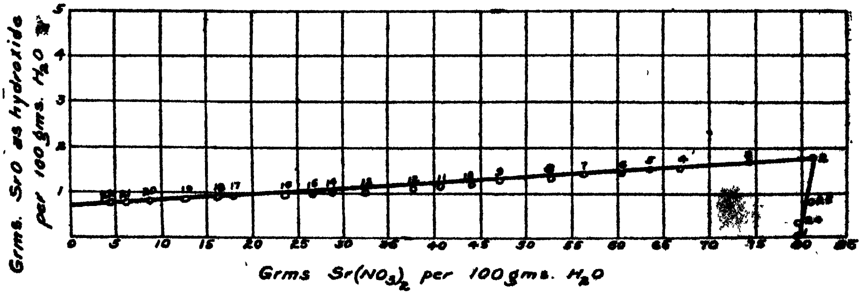

Fig. 1.

From an inspection of this chart it will be seen that there are only two distinct branches to the isotherm. As this is a three-component system, along each of these two branches there can be only one solid phase in equilibrium with the solution. Reference to the curve shows that the presence of either component increases the solubility of the other.

This curve in itself is sufficient to indicate the absence of any basic nitrate of strontium, since the composition of the solution varies with regularity. The precipitates were, however, examined through a microscope and several of them were analyzed. The microscope showed the crystals upon the first branch of the curve to be simply those of strontium hydroxide, while those upon the second branch were obviously strontium nitrate.

The analysis of the solids with adhering mother liquor was made as follows: The precipitate was spooned out in quantity sufficient for analysis, the adhering mother liquor was removed as completely as possible by pressing between filter papers and the solid was immediately placed in a closed weighing bottle and weighed. The alkalinity was determined by titrating with standard nitric acid. The total strontium was obtained as in the analysis of the solutions, by evaporation with slight excess of nitric acid. The composition of the solids analyzed together with that of the corresponding solutions is given in Table II.

TABLE II.

	Solution.		Solid	
Bottle No.	Per cent. SrO.	Per cent. N_2O_5.	Per cent. SrO.	Per cent N_2O_5.
3	21.65	21.52	37 86	1.65
8	17.66	17.49	38 61	0.56
19	6.27	5 76	38.92	0.19
24	21.86	22.54	36.50	38 00
25	22.02	22.70	36.98	38 48

An examination of these figures shows them to be entirely confirmatory of the solubility curve and that the only two solids present are $Sr(OH)_2$.-$8H_2O$ and $Sr(NO_3)_2$.

Conclusions.

The solubility of strontium hydroxide in solutions of strontium nitrate increases as the concentration of the latter increases. The curve is similar in form to the curve for barium, but the solubility of the nitrate is much greater and the hydroxide much less than that of the corresponding barium salts.

The solid in equilibrium with any solution on the longer arm of the curve is $Sr(OH)_2.8H_2O$, while along the short arm it is $Sr(NO_3)_2$.

No basic nitrates of strontium exist at 25°.

DURHAM, N. H.

THE BINARY AND TERNARY ALLOYS OF CADMIUM, BISMUTH AND LEAD.

BY WILLIAM EDWARD BARLOW.

Received August 10, 1910.

The ternary and quaternary alloys of lead, bismuth, cadmium and tin possess special interest on account of their extended practical use as fusible alloys and as bearing metals. Of the four possible ternary series, one (the Pb, Bi, Sn series) has been thoroughly investigated—as regards both constitution and physical properties—by Charpy.[1] Two others, the Sn, Cd, Pb series, and the Sn, Cd, Bi series, have been investigated from the standpoint of constitution by Stoffel.[2] The following paper deals with the constitution of the remaining ternary series: the lead-bismuth-cadmium series. My object in undertaking this investigation was to complete the fundamental data necessary for systematic work on the constitution of the quaternary alloys of the four metals.

The thermal examination and representation of this ternary series bases itself, in the first place, on an accurate knowledge of the constitution diagrams of the three binary series of alloys: those of lead-bismuth, lead-cadmium, and cadmium-bismuth. For reasons given below I have thought it necessary or advisable to re-determine the diagrams for two of these binary series.

Practical Methods and Precautions.—The metals used by me contained the following impurities:

Lead..............	0.0002 per cent. of iron.
Cadmium..........	0.004 per cent. of iron, and a trace of arsenic.
Bismuth...........	0.002 per cent. of iron, and a trace of arsenic.

In every case the weight of alloy taken for a cooling-curve observation was 40 grams. The weighed metals were melted together in a small Battersea gold-annealing crucible under paraffin (or in a stream of carbon dioxide), and the mixture was thoroughly stirred and cast in a clean brass mold. Small pieces were then cut from every portion of the solid alloy and preserved for use as seed. In a few cases the alloy to be used as seed was pipetted out of the well-stirred molten alloy.

The apparatus used for cooling-curve work consisted of a small Battersea crucible resting in an asbestos bed inside a graphite crucible, which in turn was embedded in a mixture of sand and kieselguhr contained in a sheet-iron vessel. The thicknesses of the layers of heat-insulating materials necessary to give a convenient rate of cooling were found by a few preliminary trials. The previously prepared alloy was melted (under paraffin) in the small crucible on a separate stand, the crucible was then bedded snugly in the asbestos nest, the stirrer and thermometer were warmed, and the composite crucible was then swung into position below the thermometer and stirrer, and raised until the thermometer bulb just cleared the bottom of the crucible. The outside iron vessel was then heated until the alloy was a few degrees below its first (upper) freezing point. The flame was then removed. The temperature continued to rise, until the alloy was melted and heated (usually) about 20° or 30° above its melting point. The stirrer was then started and the apparatus was allowed to cool to a convenient point for beginning the observations. With this arrangement it was not necessary to disturb anything but the small (inner) crucible, and it was found that the rate of cooling, between halting points, varied only very slightly in individual observations during the whole investigation.

---

[1] "Contribution à l'Étude des alliages," 1901, p. 200, Paris.

[2] *Z. anorg. Chem.*, 53, 137.

Both my own earlier experiences, and deductions from the published work of other investigators, have convinced me that it is a difficult matter entirely to prevent undercooling—and, moreover, that the errors caused by this lag may, under certain conditions, be very great. I therefore took special care to provide for efficient stirring, and for the systematic and periodical addition of seed. Stirring was done by means of a glass rod bent into a circle at its lower end and embracing the stem of the thermometer. The rod was moved vertically up and down, with a force capable of regulation, by means of a clock-work arrangement, the details of which I shall be glad to give to any one interested. The stirrer was adjusted so as to stop automatically as soon as the alloy arrived at a condition of decided pastiness during cooling. This left the observer with both hands free for other work.

Beginning at a temperature 5° or 6° above the expected upper freezing point of the alloy, small portions of the cold alloy were dropped into the crucible every fifteen seconds, and this seeding was continued until it was evident that stirring had ceased to be efficient. The results satisfy me that, in cases in which the first and second freezing points fell near together, undercooling (at the second halting point) was nearly always prevented; when the alloy was too pasty to be stirred at the temperature of the second or third halting point, undercooling nearly always took place.

The temperature was read every fifteen seconds by means of a reading telescope at such a distance as to enable the observer to reach round to the crucible to drop in seed. The thermometer was hung in a wide glass tube, reaching nearly to the crucible edge, so that it was possible to see every part of the mercury thread and to avoid errors due to sudden air draughts on the exposed thermometer stem. The thermometers used were standardized at the freezing points of lead (327°) and tin (232°), and were also directly compared with a thermometer (reading to 560°) tested by the Physikalisch-Technische Reichsanstalt on August

2, 1909. The correction for the exposed column was determined on each thermometer by actual observation of the mean temperature of the exposed column, under the conditions of use obtaining in a cooling-curve observation, and the addition of the correction $n(T—t)/6300$, in which n is the length of the projecting column in degrees, T the temperature to be measured, and t the mean temperature of the exposed column. These measurements were made twice for each thermometer. Up to about 220° the agreement between the two sets of corrections was very close; from 220° to 330° the mean of the two results was used as the correction.

THE BINARY SYSTEMS.

(a) **The Lead-Cadmium Series.**—The freezing point curve of the series has been determined in part by A. Kapp,[1] in part of Heycock and Neville,[2] and in part by Stoffel.[3] Stoffel's statement of Kapp's result does not agree with the published curve. I was unable to consult Kapp's thesis, and since, also, it seemed advisable to have a complete set of determinations made by one observer with identical metals and under identical conditions throughout, I have repeated the thermal investigation with the results given in Table I and Fig. 1. The position of the eutectic point was determined according to Tammann's method of thermal analysis, by measuring the duration of the freezing of the eutectic in each of the twelve alloys studied, plotting these times vertically beneath the corresponding percentage compositions, and continuing the curves free-hand to their intersection. Using the same weight of alloy and the same conditions of cooling in each case, the measured times are proportional to the amounts of eutectic present in the various alloys.

Free-hand prolongation of the upper curves points to the eutectic composition as 82.6 per cent. by weight of Pb, 17.4 per cent. by weight of Cd. This corresponds to 72.04 atomic per cent. of Pb. The prolonged time curves intersect at about 82 per cent. by weight of Pb. (I have purposely used weight percentages in constructing the diagrams, since I consider that, in spite of certain drawbacks, this method enables one to form a mental picture of the relations more easily than the use of atomic percentages. For all important points, however, I have added the atomic figures.)

The freezing point of the eutectic I have taken as 247.3°, as given by the alloys m, j, b, c, and d. The other alloys (more widely removed from the eutectic composition) were all slightly undercooled. The result agrees well with that of Kapp —249°.

On the cadmium side the freezing-time curve points to a slight solubility of lead in solid cadmium. On the lead side the limit of miscibility indicated is about 3 per cent. (by weight) of cadmium. Herschkowitsch

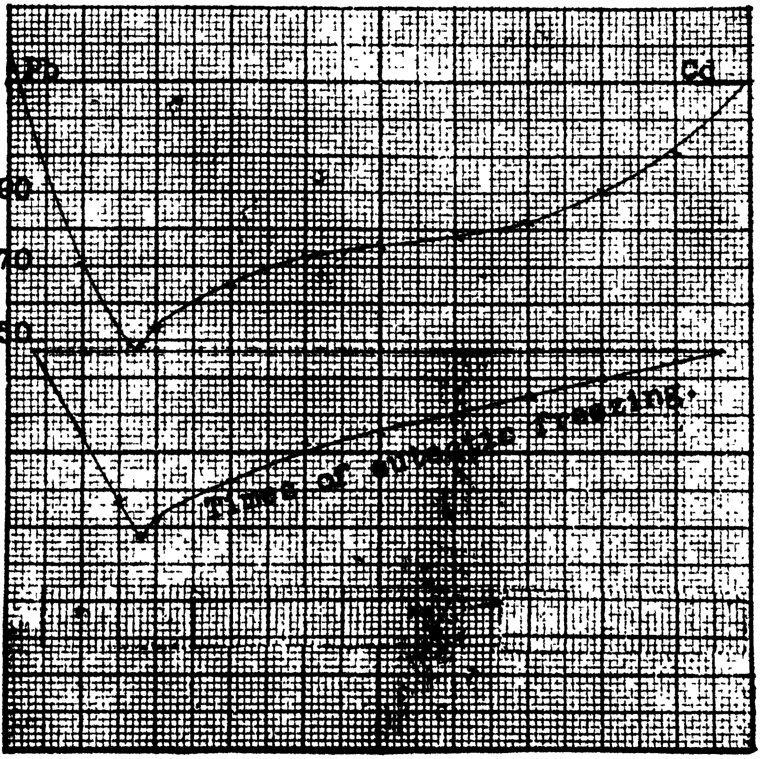

Fig. 1.—Pb–Cd series (Barlow).

(by measuring the electromotive forces of lead-cadmium alloys) found that cadmium forms mix-crystals with lead up to about 4 per cent. (atomic) of cadmium. This is 2.3 per cent. by weight. The times were measured from the cooling curves plotted on co-ordinate paper, and are given in units of fifteen seconds. The error is probably less than one time-unit in every case.

(b) **The Lead-Bismuth Series.**—The freezing-point curve has been determined by Kapp and by Charpy,[1] and is given in the upper part of Fig. 2 in weight percentages. The eutectic lies at 56.5 atomic per cent. Bi (56 6 weight per cent. Bi) and 125° C. The irregularity of the curve

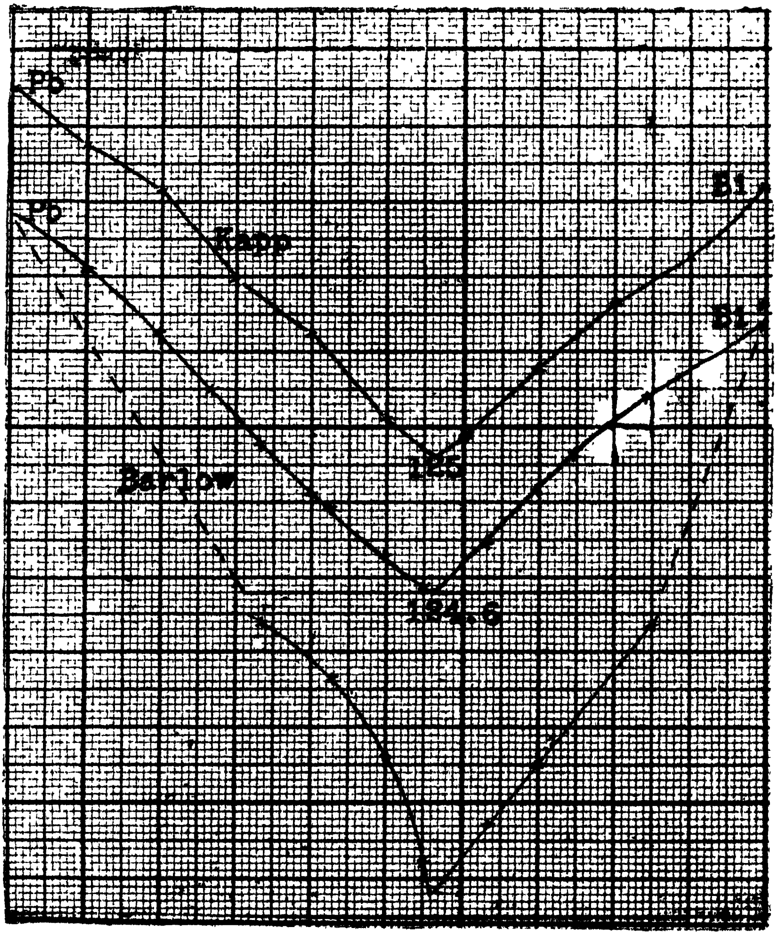

Fig. 2.—Pb-Bi series (Barlow).

The eutectic, according to my results, both from the freezing-point determinations and from the times of eutectic freezing, lies at 56.5 weight per cent. Bi, and between 124.3 and 124.8°. With regard to the limits of miscibility in the solid state there is still room for doubt. Kapp and Wiedemann were both unable to observe a second freezing point in an alloy containing 30 per cent. by weight of Bi, and I have obtained almost the same limit on this side. Shepherd, on the other hand, as a result of electromotive force measurements, states that at ordinary temperatures mix-crystals are formed at each end of the series up to 10 per cent. on each side. On the bismuth side my results agree with this statement—indicating a solubility of bismuth in lead up to about 11 per cent. by weight of lead. The letters u. c. indicate "undercooled."

(c) **The Bismuth-Cadmium Series.**—The freezing-point curve has been determined both by Kapp (see above) and by Stoffel (see above). Their results (using weight percentages) are reproduced in Table III and Fig. 3. Kapp's observations on the bismuth side are too scanty to establish the course of the curve with certainty, and differ from those of Stoffel by as much as 20°. Since Stoffel has made three series of observations, with identical results, I have used his figures on the bismuth side of the eutectic, and those of Kapp on the other side, in constructing the ternary diagram. The eutectic lies at 44.5 atomic per cent. Bi (59.8 weight per cent.) and 146°. According to the investigations of Herschkowitsch and of Heycock and Neville the two metals form no solid solutions—are entirely non-miscible in the frozen state.

TABLE III.—THE BISMUTH-CADMIUM SERIES (KAPP, STOFFEL).

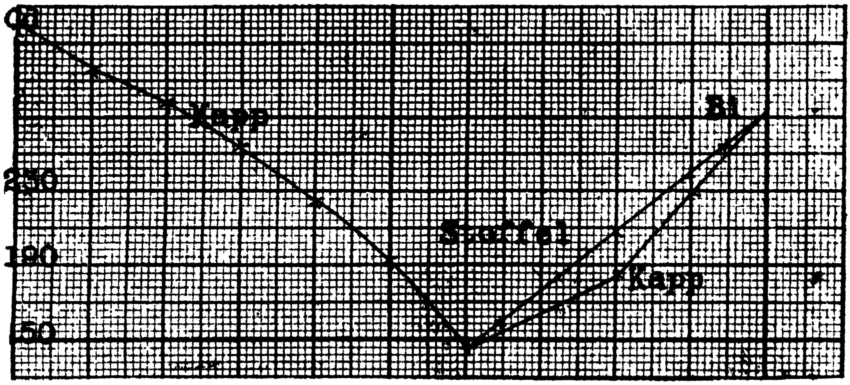

Fig. 3.—Cd–Bi series.

THE TERNARY SYSTEM: LEAD-BISMUTH-CADMIUM.

(1) **Representation of Results.**—The percentage composition of a mixture of three components may be expressed by a system of triangular co-ordinates (cutting, most simply, at 60°) in one plane. If we wish to obtain a complete representation of the equilibrium relations between the various phases of a ternary system, *temperature* must also be expressed, and must necessarily be measured along an axis lying outside of the plane of the paper, and, most simply, vertical to that plane. Within the resulting prism the seven or more surfaces of equilibrium involved may be constructed.

To represent such an equilibrium-solid clearly by a drawing is a difficult matter. If, however, we content ourselves with the representation of the upper surfaces alone (on which lie the *first* freezing points of all the possible mixtures) the projection of these surfaces on the co-ordinate triangle by means of contour lines results in a clear and intelligible diagram.

The upper surfaces of such a solid will have the general appearance of Fig. 4*a*—three more or less curved and inclined surfaces meeting in three channels or grooves (DX, EX, FX), which, in turn, dip towards their intersection at the point X. The curve ADC is the upper freezing-point curve of the binary series AC, while D represents the position of the eutectic of this series. The projection of the surfaces AEXD, etc., on the triangular plane HGK (the base of the model) would have the general appearance of Fig. 4*b*, the dotted lines representing isotherms.

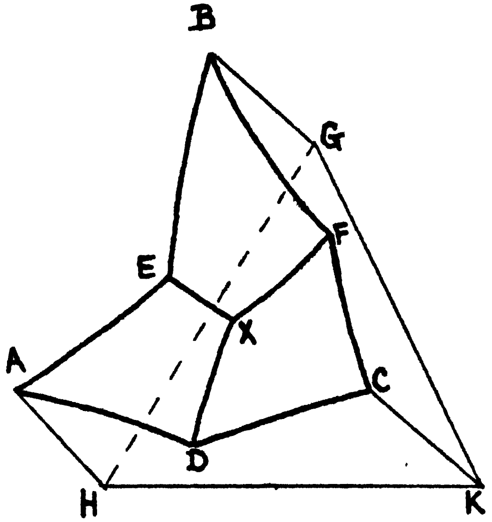

Fig. 4*a*.

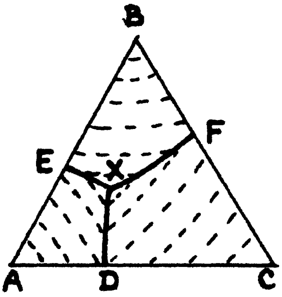

Fig. 4*b*.

Within this triangular space any point represents a mixture of the three components, A, B, C. The sum of the three lines drawn from such a point to the sides of the triangle, parallel to the sides taken in regular order, is always equal to the length of the side of the triangle. This length may be divided into 100 equal parts, when the sum of the co-ordinates drawn in this way becomes 100 per cent. of the mixture. For example, the composition marked by the point 41 in Fig. 8 is 30 per cent. Bi, 10 per cent. Pb, 60 per cent. Cd, if the measurements are made as indicated by the arrows in the margin. For a point falling on one of the sides of the triangle one co-ordinate disappears; thus the point 1 represents an alloy of composition 25 per cent. Bi, 75 per cent. Cd (the distance 1K being equal to the distance 1Bi). At the points A, B, and C, two co-ordinates vanish. A co-ordinate surface ruled according to this plan permits one to make measurements more easily than when the co-ordinates are drawn vertically to the sides of the triangle—the *altitude* of the triangle being taken as 100 per cent.

(2) Plan of Exploration.—The exploration of the upper equilibrium surfaces is best made by means of a number of *systematic* surveys, carried out and utilized as explained below. Consider, first, the freezing of the binary alloy marked 1 in Fig. 5, and assume that the two metals A and C form no solid solutions and no chemical compounds. The alloy contains more than the eutectic proportion of A. On cooling a molten mixture of this composition, freezing begins at a certain temperature. The substance which freezes out is pure A. The composition of the still molten mass therefore moves along the line AC towards C, the freezing point of the molten part gradually falling as the composition changes. When the alloy has reached the freezing point of the eutectic D the composition of the mother metal has also reached the composition of the eutectic, and the remaining melt therefore freezes completely at this temperature, before cooling farther. The solid alloy consists simply of the first-frozen crystals of pure A surrounded by the later-freezing eutectic mixture D. The cooling curve will therefore show two (and only two) sudden changes of direction (down to the point at which D has begun freezing): an upper one, at the temperature at which "excess" A begins to freeze out, and a lower one, at the temperature at which the eutectic begins (and continues) to freeze out.

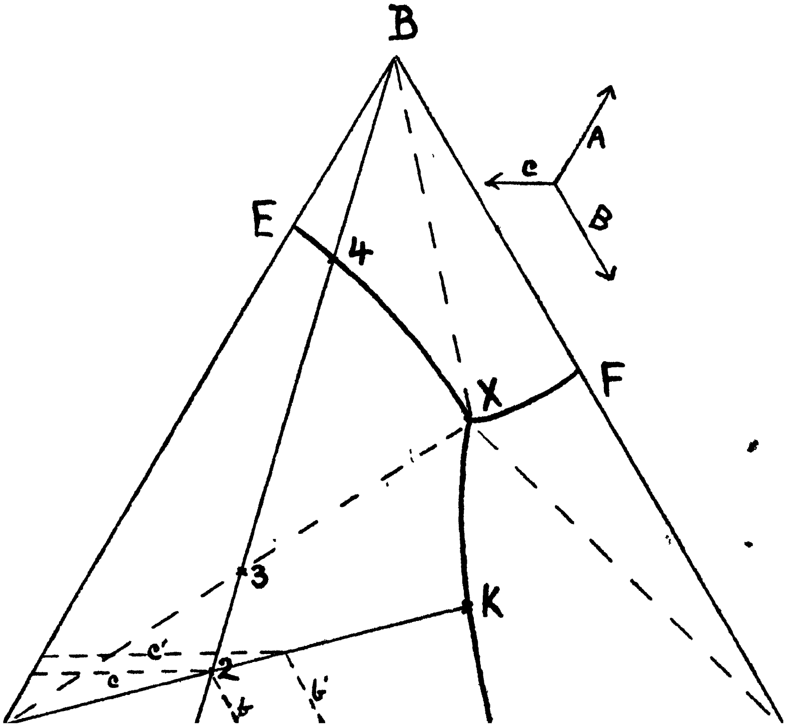

Fig. 5.

Consider, now, the freezing of the ternary alloy marked 2. At a certain temperature pure A begins to separate out. The molten part therefore becomes richer in both B and C, and both B and C are enriched in the same proportion. In order, however, that the proportion between the pairs of co-ordinates, *cb*, *c'b'*, etc., should remain fixed, the composition of the still-molten part must move along the line AK, formed by continuing the line joining A and 2. When this composition has reached the point K, all the A in excess of the binary eutectic proportion has been frozen out at a gradually falling temperature and the binary eutectic (D) begins to crystallize. The molten part therefore becomes progressively richer in B, since both A and C are being continuously removed. Solidification continues, at temperatures gradually falling, and on KX, until the temperature and composition corresponding to X are reached, when the remaining melt freezes as the ternary eutectic at a constant temperature. The cooling curve will accordingly show three sudden changes of direction down to the point at which X has begun freezing: the first at the excess A freezing point, the second at the temperature at which the binary eutectic begins to freeze, and the third at the ternary eutectic freezing point.

Suppose, now, that we observe the cooling curves of a *series* of alloys lying on the line 1B. The first freezing points will lie on a curve sloping from both sides towards the point 4, at which the eutectic line EX is cut. The second freezing points of all alloys between 1 and 3 will fall at temperatures gradually lower and lower along the curve DX. The alloy 3 will show only two freezing points—that of excess A and that of the ternary eutectic. (An alloy whose composition falls on such a line as DX will also show only two freezing points—those of the binary and ternary eutectics.) From 3 to 4 the second freezing points will lie at points along X4, at gradually rising temperatures moving towards 4. Beyond point 4 the excess metal is no longer A, but B. Alloys between 4 and B begin separating pure B at certain temperatures, the composition of the molten part moving towards the line EX, and cutting it in every case at the point 4, and then following the curve 4X. In other words, the second freezing point of all alloys between 4 and B is fixed at the temperature indicated by 4.

If we consider the alloy 1 as a single component, and pure B as the second component, we can plot the first and second freezing points of the series just as in the case of a system of two elementary components, and we shall obtain a diagram of the general appearance of Fig. 6. The temperature X is indicated (although only approximately—because of the difficulty of observing all the second freezing points with great accuracy) by the intersection of the sloping branches of the second freezing-point curves: the temperature 4 is at the intersection of the upper freezing-point curves and also at the intersection of the horizontal branch and one of the sloping branches of the second freezing-point curve.

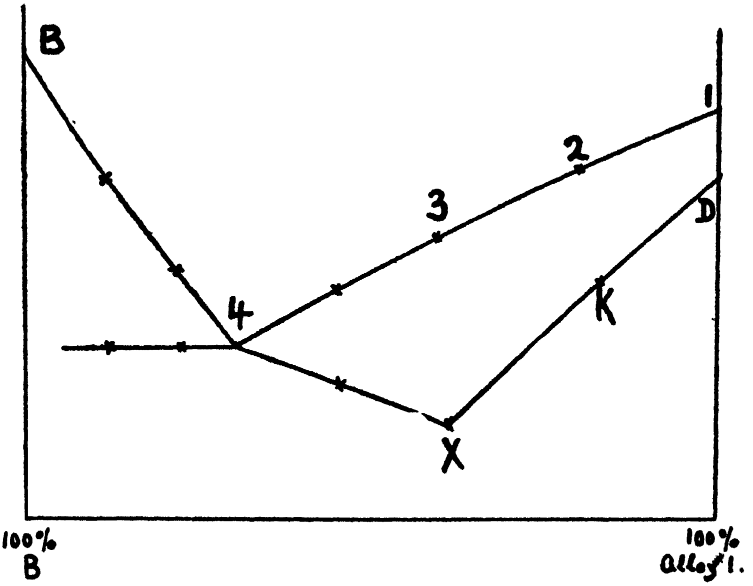

Fig. 6.

Such a survey series as 1B will furnish not only a series of first freezing points, but also an intersection on a binary eutectic line, and at least an approximation to the position of such a critical line as AX. (The line AX divides the region occupied by the alloys consisting of excess A, plus AC eutectic, plus ternary eutectic, in the solid state, from the region occupied by the alloys consisting of excess A, plus AB eutectic, plus ternary eutectic. The lines BX and CX perform analogous functions. The types included by each of the six spaces ADX, AXE, etc., will be apparent from the diagram (Fig. 5)). By taking several such surveys from each angle of the triangle we can obtain a sufficient number of binary intersections to establish the courses of the lines EX, FX and DX. The position of the ternary eutectic is established by the intersection of the binary curves prolonged, together with the approximations to the positions of AX, BX and CX, and other aids to be mentioned later.

Special Case (Survey III).—With one exception, the surveys made in this investigation are of the above type—cutting only one binary eutectic line. Survey III cuts two binary lines. The course of the two freezing-point curves may be understood by reference to Fig. 7 and the following indications:

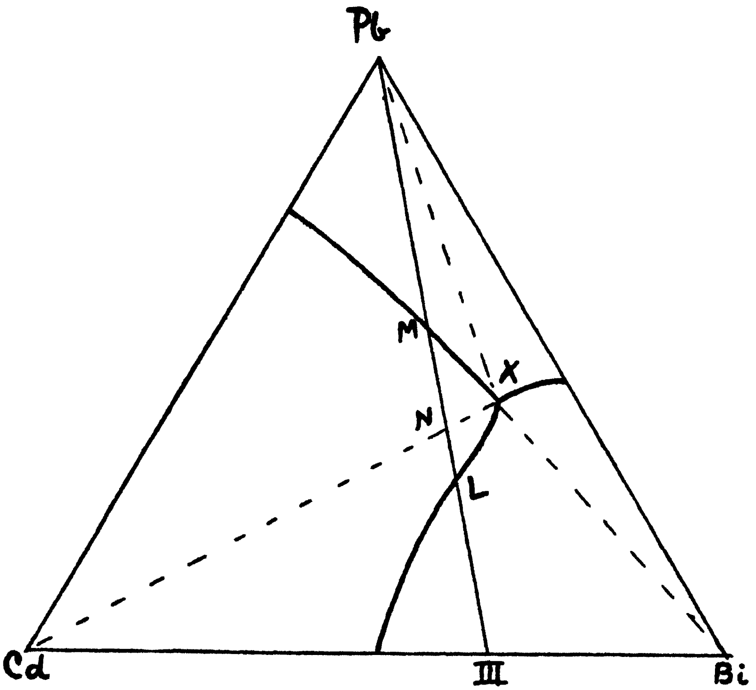

Fig. 7.

	Excess metal.	Eutectic.	1st f. p.	2nd f. p.
From III to L	Bi	Cd, Bi	falls	falls along DL
From L to N.	Cd	Cd, Bi	rises	falls along LX
From N to M.	Cd	Cd, Pb	rises	rises along XM
From M to Pb	Pb	Cd, Pb	rises	fixed at M

The actual courses of these lines are shown in Survey III, Fig. 10a.

(3) **Results.**—In Fig. 8 I have indicated the directions of the surveys used for exploration, and the compositions of the alloys actually submitted to cooling-curve observation. The alloys are numbered to aid in identifying them in the following tables and diagrams.

In Table IV, I have given the compositions, the first, second, and third freezing points of the alloys, arranged in their respective survey series. The letters n. t. signify that the halting point in question was not looked for—the observation of the cooling curve being stopped at some higher temperature. The letters u. c. indicate that the temperature was observed, but was manifestly incorrect as a result of undercooling. Pronounced undercooling was recognized at a second point only three or four times: the plotted cooling curves show that although undercooling took place in other cases, it was only very slight—not enough to interfere with the accurate determination of the freezing point, and usually extending through only a few tenths of a degree. In many cases the

two branches cut sharply. (Typical examples of observed cooling curves showing undercooling and a sharp intersection, respectively, are reproduced in Fig. 9.) Undercooling at the ternary point was naturally of more frequent occurrence, but of no importance. The ternary point was purposely not looked for in many of the alloys widely removed in composition from the ternary eutectic, since it could be determined with less likelihood of undercooling in alloys nearer the eutectic composition.

In Figs. 10*a*, 10*b*, 10*c*, I have represented the sections revealed by the survey lines, and also the second freezing-point curves. It should be

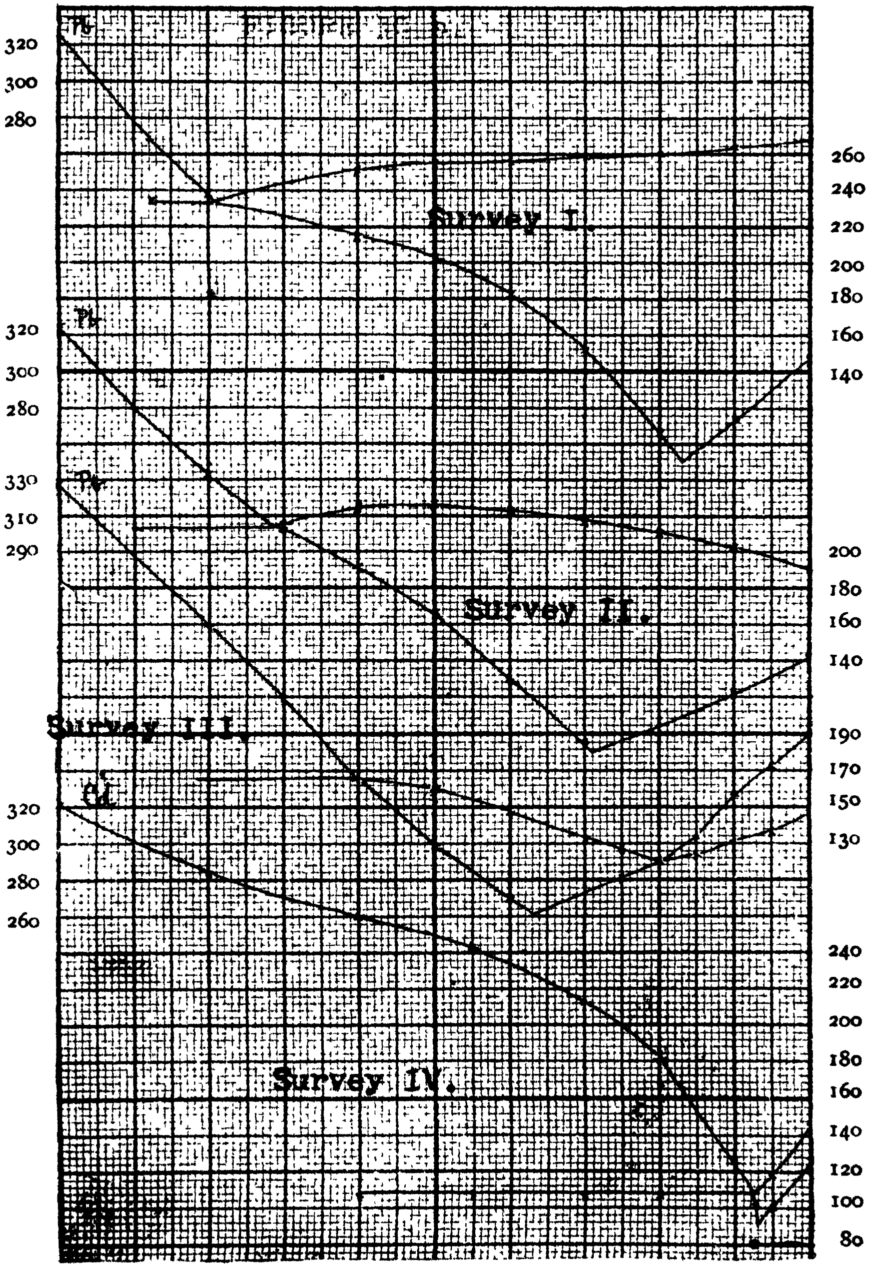

Fig. 10*a*.

understood that the *compositions* corresponding to the observed *second* points (with one exception) are not known at the time of making the survey. They lie, of course, somewhere on the respective binary eutectic lines, but the exact courses of these lines are not known at this stage

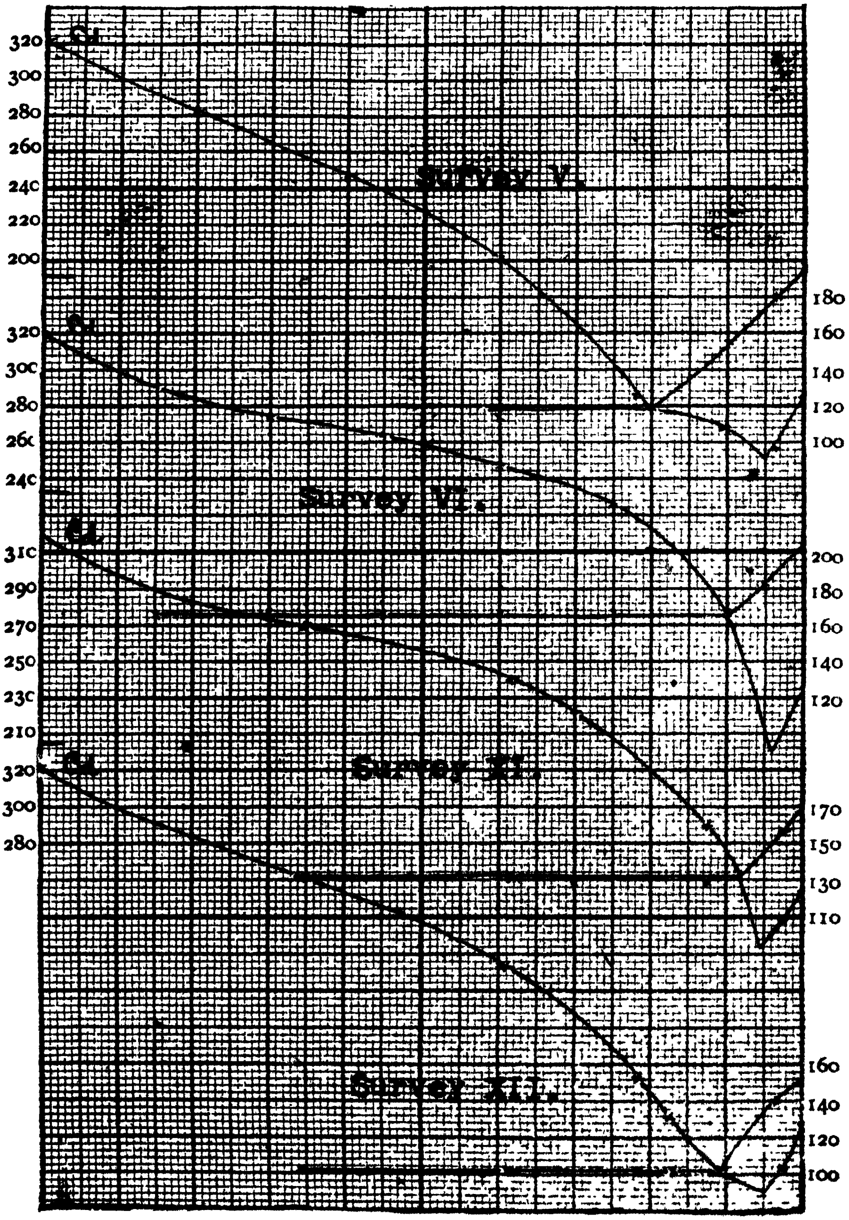

Fig 10b.

of the investigation. The one point in each survey which can be directly utilized is that at which the survey line cuts the binary eutectic line; both the temperature and composition represented by this point can be determined with considerable accuracy. I have shown below how the other observed second points in a survey series may be made use of to

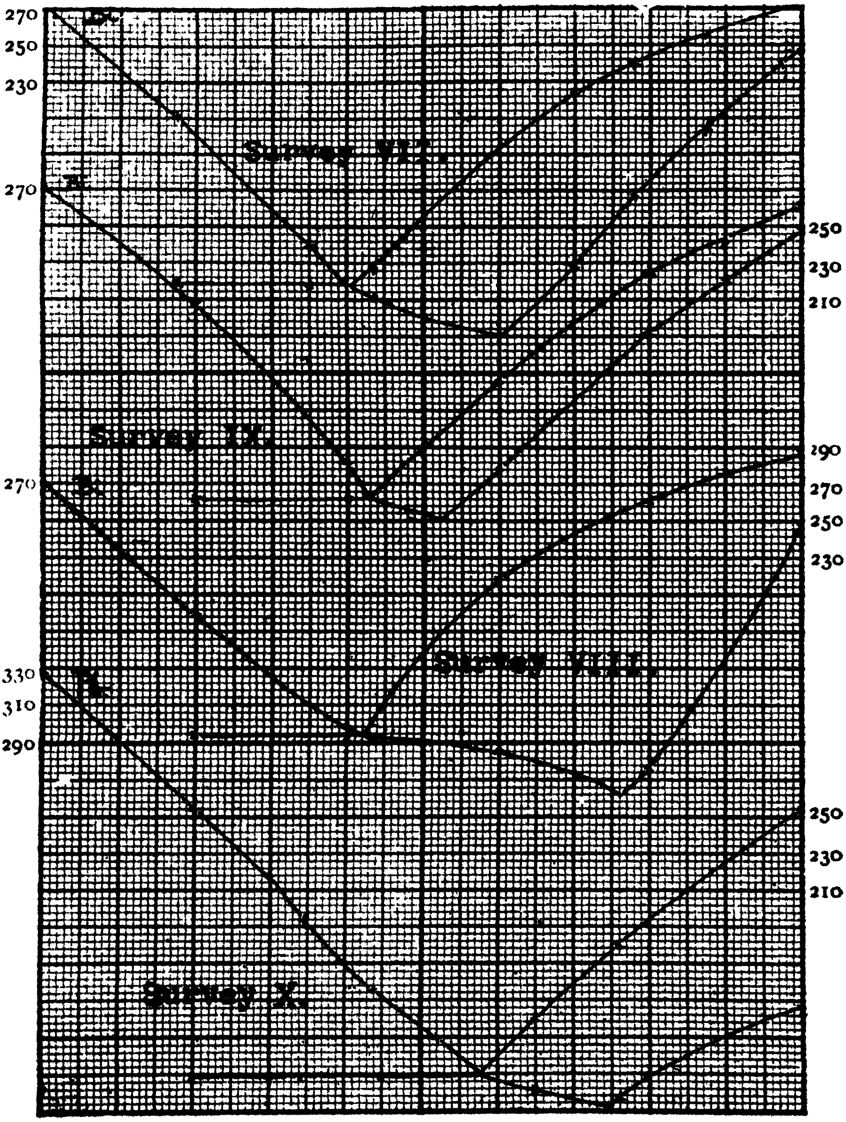

Fig. 10c.

check the courses of the eutectic lines after these lines have been determined from the survey-eutectic line intersections.

Many of the cooling-curve observations were repeated. In some cases both results are given in Table IV, in order to show the sort of agreement obtained. In other cases the average of the two (or three) results, or the single result, is used.

(4) **Construction of the Ternary Diagram.**—The first step was to mark on the triangular co-ordinate surface the positions of the survey lines, and the first freezing points observed at the respective compositions. The next step was to mark on the sides of the triangle points showing the positions of the three binary eutectics, and also a series of first freezing points (on each side of the triangle) ten degrees apart—taking these points from the binary diagrams shown in Figs. 1, 2, and 3.

The next step was to establish the direction of each one of the binary eutectic curves. For this purpose the intersections of these curves by the eleven survey lines were used. These intersections are given in the subjoined table (Table V):

TABLE V. SURVEY-BINARY CURVE INTERSECTIONS.

Survey No.	Composition at cut. Weight, per cent			1st and 2nd freezing points.
	Pb.	Bi.	Cd.	
I	78.5	5.375	16.125	234.3
II	71.2	14.40	14.40	214.0
III*a*	20.0	60.0	20.0	119.5
III*b*	60.0	30.0	10.0	165.4
IV	46.0	46.0	8.0	108.0
V	20.0	60.0	20.0	119.5
VI	60.0	30.0	10.0	165.4
VII	23.09	59.6	17.31	118.0
VIII	10.5	58.0	31.5	133.6
IX	32.25	57.0	10.75	102.0
X	42.7	54.435	2.865	109.0
XI	52.57	39.43	8.0	131.0

The cut on Survey V is actually at 20.5 per cent. Cd, and about 119°, while the cut on III is at 20 per cent. Cd. These points lie so near together that they are taken as coincident in the ternary diagram at alloy 24—the temperature assigned being 119.5°. Through the intersections found above, the curves DX, EX, and FX were drawn, as far as the points on IX, IV, and X, respectively. As an aid to the free-hand prolongation of these curves, and as a means of checking the accuracy of the work done, four additional check (or secondary) surveys were made: Survey XII, from Cd to Pb, 36.5 per cent.; Bi, 36.5 per cent. Survey XIII, from Cd to Pb, 40 per cent.; Bi, 60 per cent. Survey XIV, from Cd to Pb, 46.5 per cent.; Bi, 33.5 per cent. Survey XV, from Bi to Cd, 9.7 per cent.; Pb, 90.3 per cent. Survey XII, included in Fig. 10*b*, may serve as an example of the results obtained by these secondary surveys. The following observations were used in constructing the curve:

	Pb.	Bi.	Cd	1st point.	2nd point.
Cut on I.	12.5	21.87	65.63	262.0	103.0
Cut on VIII.	17.5	30.0	52.5	241.0	96.0
Cut on II.	22.0	39.0	39.0	213.0	102.0
Cut on VII	28.57	50.0	21.43	153.0	102.0
Cut on III	30.0	52.5	17.5	132.0	102.0
Cut on IX	32.62	56.5	10.87	101.8	101.8
Cut on X . .	35.0	61.75	3.25	139.0	103.0
Cut on Pb–Bi	36.5	63.5	0.0	150.0	124.8

The temperatures assigned are taken from the previously completed curves for Surveys I, VIII, etc.

The other secondary surveys (XIII to XV) give curves almost as smooth as XII. To avoid crowding the diagram, and because no *new* experimental results are involved, Surveys XIII to XV are not inserted in the main diagram. Their cuts on the curves DX, etc., were, however, used provisionally as guides in prolonging these curves.

The next step in the construction of the ternary diagram was to establish temperatures differing by 10° on the eutectic curves. For this purpose I fitted the edge of a strip of co-ordinate paper to the curve as drawn, and marked on the paper the intersections of the survey lines with the binary lines. I then removed the paper strip, erected perpendiculars at the points marked, proportional to the temperatures indicated, completed the curve free-hand, made marks at the edge of the strip vertically beneath temperatures differing by 10°, and finally replaced the strip and transferred the marks to the binary eutectic curves.

Before using the points so found as starting points from which to begin drawing the isotherms, I checked their positions as follows: The second freezing point of alloy No. 2 was observed at 115°. A straightedge placed so as to join Cd with alloy No. 2 cut the curve DX at, or

Alloy.	Observed. 2nd point.	Binary cut (See above)	Alloy.	Observed 2nd point.	Binary cut (See above.)
2	115.0	about 116.0	17	213.0	213.0
3	106.0	about 108.0	21	135.8	about 137.0
4	152.0	about 153.0	22	130.6	about 130.6
5	182.0	about 184.0	23	124.6	about 125.0
6	203.2	about 205.0	24	120.0	about 120.0
7	215.2	about 217.0	25	110.7	about 112.0
11	121.9	about 130.0	27	98.7	about 97.0
13	95.0	in the gap	28	128.0	about 130.0
14	127.8	about 130.0	39	108.0	about 108.0
15	165.4	about 165.4	50	167.0	about 170.0
16	192.0	about 192.0	54	116.0	about 117.0
			58	219.6	about 222.0
			59	118.5	about 117.0
			63	97.0	in the gap

about, 116°. This agreement confirms the positions of the points assigned to 110° and 120° on curve DX. Proceeding in this way I obtained the following checks. Except for alloy No. 50 (and possibly alloy No. 58) the results justified me in using the points marked on the binary curves.

The isotherms were then drawn in, and Fig. 11 was produced. For the sake of attaining clearness in reproducing the diagram on a small scale I have marked only the positions of the isotherms, the binary eutectic curves, and the ternary eutectic. The investigated alloys are shown in Fig. 8. The data for these alloys can easily be found by reference to Table IV.

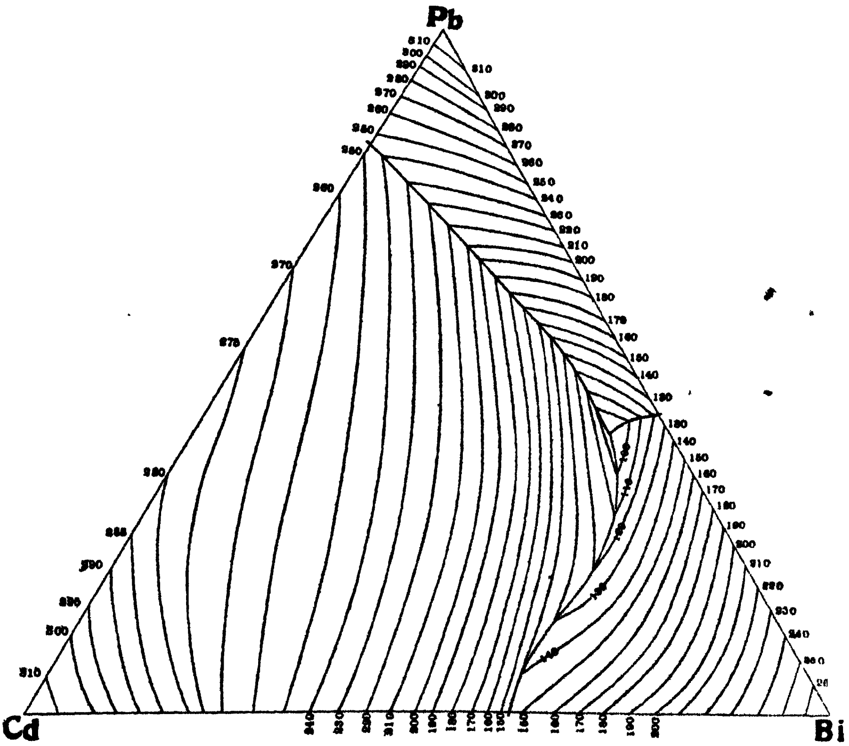

Fig. 11.—Isotherms of first freezing-points of cadmium-bismuth-lead alloys (Barlow).

REMARKS ON THE TERNARY DIAGRAM.

The three-curved surfaces all present convex sides towards the angles of the triangle. In other words, the depression of the freezing point of bismuth (for example) caused by the addition of a small amount of either lead or cadmium alone is less than that produced by the addition of an equal weight of a *mixture* of lead and cadmium; so, too, for the depression of the freezing point of lead and of cadmium.

The gradual and peculiar alteration (near the cadmium angle) of the course of the isotherms running from EX to the Cd–Bi line is what might have been expected from the shape of the freezing-point curve of the lead–cadmium series—and to some extent also from that of the lead–bismuth series. (In order to follow this gradual change of course I have inserted three isotherms between the ten-degree steps near the Cd angle.) Thus the Cd–Pb freezing-point curve shows an *inversion* from concave (from above) to convex at about 50 per cent. Cd, or about where the 275° isotherm emerges on the Pb–Cd side of the ternary diagram. In accordance with this the ternary isotherms are concave between Cd and, say, the 280° isotherm, almost straight from this point to the end of Survey VII, and gradually become convex from VII on to the eutectic E. On the Cd–Bi side the ternary isotherms retain their concavity up to the 250° isotherm—which is almost a straight line for the greater part of its course. In both cases the inversion in the freezing-point curve of the binary series evidences itself in the ternary diagram. From 250° on, towards the ternary eutectic, the isotherms are very nearly parallel.

The Ternary Eutectic.—The curves DX, EX, FX, continued free-hand from their cuts on IX (and XII), IV, and X (and XV), respectively, intersect at about 8 per cent. Cd, 40 per cent. Pb and 52 per cent. Bi.

An alloy of 5 per cent. Cd, 40 per cent. Pb, 55 per cent. Bi, was allowed to cool to 91.5°, with constant stirring and seeding, and a part of the still molten substance was then drawn by means of a suction pump into a glass tube provided with an asbestos filtering plug at its lower end. This, on analysis, gave Pb 41.1 per cent., Bi 50.5 per cent., Cd (by difference) 8.4 per cent. I am not convinced, however, of the possibility of so regulating the tightness of the asbestos plug and the force of the suction as to prevent minute crystals of a frozen excess metal, or a frozen binary eutectic, from being mechanically washed up into the tube with the molten ternary eutectic.

Cooling curves were taken of a number of alloys near the composition just given. Two of these alloys showed a very slight pause at 92°, and a sharply defined ternary freezing point at 91.4 to 91.5°. The composition of the ternary lies very near this point and may be taken, for the present, as Pb 40.2 per cent., Bi 51.65 per cent., Cd 8.15 per cent. The freezing point, as a mean of twenty determinations, lies at 91.5°, and this number, in fact, was found in the four or five cases in which special care was taken to observe the point accurately. It is interesting to note that, of the four possible *ternary* eutectics of the four metals (Sn, Cd, Pb and Bi), this one has the lowest freezing point. The ascertained temperatures are:

Sn–Cd–Pb,	Stoffel,	145°
Sn–Cd–Bi,	Stoffel,	103°
Sn–Pb–Bi,	Charpy,	96°
Pb–Bi–Cd,	Barlow,	91.5°

NOTE.—In sixteen of the alloys investigated a transformation point was noted (in addition to the three freezing points) at a fixed temperature, approximately 124°. In every instance observed the transformation took place below the temperature at which binary eutectic had begun freezing. The phenomenon was not noticed early in the investigation, and the data at hand are not sufficient to enable me to fix the limits of composition within which the change takes place. If the halt is caused by the formation in the partly-solid alloy of a binary or ternary compound, the extent to which this compound may form mix-crystals with the three pure metals will decide whether it is necessary to introduce another surface—roughly triangular in outline—at the point now assigned to the ternary eutectic. I intend to resume the investigation of the transformation at an early date, and ask for a reasonable time reservation for this purpose.

STUDIES IN VAPOR PRESSURE: III. A STATIC METHOD FOR DETERMINING THE VAPOR PRESSURES OF SOLIDS AND LIQUIDS.[1]

BY ALEXANDER SMITH AND ALAN W C. MENZIES.

Received August 20, 1910.

This paper consists of five sections dealing, respectively, with:

(1) The sources of error of a more general character involved in vapor pressure measurement.

(2) A critical résumé of the characteristics of the older methods, with particular reference to the individual sources of error in each.

(3) A description of the present apparatus.

(4) A criticism of this apparatus, in relation to the various sources of error.

(5) A set of measurements of the vapor pressures of water, made with a view to testing the efficiency of the apparatus.

The apparatus was applied in a redetermination of the vapor pressure of mercury, and in a quantitative study of the chemical constitution of calomel vapor, which will be described in separate papers.

Section 1. General Sources of Error Involved in Vapor Pressure Measurement.

A critical study of the very voluminous literature of vapor pressures reveals the fact that, where two or more independent series of values for the same substance are in existence, inconsistency is the rule and substantial quantitative agreement throughout two comparable series the exception. The differences range from a few tenths of a millimeter to several hundred millimeters.[1] In view of this discordance, which affects also our own results when they are compared with those of others, some space must be taken to discuss the general sources of error in the measurement of vapor pressure and to give some account of the older methods. The aim of this discussion is to attempt to indicate the precise conditions that must be met if these chief sources of error are to be avoided. When the sources of error have thus been defined, it is possible to show how far the method described in this paper meets the required conditions, and how far confidence may be placed in the experimental results secured by its means.

---

[1] This paper, and the two following, were read at the Boston meeting of the Society, on Dec. 30, 1909.

The sources of errors that are common to most methods of vapor pressure determination may, perhaps, be best discussed under the three heads of temperature, pressure, and impurity of material:

Temperature.—(*1*) *Steadiness and Equal Distribution.*—When the condensing vapor from a liquid boiling in a flask is used to maintain a steady temperature, the vapor, at first inevitably superheated, is expected to cool itself to the boiling point by radiation and by giving up heat to the bodies that it encounters. If the latter are too thoroughly jacketed, they may not lose the heat sufficiently fast to cool to the boiling point the vapor in the neighborhood of the thermometer. Errors, therefore, arise when the boiling is rapid, or when a sand bath or other large radiating surface is used as a source of heat. With inadequate jacketing, on the other hand, the latent heat of the vapor may be insufficient to raise the temperature of the heated bodies to the boiling point. This is a common experience, for example, in determining the sulphur boiling point of a platinum thermometer. In this connection it has not always been borne in mind that the latent heat of evaporation of water is exceptionally high, that of other liquids having, at their boiling points, only a fraction of the value for water. Again, when the liquid is boiled under reduced pressure,[2] the mass of vapor condensing is necessarily smaller, and its heating power, in virtue of latent heat, much less. It will be seen that, for a steam jacket, a much greater latitude in strength of heating (*e. g.*, of flame-height) is possible than for other jacketing vapors.

Liquid baths, having a large volume and therefore a large heat capacity, have generally been found satisfactory in maintaining steady temperatures whenever the stirring was adequate (see Section 3, below), which, however, has not always been the case. Air baths, on account of their small heat capacity, are far inferior,[3] and when employed have frequently not been stirred at all.

---

[1] See Landolt and Börnstein's, or any similar set of tables.

[2] As in Ramsay and Young's method of securing any desired temperature from 0° to 360°, by use of eight liquids (*J. Chem. Soc.*, 47, 640; 55, 483).

[3] See, *e. g.*, this series, No. V, following.

(*2*) *Accurate Determination of Actual Temperature.*—Explicit statements of the method of standardization of the thermometers used and of the degree of probable accuracy in the measurement of temperature are frequently wanting. In mercurial thermometry, it may be mentioned, the correction for external pressure upon the bulb is very uniformly omitted (see Section 2, below); too much faith is placed in an arithmetical correction for "exposed thread;" and readings to tenths above 300° are treated with too much respect.

(*3*) *Scale of Temperature.*—In few cases is the scale specified or, apparently, considered. Since even so low as 200° the difference between the constant-pressure air scale and the thermodynamic scale is of the order of 0.1° (corresponding to a pressure difference of several mm.), and at 450° the difference is nearly 0.5°, it would appear that many refinements in measuring or calculating pressures to single millimeters, not to speak of tenths, hundredths, and even thousandths of a mm. that are found in the literature, are really superfluous.

As a sample of vapor pressure thermometry, similar to dozens that might be cited, the determination of the vapor pressures of iodine by E. Wiedemann[1] may be mentioned. At 180°, for example, he found the value 687.2 mm. Since he says nothing about the style of the thermometer, about corrections, or about the scale of temperature referred to, two of these figures in the pressure are without significance. It is not remarkable, therefore, that the value is 25 mm. (corresponding to nearly 1.5°) divergent from that of Ramsay and Young,[2] and that his results add absolutely nothing to our previous knowledge.

Pressure.—The straightforward reduction of gage and barometer readings to mm. of mercury at 0° is not always stated to have been performed. Correction is made for the varying value of the gravity constant (*g*) only in very exceptional cases. Yet, in Chicago, a place not very elevated, and not far from 45° N. L., this correction amounts to 0.25 mm. per 760 mm., and in laboratories in London the value is about 0.5 mm. per atmosphere. This correction, therefore, usually considerably exceeds the error involved in the mere reading of the gage.

Impurity.—In the matter of purifying the crude material for the purposes of vapor pressure measurement, the physicist is usually admittedly at a disadvantage. But here even the chemist may be found somewhat unintelligently distilling "nine times" or freezing out or recrystallizing "fifteen times", with no guarantee that any increase of purity is being attained. How real is the necessity for purification may be judged from the statement of Tammann[3] that 0.01 per cent. of alcohol in benzene raised the vapor pressure of the latter, near the boiling point, by 12 mm.

---

[1] *Ber. physik. Ges.*, 3, 159 (1905).

[2] *J. Chem. Soc.*, 49, 453 (1886).

[3] *Ann. Physik*, [3] 32, 683 (1887).

A somewhat different class of impurity is met with in the moisture, oxygen, nitrogen and carbon dioxide dissolved in liquids or adhering to solid substances. Such impurities form undoubtedly a most constant and elusive source of error. The seriousness of the error due to this cause, however, varies much with the particular method employed. Attention may, perhaps, here be called to a fact which seems to be very generally overlooked, namely, that gases are, as a rule, much more soluble in other liquids than in water, and therefore, in general, have in other liquids more effective vapor pressure, and are less quickly and easily removed by boiling and other precautions than in the case of water. In the following table[1] the solubilities of three common gases are stated as volumes of gas held in solution by one volume of various liquids under ordinary conditions.

Liquid.	Carbon dioxide, 25°.	Nitrogen, 25°.	Oxygen, 20°.
Water	0.83	0.016	0.028
Carbon disulphide	0.87	0.059	...
Benzene	2.43	0.116	
Chloroform	3.43	0.135	..
Methyl alcohol	3.84	0.142	...
Acetic acid	4.68	0.119	...
Amyl acetate	4.12	0.173	..
Acetone	6.29	0.146	...
Alcohol	.	...	0.284
Petroleum	1.17 (20°)	0.117 (20°)	0.202

It may be pointed out in this connection that there is, probably partly for this reason, far less inconsistency in vapor pressure measurements of different observers in the case of water than in that of any other liquid. In many vapor pressure determinations there is no record of even an attempt to remove gases by preliminary boiling. Other observers boil for "two minutes" or for "some time." Not one of the widely used static methods admits of repetition of the boiling-out process till constant results are obtained, and thus the only sure proof of the effectiveness of the attempt to remove impurities is lacking[2] (see Section 2).

Section 2. The Older Methods.

Only certain methods will be here considered which are applicable over wide ranges of temperature, no mention being made of the tensimetric, gas-current, dew-point, and other methods of limited range. Regnault's classification of methods into "static" and "dynamic" may be followed.

---

[1] These figures are mainly from Just, *Z. physik. Chem.*, **37**, 354.

[2] A re-opening of the apparatus and repetition of the boiling out, or some equivalent process, so far as we have noticed, is mentioned only as follows: Ramsay and Young, *Phil. Trans.*, **177**, 91 (1888), part of the observations with a single substance (NH_4Cl) only. Lescoeur, *Ann. chim. phys.*, [6] **16**, 389 (1889). Beckmann, *Z. physik. Chem.*, **4**, 534; Raoult, *Ann. chim. phys.*, [6] **20**, 301 (1890), liquid boiled, but not the mercury; method not applicable above 1 atm. Vanstone, *J. Chem. Soc.*, **97**, 429 (1910).

Static Methods.—As representing a large class of static methods, may be taken that form in which the substance is introduced into the Torricellian vacuum of a jacketed barometer tube. A special temperature error incident to this method arises from the difficulty of adequately stirring a tall bath of liquid, such as those used by several of the French investigators. The difficulties when the vapor of a boiling liquid is used for heating have been discussed already. The pressure measurement is naturally uncertain in those cases, which are by far the majority, where every part of the mercury column is not held at the same temperature as the vapor chamber.

But the chief source of error in this form of the static method lies in the impurity of the substance. In the first place, mercury vapor may be present as an impurity. We find Ramsay and Young at one time applying the correction for complete saturation of the vapor chamber with mercury vapor, while, under other circumstances, Young assumes the entire absence of mercury vapor. If the correction be made, its value, at least above 280°, has hitherto been uncertain. Far more serious, however, is the uncertainty as to the inclusion with the substance of gases and moisture from the air, absorbed or dissolved in the solid or liquid, or adhering to the walls of the tube. Some observers attempt merely so to fill the tube with mercury that visible bubbles are absent. In such cases large amounts of absorbed gases must be liberated when the heating begins. Even with thorough boiling out, visible bubbles (not to speak of absorbed and invisible gases) may remain.[1] To remove gaseous impurities, the most careful workers, for example, Ramsay and Young,[2] boil, first the mercury and then the substance, in the barometer tube before inverting the latter. But even in such cases, save for the few exceptions mentioned in Section 1, a repetition of the boiling out, to test the success of the procedure, has never been attempted. What would the chemist say of a gravimetric method in which heating to constant weight played no part? The adhesion of the liquid to the top of the barometer tube, frequently cited, is, no doubt, evidence against the presence of free "air," but hardly excludes the presence of dissolved and absorbed "air." It may be questioned, also, whether obtaining almost identical pressures with varying volumes of liquid and vapor is a proof of the absence of foreign matter.[1] At all events, Ramsay and Young's method, the results of which usually were satisfactory when judged by those two criteria, happened to be tested in a different way in a single instance.[2] This tube was filled with mercury, which was thoroughly boiled in the tube as usual. Without the introduction of any substance, however, this tube was heated at 280.1°, as for a determination. When the tube had cooled, a permanent gas was found to have accumulated. Calculation showed that, while the tube was at 280.1°, this gas must have exercised a partial pressure of 2.9 mm. A second heating, if attempted, might have resulted in an increase in the amount of this gas. If a substance had been added, the amount of foreign gas could only have been still further augmented, so there is no assurance that these two tests are sensitive within ±3-5 mm. of foreign gas. Ramsay and Young's results are probably not subject to a systematic error, on account of filling, of such dimensions as this, but their exactness is due rather to the skill of the experimenters than to an inevitable accuracy inherent in the method.

---

[1] Tammann, in a piece of work on the effects of small amounts of impurities (*l. c.*), boiled out thoroughly, and remarks that after this treatment there was "usually no air-bubble" in the tube.

[2] *Phil. Trans.*, 175, 461 (1884). Young, *Stoichiometry*, 131.

The U-form apparatus, used by some investigators instead of a straight barometer tube, and applicable especially to pressures over one atmosphere, is open to very similar sources of error. Of quite another type is the static method in which pressure is measured by means of the Ladenburg spiral gage.[3] Here again, however, what is chiefly to be desired is a procedure which will permit of repetition of the boiling-out process until constant results are obtained.

If an individual observer with a constant personal equation has difficulty in duplicating results by the static method, it is not to be wondered at that different observers differ among themselves. Take, for example, the vapor pressures of acetic acid at 100°, all as measured by the static method: Landolt 408.5 mm., Ramsay and Young 417 mm., Wüllner 473 mm.; those of butyric acid at 20 3°: Landolt 7.3 mm., Ramsay and Young 0.35 mm.

Not the least of the objections to the static method is the almost unbearable laboriousness of work which attempts to be accurate. Schmidt,[4] after enumerating its difficulties, including one not noted by other observers, namely that a number of barometer tubes had to be rejected before one was found in which the pressures with small amounts of vapor were not larger than with greater amounts, adds: "The static method has so many disadvantages, when compared with the dynamic, that I can only warn [observers] not to use it."

[4] *Z. physik. Chem.*, 8, 629.

Dynamic Methods.—A simple form of the dynamic method consists in using a thermometer immersed in the vapor rising from a liquid boiling under various known pressures. So, for example, Regnault obtained his vapor pressure curve for sulphur, and Holborn and Henning their data for water. It is plain that such a method escapes the errors due to gaseous impurity, whether adhering or dissolved, and herein lies its chief advantage over the static methods. If a reflux condenser be employed, moisture and condensable volatil impurities do not escape; while if the vapor is condensed in another vessel, the less volatil impurities become concentrated in the residual liquid. In either case, if the current of vapor streaming into the condenser be a rapid one, the pressure within the flask is commonly slightly higher than the pressure at the distant end of the condenser with which the manometer is connected. Irregular boiling may cause large errors, and is difficult to prevent. Use of a stream of air entering through a capillary vitiates the results,[1] so far as their value as vapor pressure measurements is concerned. Schmidt[2] avoids bumping by placing a pad of cotton, saturated with the liquid, in the bottom of the flask. Regnault's difficulties and results in the case of mercury will be referred to later.[3]

Ramsay and Young sought to overcome the bumping and superheating difficulties, as well as the disadvantage of the large quantity of material required, and to avoid the need of a bath which could keep the apparatus at a constant and known temperature, by means of their well-known method.[4] In this, the liquid is allowed to trickle on to cotton enveloping the thermometer bulb. This bulb is situated in a flask surrounded by a bath, the temperature of which need not be constant or definitly known, but must be at least 20° higher than that shown by the thermometer. When the pressure, which is read by means of a manometer in connection with the flask, is altered, the temperature as shown by the thermometer changes spontaneously to correspond. It will be seen that the thermometer readings are subject to the correction for the "compression coefficient," as noted by us in a former paper,[5] although this correction, amounting in certain cases to nearly 0.2°, is not mentioned in any of the published descriptions of the apparatus, or applied so far as we have seen, with a single exception, on any of the numerous occasions on which the method has been employed.

[5] THIS JOURNAL, 32, 905. The purpose of this paper, on "A Common Thermometric Error in the Determination of Boiling Points under Reduced Pressure," seems not to have been made sufficiently clear in the paper itself. Physicists have long been familiar with the "compression coefficient," although even some of them ignore

The error due to impurity is here to be looked for from the presence of air in the cotton wool and also, more especially, dissolved in the liquid. Fresh supplies of liquid with its dissolved "air" are constantly being introduced, nullifying any possibility of permanent expulsion by boiling out. The chief advantage of the simple dynamic method is thus lost, and the chief disadvantage of the static method is re-introduced. Should the liquid have acquired a non-volatil impurity, or contain by heredity an impurity less volatil than itself, it is plain that such impurity must gradually become more and more concentrated in the cotton surrounding the thermometer bulb. The method is not applicable to pressures much greater than atmospheric, or to liquids (*e. g.*, mercury) which do not wet cotton, and is of questionable value for solids.[1]

Section 3. The Apparatus.

The special feature of the submerged-bulblet vapor pressure apparatus, already described,[2] consists in the facility with which, using only a minute amount of the substance, the expulsion of dissolved and adhering impurities may be continued until constant values for the vapor pressure are secured. This important feature is precisely the one most conspicuously required to give trustworthiness to the static method and, as we have seen, most conspicuously lacking in the standard forms of apparatus working on the static principle. Now, while the bulblet method was being reduced to suitable form, we perceived that a modification of the apparatus would convert it into a static instrument. This static apparatus retained the advantages of the important feature referred to without loss of ease of manipulation, and possessed also several additional advantages over the regular static forms of apparatus. The simple bulblet was first changed by using a wider tube, instead of the capillary, and bending the lower end of the tube upwards. The whole had thus the form of a C, and an enlargement of the open end furnished a cup into which a confining liquid could be temporarily driven during the boiling-out process. The C-formed apparatus was tied to the thermometer, just as was the simple bulblet. To allow further liberty in

it in vapor pressure work. The paper dealt with the types of thermometers commonly employed by chemists, and with the considerable dilatations occurring when large intervals of pressure are concerned. The effects cannot be ignored in vacuum distillation and in vapor pressure determinations by the cotton-jacketed-thermometer method, for example, both of which are operations much used by chemists, and not hitherto associated in their minds with the necessity of employing this correction.

[1] See No. V of this series.

[2] This Journal, 32, 907.

the choice of a confining fluid, the open limb was next lengthened so as to extend above the surface of the bath. After a series of minor changes, the form described below was finally adopted.

It is necessary to describe the apparatus and the corrections used in minute detail, as only thus can the exact conditions be understood, and only thus can the data secured retain their value if, for example, sources of error which have escaped attention should subsequently be discovered.

The Isoteniscope, Bath, and Stirrer.—The substance is placed in the spherical bulb, which is about 20 mm. in diameter (Fig. 1). The confining liquid occupies the lower half of the U-tube, which is 30–35 mm. in height. The small bulbs on each limb of the U-tube prevent the ascent of the confining liquid (by suction) into the bulb or the vertical tube. For the sake of compactness, the spherical bulb is placed behind the U-tube, and not in the same plane with it as shown (for clearness) in the figure, the purpose of the apparatus being to show when two pressures have become equal, the arrangement may be called an *isoteniscope.* The present form, to distinguish it from a different one to be described in a later paper, may be called the *static isoteniscope.* A two-liter beaker of tall shape forms the bath. The vertical tube of the isoteniscope is about 24 cm. long, so that the rubber connection is sufficiently far above the heated bath-liquid.

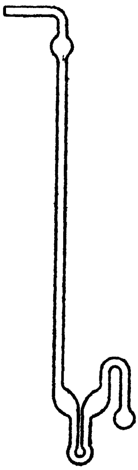

Fig. 1.

When the substance being studied is a liquid, the lower part of the U-tube is charged with *this liquid itself.* When the substance thus acts as its own confining liquid, it has the great advantage over mercury that its specific gravity is usually small. Hence, when the levels in both limbs of the U-tube appear to the eye to be identical, the error, when converted into mercury height, is negligible.

It is only when the vapor pressure of a non-fusing solid is being determined that the question of choosing a confining liquid comes up. The conditions to be fulfilled are that the confining liquid shall not have an appreciable vapor pressure of its own at the temperatures to be employed, and that the vapor of the substance shall not dissolve in it. A liquid which interacts chemically with the vapor of the substance should be avoided, especially if a gas is produced. But, as will be seen in the paper on the constitution of calomel vapor, a slow chemical action involving no gas production is not prohibitory. Among the suitable substances are mercury and melted paraffin at the lower temperatures, and fusible alloys or a molten salt or mixture of salts at high temperatures. In the case of solids, it is necessary to charge the bulb before fusing it to the U-tube.

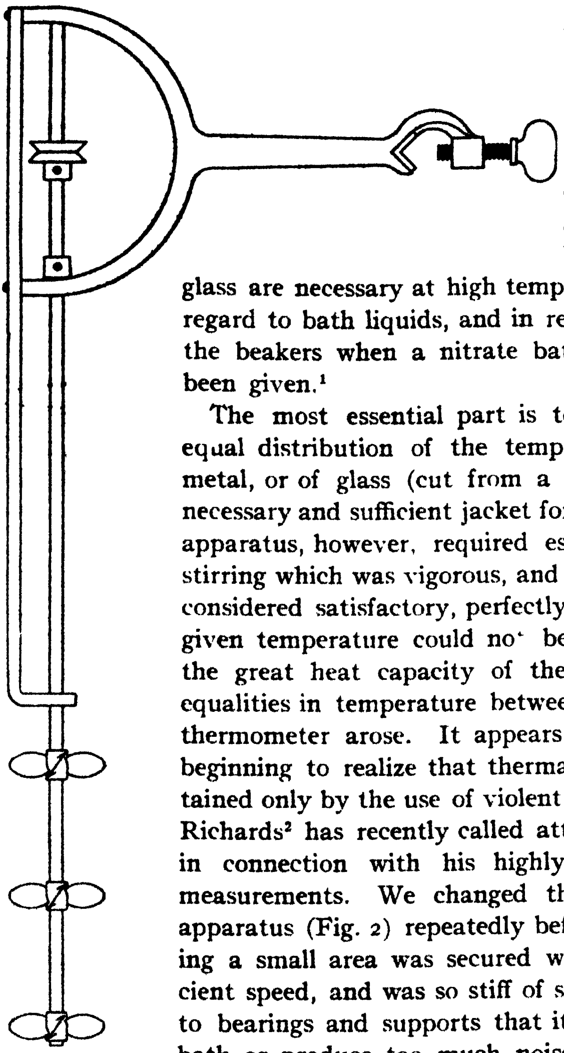

Fig. 2.

To permit sufficient immersion of the thermometer (platinum resistance, or mercury) in the bath-liquid, beakers over 23 cm. high and 11 cm. wide are used, and are filled almost to the brim. Beakers of Jena glass are necessary at high temperatures. The details in regard to bath liquids, and in regard to the handling of the beakers when a nitrate bath i, used, have already been given.[1]

The most essential part is to secure steadiness and equal distribution of the temperature. A cylinder of metal, or of glass (cut from a broken beaker), forms a necessary and sufficient jacket for the bath. The stirring apparatus, however, required especial attention. With stirring which was vigorous, and of the nature ordinarily considered satisfactory, perfectly constant pressures at a given temperature could no' be obtained. In spite of the great heat capacity of the bath-liquid, slight inequalities in temperature between the substance and the thermometer arose. It appears that chemists are only beginning to realize that thermal equilibrium can be obtained only by the use of violent, almost riotous stirring. Richards[2] has recently called attention to the same fact, in connection with his highly exact thermochemical measurements. We changed the form of our stirring apparatus (Fig. 2) repeatedly before a structure occupying a small area was secured which rotated with sufficient speed, and was so stiff of stem and so massive as to bearings and supports that it did not "whip" in the bath or produce too much noise.[3] When these conditions had been met, constant results, even with a resist-

[1] THIS JOURNAL, 32, 899.

[2] *Ibid.*, 31, 1280 (1909).

[3] The stirrer (Fig. 2) was made from an ordinary retort-stand ring. The rod (3 mm. in diameter), driven rapidly by an electric motor, rotates in two holes bored in the ring, and is supported by a stout strip of brass (seen edgewise) which extends down almost to the first vane. The length from the lower side of the ring to the lowest vane is 28 cm. The vanes are in sets of three, each set 25 mm. in diameter.

ance thermometer giving a large galvanometer deflection for one hundredth of a degree, were easily secured, where before they had seemed unattainable.

It is important to place the stirrer so that it may communicate some of its vibration to the substance (if a liquid) in the bulb. The resulting, constant agitation promotes the liberation of the vapor. It also prevents the limitation of the evaporation to the mere surface layer, a condition which would delay or prevent the complete elimination of dissolved gases.

By use of transparent quartz for the vaporizing vessel, and a quartz beaker, there is no reason why this method should not give exact determinations of vapor pressures and of dissociation pressures up to the softening point of quartz. Vapor pressures have not yet been measured accurately at such temperatures and, for dissociation pressures, the combination of a platinum heating chamber fused to a U-tube of glass, to render the confining liquid visible,[1] has several disadvantages.

The Platinum Resistance Thermometer.—While a mercury thermometer may be used, the platinum resistance thermometer is, of course, a more exact and trustworthy instrument. Quite apart from this, however, the latter has a special advantage in work of this kind, where the complete expulsion of foreign matter is ascertained by repeated observations, made at exactly the same temperature. After a second boiling out and equalization of the pressures, the temperature of the bath itself can be readjusted until the spot of light occupies its precise former position. Thus, while the actual temperature may not be known with a greater accuracy than ±0.1° or ±0.01°, according to the precautions taken, this readjustment of the bath temperature may very easily be made with an error much smaller than these.

The platinum resistance thermometer employed was of the form devised by Haagen.[2] In this form, the resistance wire is wound on a 6 cm. length of quartz tube, of diameter somewhat over 1 mm., which is then inserted into a very slightly wider quartz tube. The outer tube is then fused on to the inner one, thus embedding the resistance wire in quartz. The "bulb" so prepared is fused to a suitable length (24 cm.) of wider quartz tubing which carries the platinum and silver leads. There are no compensation leads.

For measuring resistance a Wheatstone bridge arrangement was used, with an arm ratio of 10 to 1. The box resistances, of manganin, were calibrated, and the appropriate correction applied to all measurements made. The largest error of any of the single coils employed was 2.6 parts in 10,000. The coils were not maintained at constant temperature, but, in order that the temperature correction applied might be as small as possible, the temperature of the coils was kept close to that which they possessed when the fixed points were determined. The resistance of the thermometer was about 50 ohms at 0°. The measuring current varied from 3 milli-amperes at 0° to 1.2 at 445°. No correction for heating by the measuring current was required when the thermometer was immersed in water, fused nitrates, steam at 100°, or sulphur vapor at 445°. A small correction was necessary only when moistened ice, with its badly conducting, interstitial air spaces, surrounded the thermometer bulb. The sensitiveness of the galvanometer was such that a movement of the light spot of 1 cm. on the scale corresponded to 0.04° at 0° and to 0.08° at 445°. The fixed points used were the freezing point of water, the boiling point of water and the boiling point of sulphur. The boiling point of sulphur was assumed, in accord with Holborn and Henning,[1] at 445°. Its true value may lie closer to 444.9° on the thermodynamic scale,[2] but, as this datum is liable to be changed by future observations, it was thought better to adopt the rounder number. Obtaining the ice point and the water boiling point presents little difficulty, if the usual precautions are observed. As is well known, however, the boiling point of sulphur found varies considerably with the size of the apparatus and the screening, etc., adopted.[3] We employed a gas-heated boiling tube of thin brass of 5.5 cm. diameter and 17 cm. length, jacketed by a thickness of 5-6 cm. of asbestos packing. The bulb was protected by a cone of asbestos paper, closed below, whose base was situated 10-12 cm. above the surface of the boiling sulphur and whose apex was 20 cm. below the level of condensation. We were careful to employ the roll sulphur of commerce, and used a depth of about 8 cm. Kahlbaum's crystallized sulphur contains volatile impurity. The reductions, for pressure, of the boiling points of sulphur and of water were made in accordance with the data of Holborn and Henning.[4] As the constants of the platinum thermometer are known to be changed by prolonged heating, the fixed points were redetermined whenever the thermometer had been kept long at high temperatures. The following figures will give an idea of the degree of constancy of the thermometer used, and relate to an epoch when the thermometer was being heated at temperatures of 300°-445° for many consecutive hours: 1909, October 8th, $R_0 = 50.1150$ ohms; Oct. 18th, $R_0 = 50.1161$; Oct. 22nd, $R_0 = 50.1170$. Here the total change amounts to 0.01°. The corresponding values of the fundamental coefficient were 0.00386366, 0.00386384, 0.00386671. These values approach the value for the purest platinum (0.00389).

[4] *Loc. cit.*

In reducing the results, the difference formula of Callendar was employed. The constant δ changed little from 1.6147 (using 445° as the boiling point of sulphur). If a lower value is assumed for the boiling point, the value of δ is smaller. With resistance wires of impure platinum the Callendar formula requires modification.[1] To test the degree of its applicability to our wire and to ascertain whether, in the absence of compensation leads, correction was necessary for the change of resistance of the leads used, or for any other reason, two other standard temperatures were determined. Holborn and Henning[2] have determined upon their temperature scale the boiling points of naphthalene and of benzophenone, and also the changes in these boiling points for small changes of pressure. Their values are 218.039° and 306.081°, respectively; we found (a single observation) 218.075° (Δ = 0.036°), and (mean of the only two observations made) 306.089° (Δ = 0.008°), respectively. The correction to apply to the platinum temperature of our thermometer to obtain thermodynamic temperature (b. p. of sulphur 445°) is at 218°, 4.154°, while at temperatures between 0° and 100° this correction has a maximum value, at 50°, of —0.404°. Our temperature measurements may, therefore, be considered accurate to ±0.1° in the range 250°–435° and to ±0.01° in the range 50°–90°. It may be remarked that, should it seem desirable, our temperature-scale may, from the data given, be readily reduced to correspond with any other boiling point of sulphur than that here adopted.

The Pressure Gage and Barometer.—The gage consisted of a glass tube of 11 mm. inside diameter, of which the open limb and that connected with the apparatus were, respectively, 2 m. and 1.4 m. long. The latter limb was provided with a stopcock. A long mirror behind the gage eliminated the effects of parallax.

The mercury heights were measured by means of a steel tape, the gradation of which was calibrated by comparison with a standard meter. From the results of this comparison, and the coefficients of expansion of the steel and of mercury, a table of corrections covering the whole range of the room temperatures was prepared.

The mercury heights were read by means of a fine, truly horizontal hair-line ruled on a strip of glass (a microscope slide), carried by a cursor or carriage. The cursor consisted of two spring collars of brass (10 cm. apart), connected together rigidly by a metal bar which carried a horizontal arm to support the microscope slide. The brass collars grasped a

[1] Callendar, *Phil. Mag.* [5], 47, 191 (1899); Tory, *Ibid.*, 50, 421 (1900); Waidner and Burgess, *Loc. cit.*

[2] *Loc. cit.*

mandril-drawn, seamless steel tube, 18 mm. in diameter and over 2 m. in length, which was fixed in a truly vertical position. This steel tube, along with the steel tape, gage, and mirror were attached to a long board, which was suspended by a rope and balanced by a counterweight. The whole gage could thus be moved vertically between guides, in such a way as to bring to the level of the eye the point at which the mercury stood. This kept the mercury accessible to convenient observation during the numerous manipulations connected with a reading. By the use of the cursor described above the somewhat tedious use of a cathetometer was avoided, with no sacrifice of accuracy.

The heated air arising from the bath passed directly into the flues of a draught cupboard, within which the bath stood, and did not reach the gage, which was outside the cupboard. Moreover, the gage was shielded from heat radiated by the bath.

Pure mercury from the laboratory supply was redistilled *in vacuo* before use in the gage, and was tested by the method of Hulett and Minchin.[1] A portion was redistilled twice in air to oxidize the more electropositive metals, if present. The potential difference between the two samples, when placed in *N* KCl solution saturated with calomel, was less than 0.000003 volt. The metal was, therefore, of a satisfactory degree of purity.

Since an open gage was used, the barometric height had to be read. The instrument was one made by Henry Green, of Brooklyn. The scale was already corrected for capillarity. The instrument was standardized by comparison with a barometer, in which the tube was exhausted by means of a mercury pump until the McLeod gage showed a residual pressure of less than 0.003 mm. The reading of the Green barometer was found to be correct.

The following corrections were applied to the pressures:

1. The pressures were reduced to mm. of mercury at 0°. For this purpose five carefully compared thermometers, graduated to tenths of a degree, were suspended at intervals along the gage. To eliminate differences in mass and lag between the thermometers and the mercury in the gage, the bulbs of the thermometers were immersed in mercury contained in tubes of the same diameter as the gage. The coefficient of linear expansion of mercury used was 0.0001818. The error in density of mercury due to its compressibility is negligible at the pressures employed.

2. The coefficient of linear expansion of steel used in calibrating the steel tape was 0.000011.

3. The mercury heights were reduced to the sea level at 45° N. L. The value of the gravity constant, *g*, determined in the Ryerson Physical

---

[1] *Physic. Rev.*, 21, 388 (1905).

Laboratory of the University, namely 980.34, agrees precisely with that calculated from latitude and elevation. The value of g taken as the standard[1] was 980.665 cm. sec.$^{-2}$, and the factor by which the observed heights were multiplied was therefore 0.99971. The amount of this correction is thus 0.25 mm. per 760 mm.

4. In measuring the vapor pressures of water, since the temperature error in that case was less than ±0.01°, suitable correction was made for the difference in level between the cistern of the barometer and the mercury in the open limb of the gage. A similar correction was made, when necessary, for the difference in level between the surface of the water in the bulb of the isoteniscope and the surface of the mercury in the closed limb of the gage. The amount of this correction is about 0.09 mm. per meter head of air.

Other Parts of the Apparatus.—The general arrangement of the apparatus is shown in Fig. 3, which is diagrammatic. The isoteniscope and the gage were connected with a large iron bottle. Another piece of tubing leading from the bottle gave connections, by means of T-tubes, with (1) the atmosphere, (2) a vacuum reservoir and water pump, (3) a pressure reservoir, and compression pump. A stopcock on the first, and screw clamps on each of the other two tubes permitted any one to be used at will. The rubber tubing leading to the atmosphere was so long that it hung out over the edge of the base of the draft cupboard.

The water pump, with its residual pressure of about 20 mm., according to the temperature of the water, served our purpose very well, as no measurements of vapor pressures below 80 mm. were to be made. With a mercury pump, much lower vapor pressures could be studied with the same arrangement of the rest of the apparatus.

The connections were made with thick-walled rubber tubing, wired at all junctions, and coated heavily with a suitable composition. No tendency to leakage was ever observed.

The Manipulation.—The following statements apply particularly to the determinations of the vapor pressures of water below one atmosphere. The modifications required when pressures over one atmosphere are measured, or when another liquid or a solid is used, will be understood without special description.

When the temperature has reached the desired point, and has become constant, the exit to the suction bottle and pump is opened and remains open until the pressure in the iron bottle has been reduced to such a point that the water in the bulb boils, and the vapor passes freely through the confining fluid (itself also water) in the U-tube. The confining fluid is driven into the remote side of the U-tube and the bulb above it. When

---

[1] Troisième conf. gén. des poids et mésures, 1901, 66, 68.

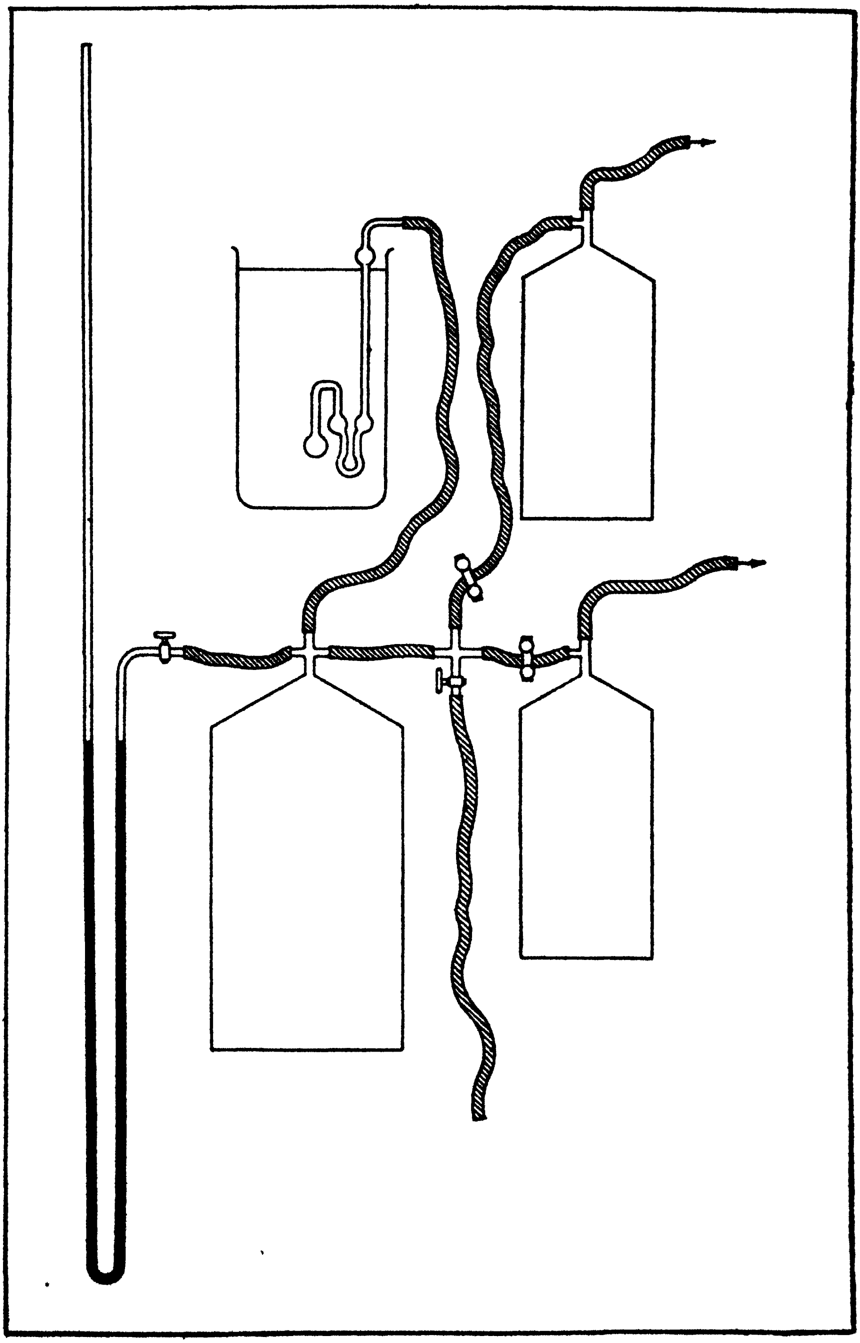

Fig. 3.

the air in the bulb, and the gases adhering to the bulb and dissolved in the water have been driven out, air is cautiously admitted to the iron bottle through the exit to the atmosphere until the levels of the water in both limbs of the U-tube are identical. On account of the cooling of the substance in the bulb by evaporation, equilibrium is not reached at once, so that the adjustment has to be repeated until the levels in the U-tube remain constant. The finer adjustment is not easy to manage by the use of the stopcock alone, and the long rubber tube opening to the air is employed. When, for example, a slight increase in pressure is required, the tube is grasped with the hands at two places and air is admitted to the bottle in small portions at a time until equilibrium is attained.

When the adjustment has been perfected, the stopcock on the gage is closed, the temperature reading is confirmed, and the gage and barometer are read. Within the time required for making the gage reading, no variation occurred in the level of the mercury due to a change in temperature in the air confined in the closed limb. To make sure that volatil foreign matter or gas has all been expelled, the whole process of boiling out, adjusting, and reading is repeated until constant values are obtained.

The temperature of the bath is then raised, and a new observation taken. Unless the substance is unstable, and decomposition products arise, repeated boilings at the second and higher temperatures produce no change in the values first obtained.

Section 4. Criticism of the Method.

It will be seen that the isoteniscope is free from the sources of error which affect the older forms of apparatus for determining vapor pressures. For example:

1. The isoteniscope substitutes for mercury a confining fluid of low specific gravity and thus eliminates the error in leveling involved in some static methods.

2. The apparatus dethrones mercury from its position as sole confining fluid, and substitutes a wide choice of liquids. In consequence, all errors due to the volatility of a foreign confining fluid, and to solubility of the substance in, or interaction of, the substance with such a confining fluid disappear entirely.

3. By being adapted to use in a liquid bath (with violent stirring), the apparatus reduces to a minimum all errors due to unsteadiness of the temperature, and to inequality in the temperatures of the substance, its vapor, and the thermometer.

4. By providing a simple method for expelling air bubbles and adhering and dissolved gases, and for repeating the expulsion until the success of the operation is demonstrated, the isoteniscope removes a source of

error (and of total uncertainty as to the amount of that error) which destroys all confidence in the exactness of the results obtained by the older static methods.

5. By permitting the making of an extended series of observations without using more than half of the sample, the apparatus obviates an error due to concentration of involatil impurities in the residue which affects some dynamic methods.

6. By allowing the expulsion of accumulated gas immediately before a reading, the apparatus makes possible accurate measurements with many substances which decompose slowly to give a permanent gas. By the older static methods, accurate measurements in such cases was necessarily impossible.

Aside from this avoidance of certain sources of error, the apparatus possesses some noteworthy advantages:

1. A small amount of material suffices (usually less than 1 gram).

2. The filling of the apparatus, and the manipulations involved in a measurement, are incomparably simpler than any other static method.

3. The correction for dilatation of the bulb of the mercury thermomter (the so-called "pressure" coefficient), which some dynamic methods involve, is avoided

4. Since, with liquids, no foreign substance (such as mercury) is present, the method permits measurements with all reasonably stable liquids, no matter how active, chemically, they may be.

5. The method is applicable to all solids, provided a non-interacting, non-solvent, non-volatil confining liquid can be found. When such a liquid cannot be found, a dynamic method to be described in a later paper ("Studies in Vapor Pressure, V") may be used.

Section 5. The Vapor Pressures of Water.

On account of the facts about water, some of which were brought out in Section 1, namely the ease with which natural impurities are removed, the relatively slight solubilities of gases in water, the more normal behavior of water as shown in the work of Tammann and of Wüllner and Grotian, and the relatively slight inconsistencies in the existing determinations of its vapor pressures, water is a suitable substance for affording a test of the merits of the method. Moreover, no other substance combines all these qualities, and water is therefore at present the only suitable substance.

There is no reason why mercury should not equal, or even excel, water in freedom from impurities and in regularity of behavior. Only the inconsistencies in the measurements which thus far have been made, and especially the utter disagreement of those above the boiling point, render it unsuitable for comparing methods.

Results.—The isoteniscope was thoroughly steamed out, and distilled water, giving no appreciable residue on evaporation, was redistilled into it. The method itself provides for the expulsion of dissolved gases. The measurements were made with the apparatus described above, and the corrections before mentioned were applied.

The observations were made by design as close as possible to temperatures, the values of which should be represented by whole numbers. The differences for one-tenth of a degree at each temperature, taken from Eckholm's[1] tables, were then used in making the very small adjustments required to reduce each observation to the nearest whole number of degrees. The results of this operation are given in the following table (I) under S & M. The pressures in this column, therefore, are not smoothed results, such as may be obtained by graphical or other methods, but are essentially *actual observations*, subject to the irregularities which individual observations usually show. This enables them to afford the most rigorous test of the method, while the adjustment facilitates the comparison with the data of other observers, which are usually given for whole degrees. The twenty-seven observations give, after adjustment, values at eleven different temperatures.

TABLE I.

65	3	187.19	187.36	+0.17	—0.019
70	3	233.44	233.53	+0.09	—0.009
75	1	288.78	289.0	+0.22	—0.018
80	1	354.90	355.1	+0.20	—0.014
85	3	433.54	433.5	—0.04	+0.002
89	5	505.87	506.1	+0.23	—0.011
90	1	525.94	525.8	—0.14	—0.007

For comparison, we give under H & H the corresponding values found by Holborn and Henning[2] in the *Reichsanstalt*. These are undoubtedly the most accurate in existence. Their temperature scale is the same as ours. Their results are smoothed values, derived from numerous observations. The greatest divergencies are 0.23 mm. and 0.019°. The algebraic sum of all the temperature differences, divided by the whole number of our observations (27), gives the mean divergence from H & H's curve of a curve drawn through our observations. This mean divergence is —0.0063°, which is well within the error which we assign to our measurement of absolute temperature (±0.01°). The corresponding mean pressure deviation is +0.08 mm. This agreement is of especial interest since our method is static, while theirs was dynamic.

[1] *Svensk. Vet. Akad., Arkiv. för Math., Astron., och Fysik*, Band 4, Häfte 2, No. 29 (1908).

[2] *Ann. Physik*, [4] 26, 833 (1908). The reason for accepting these values as the most accurate will be apparent to any one who considers the details of the method used

Comparison of Other Methods.—We may now institute a comparison between the results obtained by our method and those obtained by others, using Holborn and Henning's values as the standard of comparison.

Taking first the static methods, with which ours may most justly be compared, there are only two sets which included the region 50°–90°, namely those of Magnus and of Batelli. In both cases mercury was the confining fluid, and the U-tube form of vaporizing vessel was used. Magnus[1] boiled the mercury "well" after its introduction. He also boiled the water for 1/2–3/4 hour, and then introduced it, while yet warm, through the open limb, by inclining the apparatus. Batelli[2] "caused the mercury to boil several times." The water was introduced in a small glass bottle, after elaborate purification and subsequent boiling for twenty-four hours. No precautions to remove gases adhering to the small bottles are mentioned.

In the first two columns of the following table (Table II), only the differences between the pressure values of Holborn and Henning and those of Magnus (M) and of Battelli (Ba), respectively, are given. These numbers are to be added to the published data, to give those of H & H. The other columns will be explained presently:

TABLE II.

(Differences from H & H.)

	Static.		Dynamic.		Recalculations.		
t.	M.	Ba.	Rg.	W.	Br.	T.	E.
50°	+0.33	+1.85	+0 28	...	+0.32	—0.22	—0.34
60	+0.61	+2.3	+0.36	...	+0 31	—0.19	—0.38
70	+0.92	+2.7	+0.58	...	+0.22	—0.14	—0.40
80	+1.2	+2.7	+0.5	—0.3	+0.2	0.0	—0.34
90	+1.0	+2.1	+0.3	—0.2	+0.3	0.0	—0.2
Av.	+0.81	+2.3	+0.4	—0.25	+0.27	—0.11	—0.33

The average divergencies from H & H are: Magnus +0.81 mm. (or —0.07°), Batelli +2.3 mm. These are respectively ten and thirty times as great as our average divergence. It must be noted that the data of these two observers are all smoothed values.

Schell and Heuse[3] have recently determined the value at 50° (92.54 mm.) by a static method. Our value (static) confirms that of H & H.

[1] *Pogg. Ann.*, 61, 225 (1844).

[2] *Ann. chim. phys.*, [6] 26, 410 (1892); [7] 3, 408 (1894).

[3] *Ann. Physik*, [4] 31, 715.

On account of the extensive use which has been made of Ramsay and Young's static methods, both by themselves and by others, a comparison would be very instructive. Their barometer tube method, available up to nearly 760 mm., with the special device for filling so as to exclude foreign gases, was not applied to water, which is the only suitable substance for making a rigid comparison. Their only determinations with water[1] begin at 120°, and are therefore not directly comparable with ours. The filling of the tube[2] involved boiling of the substance, but not of the mercury in the tube. The differences between their values and those of H & H at their lowest temperatures are as follows: 120°, +4.9; 130°, +6.6; 140°, +15.5; 150°, +0.7. The average divergence is +6.9 mm., or —0.1°, and is of the same order as that of Magnus. These, again, are smoothed values. This divergence is not due to the difference between the scales of temperature used by Ramsay and Young (const.-vol. air-therm.) and by H & H, for this would not exceed 0.014° (corresponding to 1.3 mm.) even at 150°, and besides, if taken into account, would increase the divergence.

If we turn now to results obtained by dynamic methods, there are only three sets which include the region under consideration, namely those of Regnault, Wiebe (82°–100°), and Holborn and Henning. Regnault's[3] dynamic observations extended from 43° to 230°. In the column headed Rg of the foregoing Table II, we give the differences between the data of H & H and of Regnault, using for the latter the data calculated by the "H" formula. This was the formula which Regnault found most generally satisfactory, and it appears to be especially so within the region in question. Wiebe[4] made measurements from 82° to 100° only. His results (Col. W), however, seem to be considered especially good by H & H, and they are weighted very heavily in Eckholm's recalculation of the data which he considered. The average divergences from the results of H & H are: Regnault, +0.4 mm. (or —0.04°), and Wiebe —0.25 mm.

On account of the very large number of measurements made by Ramsay and Young, and by other observers, with their dynamic method,[5] in which the thermometer bulb is surrounded by cotton saturated with the substance, a comparison of its performance with that of other methods is extremely desirable. Unfortunately, although they made a series of observations with water,[6] they give no results and content themselves with stating that the values were "identical with those of Regnault."

[6] *Phil. Trans.*, **175**, 48 (1884).

It is a pity that they did not state more exactly the degree of approximation, and specify which of the appreciably divergent sets of data were used in the comparison—for example, the curve, the values calculated by "formula H" (those most commonly quoted, *e. g.*, in the *Chemiker Kalendar* and Van Nostrand's *Chemical Annual*), or Brock's recalculation (adopted by Ostwald in his *Handb.*). As we have seen, however, the method is open to serious criticism.

Finally, in the last three columns (Table II) we give the results of Regnault, as recalculated by Brock (Br), the data of all previous observers as combined and recalculated by Thiesen[1] (T), which were adopted without change up to 100° by Henning[2] in his most vigorous study of the same data, and the results of Eckholm's (E) recalculation of the same data. As before, only the differences, H & H—Br, etc., appear.

This comparison shows that, assuming Holborn and Henning's values to be correct, the results by our method lie much closer to the true value than do those by any other static method. They likewise diverge much less than do the results of the recalculations of previous determinations. They lie also much closer than do the values obtained by the dynamic methods, although all writers are agreed that the dynamic methods give more trustworthy results than do the static ones which have hitherto been employed.[3]

The degree of self-consistency of the observations may be seen by inspection of Table I. A more detailed study of the deviations from a smooth curve of the individual observations obtained by this method will be undertaken in the following paper on mercury.

To determin definitly the merits of the isoteniscope, *per se*, it would be necessary to eliminate from the older observations the effects of the errors in the measurements of temperature and of pressure, and to isolate the error due to the form of the vaporizing chamber and the method of handling the substance. It is unfortunately impossible to do this. It is to be noted, however, that the gage and thermometer errors are common to static and dynamic methods, and should be essentially alike in both. Now the average magnitude of the divergencies of the dynamic and static methods, respectively, from that of H & H are 0 33 mm. and

---

[1] *Ann. Physik*, [3] 67, 692 (1899).

[2] *Ibid.*, [4] 22, 609 (1907). This was before the redetermination by Holborn and Henning.

[3] The much closer approximation of our results to those of H & H is not due to the fact that the same scale of temperature was used by both, whereas the other observers used air thermometers (Regnault, a mercury thermometer). The difference between the scales at 50°–90°, except possibly in the case of Regnault's values, is so small that it would equal only a fraction of the divergence in each case, and besides, wherever the differences in pressure are positive in the preceding tables, an adjustment to the thermodynamic scale would only increase the divergencies.

1.55 mm. The excess of the static over the dynamic may perhaps be held roughly to represent the minimum value of the error of the older static methods *per se*. Now this difference is 1.22 mm., or about fifteen times the total divergence of our results due to all causes.

STUDIES IN VAPOR PRESSURE: IV. A REDETERMINATION OF THE VAPOR PRESSURES OF MERCURY FROM 250° TO 435°.

BY ALEXANDER SMITH AND ALAN W. C. MENZIES.

Received August 20, 1910.

Both for practical and theoretical purposes, an exact knowledge of the physical constants, and particularly of the vapor pressures of mercury, is of the greatest importance. Mercury is used in innumerable ways in research and in many instances the accuracy of the results depends on a knowledge of the vapor pressures of this substance. Since mercury shows no evidence of a tendency to association, and since its vapor is monatomic, presenting in the former respect a great contrast to water, and in the latter respect even to the liquids of more normal behavior, like benzene, an exact knowledge of its vapor pressures should be of the utmost value in the study of the laws pertaining to vaporization. The relations, for example, between temperature and pressure and between these two and heat of vaporization, on account of the absence of complicating factors, should be of special simplicity in the case of mercury. Moreover, it is more easily obtained in a state of extreme purity than almost any other substance. Yet, in spite of all this, as Laby says, "the greatest—and it should be added, unnecessary—disagreement is to be found in the current values of this vapor pressure." For these reasons, and because accurate data were required for a study of calomel vapor which will shortly be published, a redetermination of the vapor pressures from 250° to 435° was undertaken. The range chosen was limited to the region required for this special purpose, but we intend later, with a longer gage, to extend the series. The theoretical study of our results is postponed until the longer series shall be available.

Previous Determinations.—The work of previous observers has been subjected to a critical study and their data have been combined by Laby.[1] We are not concerned with the values at low temperatures, of which those of Pfaundler,[2] Morley,[3] and Hertz[4] (the latter's extend to 207°) are in excellent agreement, and are irreconcilable with the erratic values of

Van der Plaats,[1] Hagen,[2] and McLeod.[3] As regards Regnault's[4] three low-temperature series, including observations up to 205°, he himself states that they give data that are only approximate. The series of determinations discussed below are those which touch the region covered by our experiments. The data themselves will be found in a comparative table (Table VI) given towards the end of the paper.

Regnault's values at the highest temperatures are based, (1) on four old determinations of the boiling point of mercury (about 357°) made with an air thermometer, two of which differ by about 2° at the same pressure, and (2) a new series from 251° to 511.7°. In the latter, the mercury boiled under varying air pressures. The temperatures were determined with a constant-volume air thermometer. The boiling metal began to bump occasionally at 345° and violently at 428°. The values near the ordinary boiling point are obviously discordant, as the three following observations show: 354.60°, 758.20 mm.; 354.83°, 761.87 mm.; 356.69°, 754.43 mm. Later workers have made much of Regnault's statement that his results were inaccurate, but he makes no such admission in regard to these two sets of values, leaving them to speak for themselves. All he says is that the experiments were not done in the same way as those which he made with other substances, because, when the bulb of the thermometer was surrounded by vapor, constant temperatures could not be obtained, and in this case, therefore, the bulb was completely below the surface of the liquid. Owing to the great depth of the mass of mercury (50 kilos), the lowest layers must have been seriously superheated.

Ramsay and Young's[5] well-known series of vapor pressures of mercury was based upon four groups of observations. Young, in a paper which appeared five years after and seems to have escaped notice,[6] utilized later values for a part of the fundamental data, and gives a corrected and very considerably altered table (see Table VI). The four original groups of observations were:

1. Four static measurements with mercury in a U-tube[7] heated by the vapor of methyl salicylate boiling at a known pressure. The temperature of the vapor was ascertained indirectly from a previously determined p.-t. curve. This p.-t. curve not having given satisfactory

[6] *J. Chem. Soc.*, 59, 629 (1891). Not referred to in Landolt and Börnstein, [3] (1905), nor in Abegg's *Handb.*, II, ii (1905), which give the old set of values.

[7] For proof of the difficulty in excluding foreign gases from such a tube see preceding paper, Sec. 2.

results in other cases, Young, in the second paper, discards these observations and substitutes for them two new readings with aniline vapor as the heating agent at 183.7° and one with quinoline vapor at 236.9°. These temperatures (const.-vol., air-therm. scale) are therefore ascertained indirectly as before.

2. Two static measurements with mercury in a U-tube heated by the vapor of bromonaphthalene boiling at known pressures. It is a little difficult to make out the exact status of this part of the data. These were old observations, originally made as part of a study of the vapor pressures of bromonaphthalene.[1] On that occasion, the temperature corresponding to the observed bromonaphthalene pressure was ascertained by taking from Regnault's formula the temperature at which mercury exercised the vapor pressure observed in the U-tube. These, along with three other series of measurements made in a different way, were employed in making the bromonaphthalene p.-t. curve. They entered directly into the making of the curve, and were used also for ascertaining the correction of an English thermometer employed in one of the other (the fourth) series.

On the present occasion they play the reversed roles of measurements of the vapor pressure of mercury. One of these agrees with the final p.-t. curve of bromonaphthalene and the other is adjusted by altering the temperature 0 4° to bring it onto this curve. As these results are retained and used by Young in the second paper, it is necessary to consider their probable accuracy.

The values, as adjusted, were considered to be correct for two reasons. One was because they gave normal results when used in the study of certain vapor pressure relations of water and bromonaphthalene, expressed by the formula $R' = R + c\ (t'-t)$.[2] But water is an abnormal substance and is admitted to be unsuitable for the study of this relation,[3] so that the agreement of the results with the theory in this instance affords no guarantee of the accuracy of the data. The vapor pressures of mercury adopted on the basis of this observation, when compared with those of water in the light of the same relation, again showed good, but, for the same reason as before, unavailing agreement with the theory. The value of the results must be judged, therefore, solely by the other reason for considering them correct, namely, the accuracy of the p.-t. curve of bromonaphthalene on which they are based.

This curve[4] is founded on several series of observations. Two series were made by Ramsay and Young's dynamic method,[5] in which the thermometer bulb is surrounded by cotton and immersed in the vapor. No correction for dilatation of the bulb[1] is mentioned, but its absence would not affect the results at 280°, with which we are concerned, as the pressure is there atmospheric. The objections on account of the introduction of dissolved gases along with the liquid, and of the gradual concentration of impurities, however, still remain. The results of the second series are below those of the first by 0.8° at 278°. In the fourth series, the bromonaphthalene boiled in a tube under known pressures and its temperature was ascertained by means of a thermometer immersed in the vapor. This was the thermometer standardized by assuming Regnault's vapor pressure curve of mercury to be correct. The results are above those of the second series at 280° by 1.9°. The temperatures in these series were all reduced to the constant-volume, air-thermometer scale. The third series consisted of the pair of observations first referred to.

[5] For detailed criticism see preceding paper, Sec. 2.

It appears, therefore, that these two observations are not independent of the p.-t. curve of bromonaphthalene, and that the latter is made from data diverging as much as 1.9° at 280°.

In a later paper, Young[2] refers to certain discrepancies in results obtained by the use of the p.-t. curve of bromonaphthalene vapor, which he believes to be due to a slight underestimation of the temperatures at 280°. Table IV, however, will show that these two sets of observations from 183.7 to 280° are probably much more accurate than those of Hertz in the same region.

3. The third group of data pertaining to the vapor pressures of mercury used by Ramsay and Young consisted of the four boiling points of mercury originally employed by Regnault, two of which differed by 2° at the same pressure. Young, in the later paper, rejects these and substitutes Callendar and Griffiths'[3] determination of the boiling point of mercury at 760 mm., reduced to the sea level at latitude 45°, the value of which is generally quoted as 356.76° (const.-press. air-therm. scale). In this work, the details of which cannot be discussed here, the authors used values obtained with four improved platinum resistance thermometers, each compared in the vapor of boiling sulphur and at 0° and 100° with a constant-pressure air-thermometer. The mean result, reduced to the basis of the S b. p. = 444.53°, which the same observers had determined, was 356.76°. The mean of the results with five earlier, trial platinum thermometers, similarly reduced, was 356.74°. A final set of three "very careful" observations with a new platinum thermometer gave the mean value 356.73°. The final mean value with the five best ther-

[2] *J. Chem. Soc.*, 77, 1147 (1900)

[3] *Phil. Trans.*, *A*, 182, 150–2 (1891).

mometers is 356.74°, in exact agreement with that of the five earlier instruments.

4. The fourth, and last, of the groups of observations used by Ramsay and Young consisted in two static measurements of the vapor pressure of mercury when heated by boiling sulphur. For the temperature, Regnault's boiling point of sulphur, 448.34°, the only one then available, was used. Young retains the pressure data and substitutes Callendar and Griffiths'[1] value for this boiling point (444.53°). According to Ramsay and Young's table, a difference of 4°, such as this, corresponds to a change in pressure at 445° of 139 mm. Hence this substitution greatly altered the value at 445°, as well as all the values between 760 and 2850 mm., which, in the absence of intermediate determinations, were all obtained by interpolation.

The vapor pressures were determind by heating the mercury in an apparatus shaped like a round-bulbed thermometer, with the stem bent into a horizontal position. The mercury, when cold, filled the bulb and a part of the stem, and was driven along the latter, compressing the air in the end, when mercury vapor was formed in the bulb. The bulb and a portion of the non-horizontal part of the stem of this thermometer-shaped apparatus were surrounded by the vapor of sulphur boiling in a vessel which in one experiment was a flask and in the other a wide test tube. Dr. Young, whom we desire to thank for most courteously giving us additional information on a number of points, states that the air column, before compression, was approximately 400 mm. in length. At four atmospheres pressure its length was thus reduced to 100 mm. Since the reading was probably accurate to ±0.1 mm., the pressure error should be only ±1 in 1000, or about 3 mm. The accuracy of the pressure reading was therefore satisfactory.

It is unquestionable, however, that in assuming that the bulb was really heated to 444.53° by the arrangement used, a serious error is introduced. The flask and test tube containing the boiling sulphur were not covered or protected in any way. Now, Callendar and Griffiths devote much space in their paper to a detailed description of their observations on this point. They used a Victor Meyer vapor density tube 4 cm. in diameter. Even when such a tube was padded externally with asbestos to retain the heat, the temperature reached by the thermometer was only 442.38°. They showed that the temperature of their thermometer (corresponding in Ramsay and Young's experiment to the bulb) was reduced by the trickling down of condensed, cooled sulphur and by radiation to the layer of condensed sulphur on the walls. By introducing a little hood to divert the sulphur running from the stem, and two cylindrical screens (one of metal and one of glass) to stop radiation, they finally brought the observed temperature up to 444.53°. In Ramsay and Young's experiment, therefore, the temperature actually reached was probably not far from 442.38°, or about 2° short of the value assigned to it by Young.

---

[1] *Phil. Trans.*, *A*, 182, 119 (1891). See also preceding paper, Sec. 3.

Gebhardt[1] boiled mercury in a glass globe. The temperatures of the vapor were taken with "a thermometer," presumably a mercury thermometer. No attempts to standardize the instrument, or to correct the readings for exposed thread or dilatation are described. Corrections of the gage are likewise lacking. But the pressures are given to tenths of a millimeter (see Table II).

Cailletet, Colardeau, and Rivière[2] determined, by a static method, the vapor pressures in atmospheres from 400° to 880°. The results are of interest as showing the order of the pressures at very high temperatures. The authors state that their results are sensibly the same as Regnault's, so far as the latter extend. Laby used these results although he rejected Regnault's, and this accounts for the fact (see Table VI) that above 360° his figures are higher than those of Young. No information as to the values assumed for the fundamental points, or as to the scale of temperature employed, is given.

Summarizing the history of this subject, we find that our knowledge of the higher vapor pressures of mercury rests on no very secure foundation. The boiling point at 760 mm. is the only point ascertained with precision. Not one observer makes any statement in regard to the purity of his mercury. Aside from Callendar and Griffiths, Regnault is the only investigator who states what he did in every experiment with perfect lucidity and completeness. Unfortunately, his results at closely adjacent points are inconsistent, his temperatures are those of the liquid and not of the vapor, and his air thermometer was inexact in its readings.

The Vapor Pressures of Mercury.—The apparatus used was identical with that described in the preceding paper.[3] The U-tube of the static isoteniscope contained mercury. The mixture of potassium and sodium nitrates was used as the bath liquid. The vibration communicated from the stirrer prevented bumping, which otherwise might have occurred when the metal in the bulb was allowed to boil.

The mercury, already distilled *in vacuo*, was redistilled in the same way at the rate of 30 cc. per hour. It was then washed ten times with dilute nitric acid in a tube 1.3 meters long, by the method recommended by Hildebrand.[4] This method is like Ostwald's excepting that the metal is strained through muslin, which divides it into extremely small streams, instead of being allowed to enter the acid in a single stream. It was then dried and tested by the method of Hulett and Minchin,[1] which is incomparably the most sensitive. A portion of the metal was distilled twice in air, which oxidizes the more active metals, if present. Samples of each lot were then placed in a cell containing *N* KCl solution saturated with calomel. The potential difference of the two samples was less than 0.000002 volt, the limit of sensitiveness of the galvanometer employed. The method is capable of detecting one part of zinc in 10^{10} parts of mercury, and corresponding amounts of other active metals. The mercury in the gage was also tested and found to be of a like degree of purity.

[1] *Ber. physik. Ges.*, 7, 184 (1905).

[2] *Compt. rend.*, 130, 1585 (1900).

[3] THIS JOURNAL, 32, 1419.

[4] *Ibid.*, 31, 933 (1909).

The corrections and the precautions, such as frequent redeterminations of the fixed points, were identical with those used in the observations with water which are recorded in the preceding paper.

Two series of readings, hereafter named the first and second series, were completed. In the first attempt to make the second series, the isoteniscope broke after the fourth reading. Since the next, and successful second series overlapped the first series for a considerable distance, rendering the four observations in the same region unnecessary, and since the instrument may have been defective before the breakage occurred, the four readings of the abortive series were not used. Aside from those four, every observation that was completed is recorded in Table I. The results, 43 in all, are given in the order of ascending temperatures, in which they were obtained. The members of the second series are distinguished by an asterisk.

It may be noted that an alteration in the zero of the thermometer, requiring a change of about 0.1°, occurred between the first and second series. On account of the overlapping, however, the individual observations are affected only to the extent of 0.05°. The aim was to secure observations with a temperature error of less than ±0.1°. The temperatures are worked to hundredths of a degree as, although not accurate to one unit in this place, the second decimal has nevertheless some significance.

The temperatures are on the thermodynamic scale, and assume the boiling point of sulphur to be 445° on that scale. If, later, a slightly different value for this point should be finally accepted, the preceding paper supplies the data required for any recalculation. If the S b. p. is taken 0 1° lower (*i. e.*, 444 9°), which is the present most probable value, then at 357°, for example, a correction of —0.06° is required.

The error of the individual gage readings, considered by themselves, is less than ±0 2 mm. The pressures are given to hundredths, although the second place has very little significance.

---

[1] *Physic. Rev.*, 21, 388 (1905).

Critical Study of the Results.—The observations were first plotted on a large scale, equivalent to a piece of cross-section paper 118 x 220 cm., and a smooth curve was drawn through them. This made easy the selection of three points, from which a Kirchoff-Rankine-Dupré formula was calculated. From this formula the pressures at every 2° in the region studied were reckoned. By linear interpolation, which is sufficiently accurate for intervals of 2°, the calculated temperatures corresponding to the observed pressures were then obtained. A study of the divergencies of the calculated and observed temperatures now showed that an alteration in two of the fundamental points would cause the formula better to fit the observations as a whole. With the very slightly altered points the whole process was repeated, and a further slight change in all three points was made. Thus, after two approximations, a final set of three points and a corresponding formula of a very satisfactory nature were secured. The fundamental points on which the final formula is based are:

264.16°, 106.52 mm., 356.95°, 760 mm.; 433.96°, 2598.67 mm.
The formula is $\log p = A + B/\theta + C \log \theta$, or, with the constants inserted:

$$\log p = 9.9073436 - 3276.628/\theta - 0.6519904 \log \theta, \qquad \text{(R)}$$

where $\log B = 3.5154272$; $\log C = \bar{1}.8142412$.

The following table contains. the reference numbers of the experiments (Col. 1), arranged in the order of ascending temperatures, with those of the second series distinguished by an asterisk; the observed pressures (Col. 2); the observed temperatures (Col. 3); the temperatures calculated with the use of the formula by the process indicated above (Col. 4); and the differences (Δ) between the observed and the calculated temperatures.

If the formula fitted the observations exactly, the algebraic sum of the divergencies should be zero. It is actually +0.07°. A change of 0.003° in the middle point might improve the correspondence, but it did not seem desirable at present to attempt any such refinement.

Since the calculated temperatures lie on a smooth curve, the divergencies from them of the observed temperatures represent essentially the irregularities in the individual observations. A study of column 5 will, therefore, show the degree of consistency of the results. Of the forty-three observations, thirty show very small deviations, ranging from 0.00° to 0.05°. In eight cases the divergence is from 0.06° to 0.10°, in only five cases does it exceed 0.10°. Observation No. 37 is undoubtedly defective, on account of a misreading of the resistance or of the gage. The mean deviation from the smooth curve of a single observation (including No. 37) is 0.050°. This is well within the limit proposed for the accuracy of the absolute temperature measurements.

TABLE I.—THE OBSERVATIONS.

Comparison with Other Methods.—The qualities of the method used are best seen by applying the same mode of study to the observations of other observers. Cailletet, Colardeau, and Rivière do not publish their observations, but only the rounded results. Ramsay and Young's observations are not numerous enough for the purpose. Only in the cases of Regnault and Gebhardt[1] can the data be investigated as regards their consistency. In the following table (Table II) the observations of Gebhardt (taken from Laby's paper, as the dissertation is not accessible) are given. It contains the observed pressures (Col. 1), the observed temperatures (Col. 2), the temperatures calculated by the use of formula R (Col. 3), and the differences (Δ_1) between the temperatures as observed and as thus calculated (Col. 4). The algebraic sum of these deviations divided by the number of observations is +0.81°, showing that the observed temperatures are on the whole 0.81° below those calculated.

A curve was drawn fairly to represent his results, and the divergencies of the individual observations from this curve are given under Δ_2 (Col. 5). The sum of these divergencies is +0.2°, that is, approximately zero, as it should be. It will be noted that the individual temperatures, besides being, as we have seen, on the whole 0.81° too low, are exceedingly irregular. The mean deviation of a single observation from the smooth curve is 1.2°, or about twenty-four times as great as in the case of the present observations. The method is, in part, responsible for this.

Regnault's main series (251° to 512°) is exhibited in Table III. Col. 3 contains the temperatures calculated by our formula, and Col. 4 the differences between the temperatures as observed and as thus calculated. The mean deviation of a single observation is 2.84°. Col. 5 shows the temperatures as calculated by Regnault's own formula (shorter form) and Col. 6 the differences between the temperatures as observed and as thus calculated. The mean deviation of a single observation from the smooth curve represented by Regnault's formula is 3.29°. Our formula thus fits his results better than does his own. The character of his work on this subject hardly justifies the extent to which his results have been quoted and used. It must be remembered, however, that he does not discuss their exactness, much less claim for them any special accuracy.

TABLE III.—REGNAULT'S OBSERVATIONS

Comparison of all Observations.—Since it thus appears that the present observations are probably of a relatively high order of accuracy, it is instructive to compare the results of other observers. In the following tables are given all the published observations, omitting those of Regnault and most of Gebhardt's. The initials are those of the observers: Young (Y), Ramsay and Young (R Y), Hertz (H), Callendar and Griffiths (C G), Cailletet, Colardeau, and Rivière (C C R), Pfaundler (P), Morley (M).

In the first table (Table IV) appear the observations above 200°, with two others, and also the rounded values of C C R (no observed data having been published by them). Since in this region the chief experimental error lies in the measurement of temperature, rather than of pressure, the comparison is made in the same way as before.

TABLE IV.—OTHER OBSERVATIONS, CHIEFLY ABOVE 200°.

Callendar and Griffiths' value is the mean of all their boiling-point observations reduced to thermodynamic temperature (S b. p. = 445°). None of the other temperatures have been reduced. At the high temperatures (C C R), where the reduction would make the most difference, no data are furnished by the authors. The values of the temperatures near 443–444° (Young) are about 2° too high, for the reason already given.

Table V contains all the observations below 200°. Since in this region the pressures are very low, the chief errors affect the pressures rather than the temperatures. In this table, therefore, the observed pressures (Col. 3) are compared with those calculated by formula R (Col. 4). The differences are given in column 5, and in column 6 is stated the percentage of the calculated value which was observed (*i. e.*, calculated value = 100).

Morley's results were obtained by saturating carbon dioxide with mercury vapor. The calculated values seem to represent the results as a whole fairly well.

The preceding comparative table (Table VI) gives the smoothed results of various observers, for the most part for every ten degrees. It comprises only the region of the present experiments, with an extension of 450°, to include the boiling point of sulphur and two values by C C R. The values under S & M are calculated from formula R, and those which are extrapolated are in italics. Laby's recalculation took into account all the preceding data, excepting those of Regnault. But it will be seen that, above 340° at least, the errors in the latter are not as great as was at first suspected.

The Boiling Point of Mercury.—As considerable interest attaches to the knowledge of the exact boiling point of mercury at 760 mm., the values found for that point by different observers may be compared.

Regnault made seven measurements close to this point. The mean, when the results are reduced to 760 mm. and to thermodynamic temperature[1] (S b. p. = 445°), and when all are given equal weight, is 357.7°. The average deviation of a single observation from this mean is 1.34°.

Callendar and Griffiths' result with the five best thermometers, giving equal weight to each determination, is 356.74°. The correction to the thermodynamic scale (S b. p. = 445°) is about +0.34°, making the value 357.08°, with an average deviation of the individual observations from this mean of 0.02°. They believe that their absolute temperature measurement is correct ±0.1°. In judging of the probable accuracy of this value it is to be noted that they heated their mercury at the bottom with a small flame. The layer from which the vapor proceeded was therefore under a head of mercury indicated by the scale of their drawing to have been about 53 mm. The vapor was therefore probably superheated, and no mention is made of experiments to ascertain whether lowering or raising the thermometer altered the value of the observed temperature. We should expect, therefore, that their temperature would be, if anything, too high.

The present value, from the formula, is 356.95°, with the absolute temperature measurement believed to be accurate to ±0.1°. The possibility of superheating is here eliminated.

Table of Smoothed Results.—Finally, a table (VII) of the vapor pressures of mercury for every two degrees from 0° to 458°, calculated by formula R, is given. The extrapolated values, below 255° and above 435°, are in italics. The values below 255° probably represent, as we have seen, the somewhat divergent observations as well as would smoothed values made from these observations themselves. Intermediate values may be obtained by linear interpolation:

---

[1] As reduced by Dr Edgar Buckingham, whom we have to thank for a private communication on the subject. His value, 357.1°, was on the scale S b p. = 444.9°, and we have adjusted it to our scale

STUDIES IN VAPOR PRESSURE: V. A DYNAMIC METHOD FOR MEASURING VAPOR PRESSURES, WITH ITS APPLICATION TO BENZENE AND AMMONIUM CHLORIDE.

BY ALEXANDER SMITH AND ALAN W. C. MENZIES.

Received September 10, 1910.

For high vapor pressures, to the measurement of which a vessel closed with a rubber stopper is unsuitable, a modified form of the submerged bulblet apparatus[1] may be used. The new apparatus is less easily constructed, but, when made, has several advantages, for all purposes, over the simpler form. To avoid repetition, we mention only the few points in which the new apparatus differs from the old, and refer the reader for all further description and directions, and for a discussion of the theory and characteristics of the method, to the former papers. This instrument, to distinguish it from the static apparatus described in a preceding paper, will be called the "dynamic isoteniscope."

THE EXPERIMENTAL METHOD.

The Apparatus.—The opening *C* (Fig. 1) is connected with the gage, the exit to the air, and the pressure (or vacuum) bottle and pump.[2] The bulb *B* (diameter 23 mm.) contains the liquid through which the stream of vapor is discharged. The bulblet *A* is made as a separate part and, after being charged with the solid or liquid substance under investigation, is fused on to the side tube at the dotted line. When cut apart carefully at this point, after use, the apparatus may be employed repeatedly. The bulb between *A* and *B* prevents access of the liquid in *B* to the bulb *A*. The total length from *B* to *C* is about 30 cm.

The method of manipulation is the same as that described in connection with the submerged-bulblet vapor pressure apparatus.[3]

Necessary Corrections.—When the apparatus is employed, the usual precautions and corrections in connection with the gage and thermometer are required. Two corrections are peculiar to this apparatus. One is that for immersed depth, measured in this instance from the surface of the liquid in *B* down to the opening of, or the point of ascension in, the capillary.[4] The second is that due to capillary ascension, which increases the pressure beyond that shown by the gage.[5] The amounts of both corrections may be measured together as follows: After the observations are completed, and the bulb *A* has been cut off, the opening

C is connected with a wide tube standing in a beaker of water. The latter tube is raised, drawing its water content with it until the surface of the confining liquid in *B* falls to the point of ascension, or until bubbles issue from the capillary, as the case may require. The elevation of the water above the surface in the open beaker gives the value in water height of the capillary effect plus the submerged-depth effect. This is reduced to mercury height at 0°, and added to the gage pressure, as usual. The interior of the capillary must be wet with the substance just before the measurement is made. As we have seen, the amount of these corrections is small.

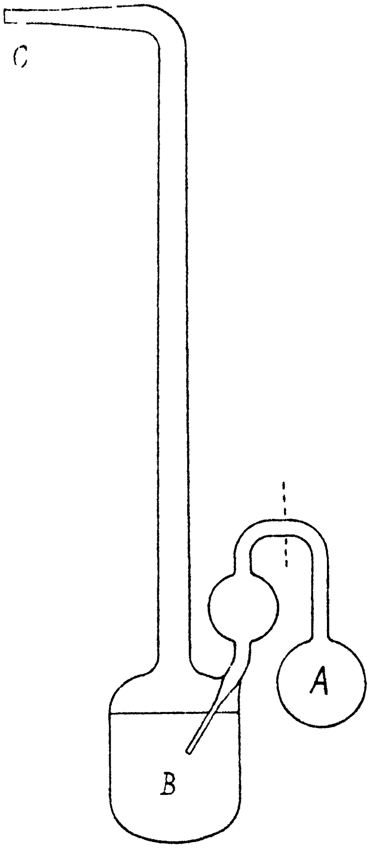

Fig. 1

Characteristics of this Method.—The valuable characteristics of the submerged-bulblet apparatus, which have already been described in full are, of course, retained in this dynamic isoteniscope. This form of the apparatus possesses, however, several additional advantages: (1) It can be used for high pressures as well as low. (2) The test tube in the former apparatus contains a large volume of the confining liquid. This acquires the temperature of the outside bath—and therefore transmits it to the bulb of the thermometer—rather slowly. Here the quantity of the confining liquid is much smaller. Then, too, the thermometer is hung directly in the bath liquid and a slight lag in the temperature of the confining liquid in the bulb *B*, if any existed, would have little or no effect upon the vapor pressure values obtained. This arrangement, therefore, permits the making of measurements of equal accuracy more rapidly. (3) The thermometer is not subjected to varying pressures, and the correction for the dilatation[1] of the bulb when the pressures are below 760 mm. is eliminated. Correction for compression of the bulb, due to the immersion in a liquid, may be made, but the magnitude of this correction is very small, averaging only 0.02° for 10 cm. immersion in water.

---

[1] THIS JOURNAL, 32, 905.

When compared with the static apparatus, this dynamic apparatus will be seen to retain all the characteristics enumerated when that apparatus was described,[1] and to possess several additional advantages: (1) There may be difficulty, with the static apparatus, in finding a suitable confining liquid. This difficulty cannot arise when the substance is a liquid, since the substance is employed in the U-tube to confine its own vapor. But when the substance is a solid, no liquid which has an appreciable vapor pressure of its own at the temperatures concerned, and none which interacts with the substance to give a gaseous product, and none in which the vapor of the substance is soluble, may be employed. Cases, such as those of the ammonium halides, phosphorus pentachloride, etc., therefore arise in which suitable confining fluids for certain ranges of temperature are hard to find. Thus, for ammonium chloride, fused silver chloride might be used, but would be available only above its melting point (450–460°). The present dynamic method is much more flexible, since possession of an appreciable vapor pressure by, or miscibility of the substance with, or chemical activity of the substance toward the confining liquid do not usually interfere with the operation of the apparatus, and would not, save in extreme cases, impair the accuracy of the results. The dynamic isoteniscope is therefore applicable to a wider range of cases.

(2) This dynamic method would find application when results by the static and the dynamic methods are to be compared. Such a case is mentioned, for example, by Smits and Scheffer,[2] who give reasons for anticipating that the values of the dissociation pressures of substances like aldehyde-ammonia might be widely different, according as the one or the other method was used.

This method has one disadvantage when compared with the static method, namely, that, in the latter, no corrections for submerged depth or for capillarity are required. The static method is therefore to be preferred, save where use of the dynamic one is indicated by considerations such as those mentioned in the preceding paragraphs.

The Sample Determinations.—As we have seen, water is at present the only substance suitable for testing the accuracy of a method of measing vapor pressures. The determinations with this substance, using the simple form of the submerged bulblet, have already shown, however, that an apparatus operating on this principle is capable of yielding results of a high order of accuracy. The present form of the apparatus was applied, therefore, to the measurement of the vapor pressures of benzene and of ammonium chloride.

The bath, stirrer, barometer, gage, and platinum resistance thermometer, and the corrections involved in their use, were the same as those employed in the work with the static isoteniscope.[1] It is sufficient here to say that the temperatures are on the thermodynamic scale, assuming the boiling point of sulphur to be 445°, and that the error below 120° (benzene) was ascertained to be less than ±0.01° and above 120° (ammonium chloride) less than ±0.1°.

THE VAPOR PRESSURES OF BENZENE.

Determinations by Previous Observers.—The sample used by Regnault[2] melted at 4.45°, nearly a degree too low, and must have been impure. He employed the dynamic method above 24°. Ramsay and Young[3] removed thiophene and otherwise purified their sample, but do not give the melting point. They used their dynamic method[4] (up to 80°), in which the liquid trickled onto cotton surrounding the bulb of the thermometer. In this instance they state that correction was made for the dilatation of the bulb of the latter *in vacuo*. Young[5] continued the series above 80° by the barometer-static method[6] over mercury, using a part of the original material, and giving temperatures on the scale of the constant-volume air thermometer. Neubeck[7] used purified benzene boiling at 79.9° at 760 mm. The freezing point is not given. He boiled the substance in a flask under reduced pressure. His thermometer was compared with an air thermometer, but he did not correct for dilatation of the bulb *in vacuo*. The values given below are obtained by graphic interpolation from his data. Mangold[8] used benzene from benzoic acid. He gives the melting point 5.5°. He used Schmidt's[9] dynamic apparatus and did not correct for dilatation of the thermometer bulb *in vacuo*. Kahlbaum[10] purified his benzene, but gives no melting point. He determined the boiling points under reduced pressure, admitting air through a capillary, and did not correct for dilatation of the thermometer bulb. Woringer[11] gives no melting point of his purified benzene. He used the static method, over mercury, admitting the substance through a stopcock, but gives no facts in regard to exclusion of dissolved gases. The results found by these six observers are tabulated along with our own below.

Purification of the Benzene.—Kahlbaum's "thiophenfrei," crystallizable benzene was used. It was boiled under reflux with much sodium for three hours, at the end of which time no trace of hydrogen evolution could be detected. It was distilled, and the middle portion of the distillate, amounting to 1.46 liters, was used. This came over, after correction of the temperatures for changes in the barometric pressure, within 0.01°. A portion used for a freezing-point determination was boiled for fifteen minutes to remove dissolved gases. The freezing point was taken by two thermometers, the ice points of which had been ascertained immediately before, and they agreed in giving the value +5.40°.

The physical properties of benzene have been carefully investigated by Lackowitz,[1] who found that they were greatly affected by dissolved air. He showed, for example, that the removal of dissolved air, not considered by previous observers, produced a marked lowering in the specific gravity. His freezing point was 5.42 ± 0 02°. The lower freezing points of previous observers, namely, Regnault 4 45°, Jungfleisch 3 00°, W. Fischer 5.3, and Schoop 5.04, undoubtedly indicate insufficient purification. Linebarger[2] found 5 4° and Mangold 5 5°. Only Flink[3] claims to have reached 6.06°.

It appears, therefore, that our sample was probably as pure as that of Lackowitz. Even if we ignore the possibility, which he admits, that his freezing point may have been 0.02° too high, and assume that ours was lower than his by the same amount, the proportion of impurity which this represents would not noticeably affect the accuracy of the results. At the boiling point (about 80°) it would give an elevation of only 0 01° and lower the vapor pressure by only 0 2 mm. This is the maximum effect reached by assuming that the whole of the supposed impurity was involatil, for our method provides for the removal of dissolved gases during the measurement.

The Vapor Pressures of Benzene.—Concentrated sulphuric acid was used as confining liquid in the bulb *B*. Since benzene vapor is soluble in this liquid, the reading was taken when the liquid had ascended the capillary to a fixed mark. Correction was made for submerged depth and for capillarity. The values obtained were as follows:

T..	63 16	66.55	71 09	74 79	80.30	90.48	95.67	100.42	105.97	111.54	119 93
P..	439 1	492.0	563.7	640.8	765 5	1031	1197	1364	1581	1820	2235

The observed pressures were plotted against the temperatures, a smooth curve was drawn through the resulting points, and the value of the pressure every 5° was read off. The results are given in the following table: For comparison, the corresponding values of Regnault (Rg), Ramsay and Young and Young (Y), Neubeck (N), Mangold (M), Kahlbaum (K), and Woringer (W) are given. The essential details of their methods have been discussed already.

THE VAPOR PRESSURES OF AMMONIUM CHLORIDE.

In order further to test the value of the dynamic isoteniscope method of measuring vapor pressures, we sought some substance difficult of study by the older methods. A non-fusing solid, the vapor of which attacked mercury, was required. That comparison might be possible, it was desirable also that the vapor pressures of the substance should have been previously determined by more than one observer and using methods professing some degree of accuracy. Ammonium chloride seemed to be the only such substance. Even with the present exceedingly adaptable method, this salt presented a problem of exceptional difficulty, and the results cannot claim the same degree of accuracy as do those with water and benzene. It will appear, however, that even in this case the limits of accuracy can be stated, and that the results are free from the undefined, and undoubtedly considerable sources of error with which the previous determinations may be charged.

Previous Determinations.—The vapor pressures of this salt have been determined by Horstmann,[1] by Ramsay and Young,[2] and by F. M. G. Johnson.[3] Horstmann's method was a dynamic one. He heated ammonium chloride in a combustion tube and noted the readings of a mercury thermometer immersed in the vapor, while the pressure of the air in the tube rose by stages from about 10 mm. to 760 mm.

Ramsay and Young made a large number of observations by several methods. One series from 98° to 280° was obtained statically over mercury in a barometer tube. Some permanent gas accumulated during the observations, and the value at the highest of these temperatures, for example, may be in doubt on this account alone about 0.5° (or 4.5 mm. = 3 per cent. of the whole). Observations from 290° to 340° were secured by enclosing a lump of the salt above a constriction in the closed limb of a U-tube. The bend was filled with mercury, and air pressures of known value could be applied to the vapor of the metal through the open limb. The U-tube was heated by the vapor of mercury boiling under various known pressures, and the corresponding temperatures were taken from Regnault's data, with an error, therefore, of 1° at 340°. Foreign gases and vapors were expelled by lowering the pressure, and allowing the vapor of the salt to escape past the mercury in the U-tube. At 320° and 340° the vapor pressure of the ammonium chloride did not give a constant value, but increased continuously. At 320° this increase was a linear function of the time, but the rate of increase per minute varied in different experiments from 0.2 mm. to 1 mm. per minute. The increase was under observation for as long as 390 minutes in one instance. With the help of time curves, the observations were corrected. This increase is attributed by the authors to the liberation of hydrogen by chemical action of the hydrogen chloride on the mercury. At 340° there was always a very rapid rise in pressure, amounting to from 32 to 67 mm., during the first twenty minutes, before the slower, uniform rise (of from 0.2 to 1 mm. per minute) set in. The authors suggest that the salt was cooled by the immediately preceding, rapid vaporization, and during the twenty minutes was regaining the temperature of the vapor bath. But this effect should have been almost as great at 320°, where no rapid rise was observed. In explaining both of these increases in pressure, the authors ignore entirely the effect of diffusion of the mercury vapor backwards to the surface of the salt. The result of this diffusion must be to increase the pressure and, if complete interdiffusion of the vapors had occurred, the limit would have been reached only when the total pressure equaled the sum of the vapor pressures of ammonium chloride and mercury. The evident fact is that when the confining liquid has a considerable vapor pressure of its own, and the interdiffusion of the vapors is possible during the observation, the resulting measurements of vapor pressure must always be of uncertain value. When we consider the fact that here the vapor pressure of the confining liquid, although less than that of the substance, was of the same order (at 320°, the pressures are 369 mm. and 445 mm., and at 340°, 548 mm. and 760 mm., respectively), it is surprising that the readings could be utilized at all.

The same observers made an independent series of measurements by their dynamic method, described in an earlier paper.[1] Here a block of the salt surrounded the thermometer bulb, and the distilling vessel containing the thermometer was heated by means of boiling mercury. The observations were made from 178.5° to 338.9°. The results, when plotted, were found to be somewhat scattered, and all on one side of the rather smooth curve that could be drawn through the points determind by the static method. The pressures at corresponding temperatures are all higher, being at 320° on an average about 56 mm. higher (estimated graphically), at 330° about 80 mm. higher, and at 333.5° about 100 mm. higher. The results by the static and dynamic methods, separately, as well as the values finally adopted, are given in a table at the close of this paper. A supplementary observation by a different dynamic method, in which the mass of the salt surrounding the thermometer bulb was placed in a combustion tube and heated with a Bunsen burner, gave a value at 338.35° of 762.1 mm. This confirmed the results by the static method rather than those by the dynamic, being less than 2° (equivalent to about 35 mm.) below the static temperature at the same pressure, while the dynamic temperature at the same pressure was 6° below static. Hence, the dynamic results were considered to be the less trustworthy, and in the curve which embodies the final results, much greater weight is given the static results. The final data are therefore essentially derived from a static method. The authors state that the difference of less than 2° above mentioned "may well be due to error of experiment." The results at the highest temperature are thus estimated to be subject to an error of at least ±2°, or, according to their curve, ±35 mm. Considering the extreme experimental difficulties involved in the method, this error cannot be considered excessive. The specific sources of error in these methods have already been discussed at length.[2]

F. M. G. Johnson employed the Ladenburg manometer, consisting of a flattened glass tube, wound in a spiral. The external pressure required to bring the attached mirror back to the zero position was measured. His method was therefore static, but he avoided the great difficulties connected with the common static methods in which mercury is used. Assuming that, as the author says, the spiral was capable easily of showing a pressure change of "the order of 1 mm." (although he does not state that this degree of sensitiveness was maintained at 335°), the chief errors to which his method was liable arise from four causes, namely, gases ocoluded in or absorbed by the solid substance, unequal distribution of temperature in the air bath he used for heating, the untrustworthiness of mercury thermometers at such high temperatures, and the unfortunate method used for standardizing the thermometers. The efficiency of the whole arrangement was, indeed, tested by a determination of the vapor pressures of iodine, and the results were found to agree well with those of Ramsay and Young. But the test ranged from 80.5° to only 178.5°, while the experiments with ammonium chloride ran from 211° to 335°. The temperature errors would not assert themselves strongly until above 200°, so that this test cannot be accepted as a rigid demonstration of the adequacy of the precautions. Attention must therefore be drawn to the sources of error individually.

[2] This series, No. III, Secs. 1 and 2, THIS JOURNAL, 32, 1413–9.

The apparatus and material were freed thoroughly from moisture by means of phosphorus pentoxide, and to effect this the former was pumped out repeatedly and left evacuated for a long period. The apparatus was heated during the process, for the purpose of assisting the desiccation and of driving out adhering air. But the parts containing the pentoxide and the salt could not be heated. The salt had previously been sublimed twice. It will be seen, however, that the complete expulsion of adhering gases was not insured. The quartz spiral gage used by Preuner and Schupp[1] is so constructed as to permit of boiling out before sealing, when vapor pressures are to be determined. But this process could not be applied when, as was the case with Johnson's apparatus, a bulb for the simultaneous determination of the vapor density was attached. It is a pity that the zero of the gage was not redetermind after the experiments, as this would not only have shown whether any permanent gas had been liberated, but would also have afforded a means of detecting other irregularities, such as a permanent distortion of the spiral.

Johnson's apparatus was heated in an unstirred air bath provided with a gas pressure regulator which kept the temperature constant ± 1°. As we have seen,[2] however, an air bath is by far the least satisfactory means of keeping the temperature uniform and constant. Aside from the inherent causes of defective thermal equilibrium, in this case a copper tube was inserted through the top of the bath, forming a separate compartment surrounding the pocket containing the solid ammonium chloride. The purpose of this was to keep the salt cooler than the bulb and spiral. The temperatures in the copper tube and in the rest of the bath differed by 22° at 323°. Now, if maintaining *one* temperature in an air bath is difficult, keeping *two* temperatures each constant and uniform is much more difficult. This feature of the apparatus, therefore, involves a source of considerable uncertainty.

The temperatures were ascertained with a nitrogen-filled, mercury thermometer. It is well known, however, that such a thermometer, when kept for a considerable time at a high temperature, suffers distillation of the mercury into the upper part of the bore,[1] and gives untrustworthy readings, with an error of about ±1°. On account of the difficulty in making due correction, the error is greater when the thread is not completely immersed.

[2] This series, No. III, Sec. 1, THIS JOURNAL, 32, 1413.

Finally Johnson standardized the thermometer by using the vapor pressure curve of mercury. The data used were those of Ramsay and Young.[2] Young,[3] however, has himself pointed out and corrected some of the most serious inaccuracies which have meantime come to light in these data. His corrections alter the temperature at 340° by 1°.

The present status of our knowledge of the vapor pressures of ammonium chloride may now be summed up. Horstmann makes no professions of exact thermometry and ±5° at the highest temperature is a conservative estimate of the limits of error involved. The known error of Ramsay and Young's measurements is ±1° at the lower temperatures and ±2° at the highest. But the uncertainty of interpreting the progressive increase in the pressures at 320° and 340° introduces an additional possibility of error, the magnitude of which cannot be assessed. Johnson's measurements are affected by such considerable temperature errors, the most serious of which are of unknown magnitude, that his measurements can be regarded as approximate only. In considering all these determinations, it must be remembered that, at 335°, an error of ±1° corresponds to an error of ±15 mm. in pressure. It is therefore evident that the vapor pressures of ammonium chloride are in need of re-determination by a method which permits of the definite estimation of the limits of error involved.

The Vapor Pressures of Ammonium Chloride.—The bulb *A* (outside diameter 22 mm.) was filled completely with ammonium chloride. The latter, Kahlbaum's purest form of the salt, was finely pulverized and was purposely used without drying. Since the method itself involves a fractionation, special treatment to remove volatil impurities was unnecesssary. Hydrochlorides of coal-tar bases were proved to be absent.

The bath was filled with the mixture of potassium and sodium nitrates, and, no other transparent, fusible substance of a suitable nature being available, the outer bulb *B* was charged with the same mixture. The ammonium chloride vapor, in passing through this liquid, caused a continuous production of nitrous oxide. The method was therefore seen under the greatest disadvantage, since it was impossible to observe a complete cessation of the stream of vapor. The pressure taken was that at which the stream of gas reached a minimum volume.

---

[1] Ostwald-Luther, *Physikochem Mess*, [1902] 78. In such a thermometer we have frequently observed with a lens droplets of mercury and particles of a red substance (HgO?) accumulating above the thread.

[2] *J. Chem. Soc.*, 49, 37 (1886). We are indebted to the author for privately informing us of this fact.

[3] *J. Chem. Soc.*, 59, 629 (1891).

Our temperature error of less than ±0.1° corresponds at the lowest temperature to ±0.25 mm. and at the highest to ±1.5 mm. These are therefore the limits of error of the apparatus *per se.* The difficulty in observing the point of minimum gas evolution, however, introduces a special source of error peculiar to this substance. From a consideration of the degree of sharpness with which the observations could be made, we estimate this error at about ±5 mm. in the individual readings. The consistency of our results, as shown by the way in which they lie upon a smooth pressure-temperature curve, confirms our belief that the errors are not greater than this.

The following results are corrected for immersed depth and for capillarity, and are given to the nearest millimeter:

Temperature........	278.3	291.6	298.7	308.5	316.4	325.4	332.9
Pressure............	131	199	240	322	406	518	633

For comparison, the data of Horstmann (two points, ×), Ramsay and Young[1] (curve I), Johnson, undried substance[2] (curve II), and Smith and Menzies (curve III), are plotted in Fig. 2. It will be seen that the last curve lies between the other two.

The following table contains the data read from the various curves. As throwing some light on the relative trustworthiness of Ramsay and Young's static and dynamic methods, as applied to a substance like this, the observations obtained by each of these have been treated separately and the resulting pressure readings are given in two additional columns:

		R & Y.				
			Observations.			
t.	H.	Curve.	Static.	Dynamic.	J.	S & M.
280	...	143	140.5	147	132	138
290	...	195.5	189	200	178	189
300	259.5	264.5	251	275	237	252
310	...	350	333.5	367	309	336
320	...	460.5	443.5	500	401	447
330	...	599.5	596	675	518	587
333.5	...	661	653	750	566	642
340	778.1	777	759.5	...	678	...

From this comparison it will be seen that Ramsay and Young's static results, when taken by themselves, agrees remarkably well with our dynamic results, the divergencies exceeding the estimated error of our measurements, namely ±5 mm., only above 320°. The inferiority of their

---

[1] Reproduction of the author's own curve. Johnson ignores the curve, which embodies the authors' conclusions from all their observations, and uses for comparison only certain of the single observations, all taken from the static series.

[2] Dr. Johnson informs us that in his first paper (p. 462), the last temperature, 335°, should be 345°. In the curve on the opposite page, the 211° point is misplaced. In the second paper (p. 37), the NH_4Cl curve is incorrect.

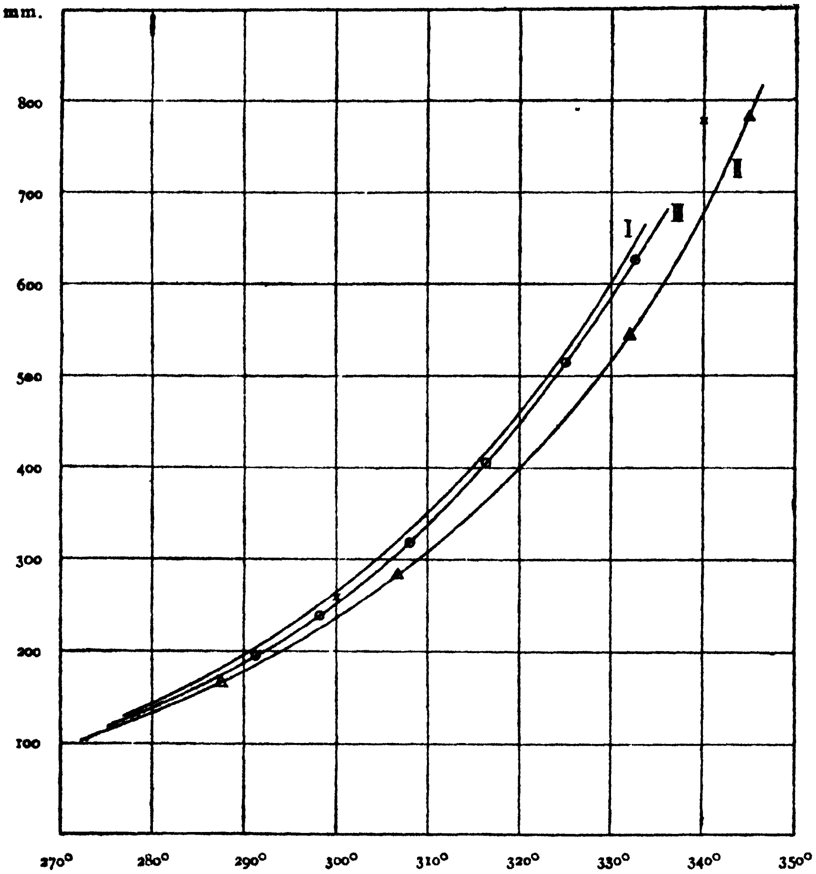

Fig. 2.

dynamic method, at least when applied to a substance like this, is apparent.

THE POTENTIAL OF THE SODIUM ELECTRODE.

BY GILBERT N. LEWIS AND CHARLES A. KRAUS.

Received October 3, 1910.

The electrode potentials of a number of important groups of metals have not been measured hitherto, because their action upon water is such as to preclude the possibility of obtaining equilibrium conditions. Among these groups, those comprising the alkali metals and the metals of the alkaline earths are the most notable examples. In the present paper we shall describe a method which may be employed in the determination of electrode potentials of this kind. We shall show, moreover, that this method permits the determination of the potential of the sodium electrode with a higher degree of precision than has yet been reached in the case of any other solid electrode.

Our problem, consisting in the determination of the potential of metallic sodium against an aqueous solution of sodium ion of normal concentration, can evidently be solved only by indirect means. We have found it possible with certain precautions to measure the potential of a dilute sodium amalgam directly against an aqueous solution. It only remained, therefore, to find the difference between this potential and that of pure sodium. This difference in potential measured in any cell where the only process which accompanies the current is a transfer of sodium from the pure state to the dilute amalgam, must be independent of the nature of the electrolyte used. We succeeded in measuring this difference in potential in a cell containing sodium and sodium amalgam electrodes, and an electrolyte composed of a solution of sodium iodide in liquid ethyl amine.

The Electrode Potential of Dilute Sodium Amalgam.

The dilute sodium amalgam used throughout this investigation was prepared and preserved in the apparatus shown in Fig. 1. A bulb, E, is connected by means of a small capillary, F (having a uniform bore of about 0.2 mm.), with a straight tube, GK. While this tube is open at K, a piece of metallic sodium (Kahlbaum) is cut from a larger piece, quickly rolled into cylindrical form and placed in the tube at G. A small glass rod, H, is placed immediately above to serve as a weight in the operation about to be described. The tube is then sealed at K and the apparatus exhausted at A through the 3-way cock B, the cock J being closed and the cock I open. When the apparatus is completely exhausted I is closed and J, which communicated with a reservoir of ammonia (not shown in the figure), is opened for an instant, thus filling the tube IJ with pure ammonia gas. The tubes F and G, and the lower part of E are now surrounded by a paraffin bath and heated gradually to the melting point of sodium. When this point is reached, and the liquid sodium, pressed by the glass weight above, breaks its thin shell of oxide, the cock I is opened cautiously and the pressure of the ammonia slowly forces the molten sodium into the bulb E. The sodium is thus filtered by the small capillary from every trace of oxide or other solid impurity and appears as a bright metallic globule. The paraffin bath is now removed and the capillary is sealed off at F, the left-hand portion of the apparatus being thus removed. After the exhaustion has been continued to remove all of the ammonia gas, pure mercury is allowed to enter the bulb D at C (from an apparatus not shown in the figure) and the tube C is sealed off. B is closed. The lower part of the apparatus, comprising the bulbs E and D and the connecting tube, is then warmed in a paraffin bath to 180° centigrade. The mercury vapor passing slowly from D to E amalgamates quietly with the sodium. When the latter is completely amalgamated, the apparatus is allowed to cool. It is then shaken to provide for thorough mixing of the contents and clamped in an inverted position. It may now be sealed at A to any apparatus in which the sodium amalgam is desired and the filling carried out *in vacuo*. The 3-way cock B merely serves to facilitate the cleaning of the tube A after such a filling.

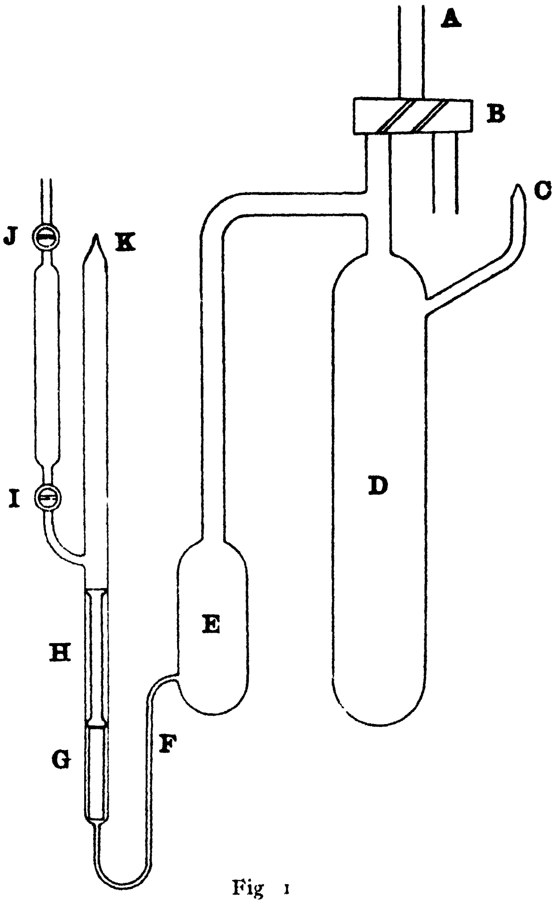

Fig 1

The amalgam so prepared and kept does not differ in appearance from pure mercury, and remains unchanged for years.

Two portions of the sodium amalgam were treated with standard hydrochloric acid until the sodium was removed, and the remaining acid was titrated with standard alkali. According to these two analyses (which agree within less than 0.1 per cent.) 100 grams of amalgam contained 0.2062 gram of sodium.

In determining the potential of this amalgam against fifth normal sodium hydroxide, a portion of the amalgam was introduced into the reservoir sketched in Fig. 2. This reservoir was sealed to the apparatus of Fig. 1 (at the points Q and A) and after complete exhaustion the amalgam was allowed to enter through the cock B. The reservoir was then sealed at Q. The side tube L contained phosphorus pentoxide and per-melted the entrance of dry air to take the place of amalgam drawn off through M. The amalgam surface at P formed the electrode and electrical contact was provided through a platinum wire sealed in at N. The tube OP was inserted in a half-cell of the usual type, filled with 0.2 *N* NaOH, and was joined thereto by a rubber stopper, O. This half-cell dipped into another containing 0.2 *N* NaCl, which in turn communicated with 0.2 *N* KCl and finally with a normal calomel electrode. The whole system was placed in a thermostat at 25°.

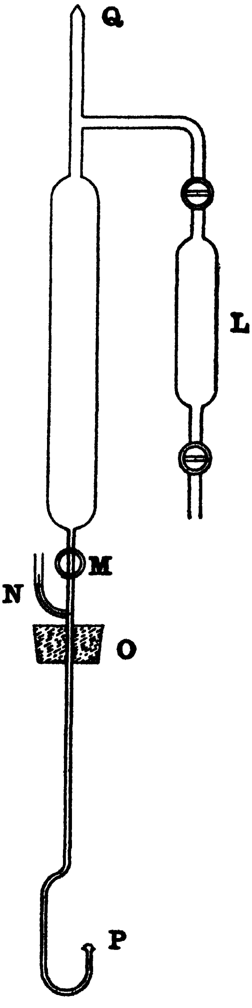

Fig. 2.

The amalgam surface at P when first placed in the sodium hydroxide evolved considerable hydrogen. The action appeared to take place at certain spots where a few extremely minute solid particles accumulated. The extraordinary influence of small amounts of catalyzers in this action of sodium amalgam upon water has already been pointed out.[1] Fortunately it was found that by opening the cock M and allowing one or two drops of amalgam to flow out at P, the minute particles that seemed responsible for the action were carried down. The new surface was acted upon less vigorously, and after this process had been repeated a number of times the surface remained clear of hydrogen for ten to twenty minutes, and showed a constant and perfectly reproducible potential within 0.1 millivolt.

The measured electromotive force was then 2.1749 volts,[2] inclusive of liquid potentials, for the combination, Na amalgam (0.206 per cent.); NaOH 0.2 *N*; NaCl 0.2 *N*; KCl 0.2 *N*; KCl *N*; normal electrode (N. E.).

The liquid potential between KCl *N* and KCl 0.2 *N* is negligible. That between NaOH 0.2 *N* and NaCl 0.2 *N* is 0.0287 v.; that between NaCl 0.2 *N* and KCl 0.2 *N* is 0.0050 v.[3]. Both these potentials oppose the main

---

[1] Walker and Patterson, *Trans. Am. Electrochem. Soc.*, 3, 185 (1903); Lewis and Jackson, *Proc. Am. Acad.*, 41, 403 (1906).

[2] This experiment was repeated with the same amalgam nearly two years later and gave the electromotive force 2.1742 volts. Considering the possible change in the composition of the amalgam and the use of different electrical standards, this may be regarded as a satisfactory check.

[3] Lewis and Sargent, This Journal, 31, 363 (1909).

e. m. f. of the cell. Adding these figures, therefore, to the measured e. m. f. we obtain for the above cell, exclusive of liquid potentials,

Na amalg. (0.206 per cent.), NaOH 0.2 *N*, N. E.; E. = 2.1986 v.

In order to calculate now the potential of this amalgam against sodium ion at normal concentration, it is necessary to know the degree of dissociation of fifth normal sodium hydroxide. Instead of calculating this directly from conductivities, we shall assume provisionally, for reasons that will be explained in another place, that the degree of dissociation of 0.2 *N* NaOH is the same as that of 0.2 *N* KCl, and that the latter is 82.8 per cent., as found from conductivities. If now we apply the Nernst equation, we find

Na amalg. (0.206 per cent.), Na^+N, NaOH 0.2 *N*, Na amalg. (0.206 per cent.); E = 0.0461 v.

Combining this equation with that given above we find

Na amalg. (0.206 per cent.), Na^+N, N. E.; E = 2.1525 v.

The Difference in Electrode Potential between Sodium and Dilute Sodium Amalgam.

The difference in electrode potential between sodium and a sodium amalgam in the same electrolyte will be independent of the nature of that electrolyte, provided it is one in which the metal and the amalgam act as completely reversible electrodes. Our problem consisted, therefore, in finding a solvent which is not attacked by sodium, and which dissolves some sodium salt to form a conducting solution. Ethyl amine was finally chosen as the solvent, and attempts were made first to use sodium chloride and sodium bromide as solutes, but neither of these substances proved to be sufficiently soluble to give the solution the desired conductivity. Sodium iodide, however, proved to be extremely soluble and its solution is an excellent conductor.

Anhydrous ethyl amine was prepared and kept for use in the following way. About 200 cc. of Kahlbaum's ethyl amine were treated for several days with metallic lithium, the solubility of which in the amine makes it especially efficient in removing water and other objectionable impurities. The liquid was then distilled into a vessel shown in Fig. 3.

The volatility of ethyl amine, and its great solvent power for such substances as are commonly used for stopcock lubricants, prevents its storage in an apparatus closed with ordinary stopcocks. For this reason a special form of valve, shown in Fig. 3, was designed. The ethyl amine is stored in tube A. In the position of the apparatus shown in the figure, its vapor may pass freely out through B, C, and the cock D. The lower part of the valve HGF contains mercury. The glass plunger I is rigidly connected with an iron rod, J, encased in a sealed glass tube. By means of a magnetic helix placed around J, this plunger may be raised or lowered. If lowered it causes the mercury on the right-hand side to rise and lift a glass float, E, which is ground to fit the conical end of the tube C. The mercury rises above this joint, tightly sealing the exit tube C. If the cock G is now closed the helix may be removed and the apparatus remains sealed until it is desired to withdraw more amine from the reservoir, when the plunger is once more raised and the valve opened. The cock D prevents the entrance of air into the reservoir when the vapor pressure of the amine falls below atmospheric pressure.

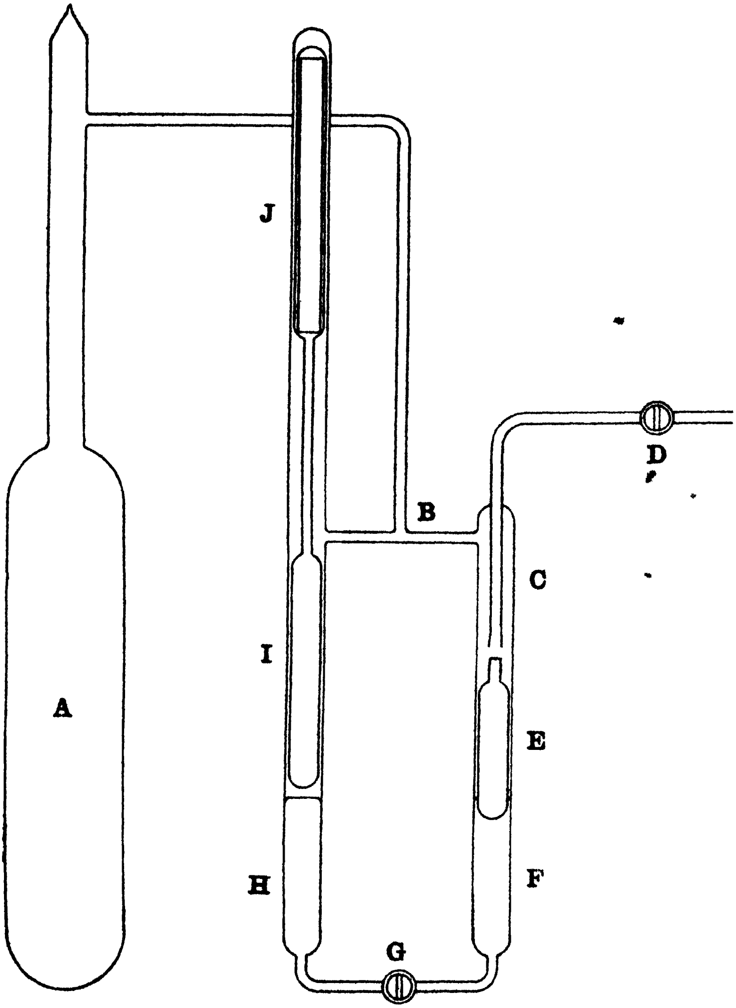

Fig. 3.

The cell in which the measurements were made is shown in Fig. 4. Two platinum wires are led to the electrodes through the tubes K and L. The capillary P is connected with the device for introducing metallic sodium, which we have already described. The tube Q is sealed to the ethyl amine reservoir, the tube S to a vacuum pump, and the tube N to the amalgam reservoir. A suitable amount of dry sodium iodide is introduced through the tube M which is then sealed off. The apparatus is thoroughly exhausted, sodium is introduced at P by the method already described, and the tube P is sealed off. The apparatus is further exhausted, the amalgam is allowed to enter through the tube N which is then sealed off. The connection to the pump is then sealed off at S. Finally the cell is cooled in ice, and the valve of the amine reservoir being opened, the amine is allowed to distil in until it rises above the connecting tube R. The tube Q being now sealed off, the cell is entirely free and its contents may be thoroughly stirred by slowly tipping from one side to the other. The bulge in the cell at O prevents any amalgam from reaching the sodium electrode in this process. The platinum terminals are completely covered, one by amalgam and the other by metallic sodium.

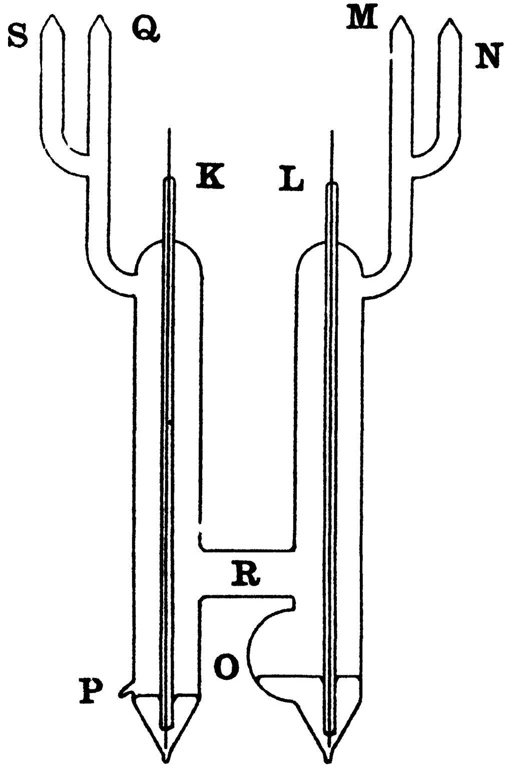

Fig. 4

In the first cell that was set up, the sodium surface became coated with a substance that we assumed to be sodium hydroxide. The cell gave, however, a very constant electromotive force of 0.8457 v. at 25°. The coating we attributed to the presence of a trace of water in the sodium iodide, which, though it had been heated and dried, was in the form of powder and might have taken up some water while being introduced. The cell was therefore refilled, using sodium iodide which had previously been fused. This time the sodium surface was perfectly clean and remained so after the cell had stood many days.[1]

This cell gave immediately after its preparation a constant electromotive force which did not change during a number of days, in which measurements were made. Differences of 0.1 to 0.2 millivolt occasionally were found but disappeared when the contents of the cell were stirred. The electromotive force at 25° was 0.8456 v., which is only 0.1 millivolt different from that found above in the cell with the coated sodium surface. Another cell filled in the same way, containing a relatively small amount of sodium iodide, also gave 0.8456 v. A good idea of the constancy of the cell may be obtained from the following measurements made to determine the temperature coefficient of the electromotive force. The cell was changed back and forth from a thermostat at 10° to one at 35°. The electromotive force at 10° was about 1 millivolt higher than at 35°, the successive differences measured being 0.00100, 0.00093, 0.00091, 0.00100, 0.00101, 0.00102, 0.00103, 0.00103, 0.00102, the last six differences were constant within 0.00003 volt and we may take $0.00102 \div 25 = 0.0000408$ as the diminution in electromotive force per degree rise of temperature. It is evident that the cell exhibits a higher degree of constancy and reproducibility than any cell having an electrode of solid metal which has hitherto been studied. The electromotive force of such cells usually varies very greatly, owing to surface changes in the metal. It was perhaps to be predicted that in the case of so soft a metal as sodium, such variations would not appear.

The Potential of the Sodium Electrode; the Heat of Solution of Sodium in Mercury.

In order to determine finally the electrode potential of sodium against a normal solution of sodium ion, it is only necessary to add the difference between the potentials of sodium and sodium amalgam to the electrode potential of the amalgam obtained above. This gives

$$\text{Na, Na}^{+}N\text{, N. E.; E} = 0.8456 + 2.1525 = 2.9981 \text{ v.}$$

On account of some slight uncertainty as to the electrical standards used, this final value of the potential of sodium may be in error by nearly 1 millivolt.

Wilsmore[2] in his valuable critique on electrode potentials calculated the potentials of some of the metals which decompose water from the heats of formation of their salts, according to Thomson's rule. He calculated for the sodium electrode the potential of 3.10 v. against the calomel electrode, a value differing from ours by 102 millivolts.

---

[1] In the course of a few weeks a very thin black coating appeared on the metal surface and after two years' standing a considerable portion of the sodium has disappeared.

[2] *Z. physik. Chem.*, 35, 291 (1901).

The temperature coefficient of the cell with sodium and sodium amalgam electrodes permits a remarkably accurate calculation of the heat of solution of sodium in a 0.206 per cent. sodium amalgam. We may use the equation of Helmholtz

$$E - \frac{Q}{F} = T\frac{dE}{dT},$$

where Q is the heat evolved in the solution of one equivalent of sodium in a very large quantity of 0.206 per cent. amalgam. F is the Faraday equivalent, 96580 coulombs. Substituting 0.8456 for E, and —0.0000408 for dE/dT, we find $Q = 82850$ joules or, if one calorie is equal to 4.186 joules, $Q = 19790$ calories. Were it not for some uncertainty as to the exact value of the factor to be used in passing from volts to calories, the above value of Q would be reliable within 2 or 3 calories. Berthelot found by calorimetric methods the heat of solution of sodium to form a 0.5 per cent. amalgam equal to 18800 calories. The difference between this value and ours is probably to be attributed to the heat of dilution of the amalgam from 0.5 to 0.2 per cent.

The method of handling an amalgam of an oxidizable metal, which we have described, may be of use in other lines of investigation than the present one, especially in the determination of the electromotive force of amalgam concentration cells. For this purpose the amalgams might be compared with one another in aqueous solutions by means of the apparatus of Fig. 2, but in many cases it will be preferable to work in amine solutions where the oxidation of the amalgam may be completely avoided. It is not, however, our intention to prosecute this line of research, but rather to investigate in the immediate future the electrode potential of other metals of the alkalies and alkaline earths by the method which we have found so successful in determining the potential of sodium.

In conclusion, we wish to express our indebtedness to the Bache fund of the National Academy for a grant which enabled us to carry out this investigation.

Summary.

The potential of sodium in a normal solution of sodium ion at 25° is found to be 2.9981 volts against the normal calomel electrode taken as 0.

This is the sum of two values (1) 2.1525 volts, the potential of 0.206 per cent. sodium amalgam against normal sodium ion and (2) 0.8456 volts, the difference in potential between sodium and 0.206 per cent. sodium amalgam, in a solution of sodium iodide in ethyl amine.

The temperature coefficient of the latter electromotive force is —0.0000408 volt per degree. Hence, from the Helmholtz equation, the heat evolved when one equivalent of sodium dissolves in a large quantity of 0.206 per cent. sodium amalgam is 19790 calories.

Methods are described for preparing and keeping pure sodium amalgam and anhydrous ethyl amine, and of measuring the true potential of the amalgam of an oxidizable metal in aqueous solution.

THE ELECTROLYTIC DETERMINATION OF CHLORINE IN HYDROCHLORIC ACID WITH THE USE OF A SILVER ANODE AND A MERCURY CATHODE.

BY JACOB S. GOLDBAUM AND EDGAR F SMITH

Received July 23, 1910.

With the introduction of the silver anode and mercury cathode, many new and interesting determinations and separations have been effected. Much attention has been paid in this laboratory to this phase of electroanalysis, and exact and satisfactory results have been obtained.[1]

Recently there appeared an article by Gooch and Read[2] on the "Electrolytic Determination of Chlorine in Hydrochloric Acid, with the Use of the Silver Anode." From this communication it would seem that upon extending the analysis of chlorides, in neutral aqueous solution, to the determination of chlorine in free hydrochloric acid, the method as presented in previous communications from this Laboratory yields values which are "very irregular and always low." It is, therefore, proper to consider the question raised by Gooch and Read, and to submit additional evidence, together with some of the details of procedure.

Experiments were made with hydrochloric acid precisely as described by Gooch and Read, and behaviors similar to those noted by these chemists were observed; that is, the electrolysis resulted, not only in the fixation of chlorine at the anode and the liberation of hydrogen at the cathode, but also in a secondary decomposition, which gave rise to the production of hypochlorites. As a consequence, some of the silver of the anode dissolved in the electrolyte, and at times appeared at the cathode. The fixation of the oxygen at the anode was likewise observed and, indeed, when this oxygen was driven off, low and non-concordant results were obtained. Now, in these experiments a platinum cathode was employed and with the exception of a single determination, the experiments performed by Gooch and Read were with a platinum cathode, whereas, in all the work done in this laboratory on the fixation of anions, a mercury cathode has been employed. Indeed, Gooch and Read were really not using "similar means," and the criticism of the original method because of the failure of an altered arrangement is hardly fair. Hence, it is only natural that we should try the effect of a silver anode and mercury cathode in the analysis of hydrochloric acid, and to this end, experiments were accordingly conducted.

[1] THIS JOURNAL, 29, 447, 1445, 1455, 1460; *Ibid.*, 30, 1706.

[2] *Am. J. Sci.*, 544 (1909).

The platinum gauze anode was plated with silver from a potassium silver cyanide electrolyte. It is true, as stated in the article by Gooch and Read, that there is a possibility of the retention of some soluble cyanide in the gauze, even after the plated anode has been treated with boiled water, and subsequently ignited gently. We have been aware of this fact, however, for several years, and while making no mention of it, have succeeded in obviating the difficulty by dipping the freshly plated silver gauze in dilute hydrochloric acid, washing it thoroughly with distilled water, and then igniting it to incipient redness in a low Bunsen flame. By this means, any admixed cyanide is destroyed. The solution undergoing analysis could not then become contaminated by material derived from the plating bath. Care should be taken not to ignite the anode too strongly in the Bunsen flame, as it is most desirable that the silver should not fuse, and that its porous nature should be preserved. A complete retention of the chlorine is favored by these means, whereas with a smooth silver surface there is a possibility that molecular chlorine may be liberated, with a consequent production of hypochlorites and chlorates.

Another fact, known to us for some time, is the secondary formation of oxide upon the anode along with the halide. To obviate its disturbing effect upon the weight of the anode, we have had recourse to a home-made electric oven heated to 300°. Silver oxide is completely decomposed at 250°, giving off oxygen and leaving metallic silver, so that at the end of an electrolysis the anode is at once placed in an oven with the temperature mentioned for a period of ten or fifteen minutes, when nothing will remain but silver and silver chloride, so that the increase in weight of the anode would represent only the weight of the added halogen. These and certain other perfections of our original procedure in the analysis of halides in the double cup, which have come as results of experience, will be more fully described in a later communication relating to the determination of the atomic weight of chlorine in the electrolytic way.

During analysis, the anode should not be placed too near the cathode. By observing this point a too-high current density will be avoided and one need not fear a possible loss due to the loosely adherent silver halide because of its too-rapid formation. It is advisable with the pressure usually employed (2.5–5 v.) with the double cup to place the anode at least 15 mm. from the level of the mercury. No turbidity of the electrolyte will then follow.

The hydrochloric acid used in the determinations which appear in this paper was standardized by the well-known precipitation method with silver nitrate. The residue from 40 cc. of the solution, containing

0.1418 gram of hydrogen chloride, weighed 0.0001 gram. Only freshly distilled water was used for dilution. In the first two determinations, a "double-cup" was used, but since in the case of hydrochloric acid this presented no advantage over a cell with a single compartment, the latter was employed for the subsequent determinations. This cell consisted of an ordinary beaker, 6 cm. in diameter and 8 cm. high, containing a layer of pure mercury 3 mm. deep. Cathode connection was made with the mercury by means of a platinum wire sealed in a glass tube. The anode was the usual disk gauze type. It made 300 revolutions per minute. The total dilution of the electrolyte was 90 cc. The liquid remaining in the beaker after the current was interrupted was found in every case to be neutral to methyl orange, and when tested with silver nitrate and with starch, and potassium iodide, hypochlorous acid or hypochlorites were invariably absent. In experiments 3 and 4 the electrolyte showed a slight turbidity, due to the fact that the electrodes were too close. In all other determinations the liquid remaining after the electrolysis was perfectly transparent and clear. The liquid from determinations 8 and 9 was evaporated to dryness and gave no appreciable residue. The mercury used for cathode had been distilled several times and was carefully examined for silver before and after the electrolysis, but none was found. Hence there was no transference of the metal from the anode to the cathode.

	Chlorine taken in HCl, gram.	Time. Min.	V.	A	Chlorine found.	Error.

11	0.1418	35	2.5–5.0	0.80–0.005	0.1420	+0.0002

From the foregoing tests it would appear that the electrolytic determination of chlorine in hydrochloric acid by means of a silver anode and mercury cathode is not only possible but is, moreover, extremely accurate and reliable.

Since the preceding determinations were made, W. B. Coleman, a student in this laboratory, carried out a series of determinations of bromine in hydrobromic acid. The results obtained by him are submitted in the following table. These results confirm those obtained with chlorine and prove beyond question that this method of analysis is reliable and exact.

ELECTROLYTIC SEPARATIONS.

BY IRVING H BUCKMINSTER AND EDGAR F. SMITH

Received July 23, 1910.

During the last three years there have been carried out in this laboratory certain metal separations in the electrolytic way, which may be of interest to those who are engaged in work of this character, so that it seems only proper that the results should be brought together in a single communication. The following paragraphs give in sufficient detail all the data necessary for those who may have occasion to repeat the separations. Thus, the separation of mercury from nickel was conducted in the presence of sulphuric acid. The anode consisted of a flat platinum spiral, which was rotated. The cathode was an ordinary platinum dish. With 0.1437 g. of mercury, and 0.2772 g. of nickel in the presence of 0.1 cc. of concentrated sulphuric acid, a current of N. D.$_{100}$ = 0.3 amp. and a pressure of 2.9 volts there was precipitated in the course of thirty-five minutes 0.1436 gram of mercury. Again, 0.2876 g. of mercury was separated from 0.1386 g. of nickel in the presence of 0.1 cc. of concentrated sulphuric acid, by the means of a current of N. D.$_{100}$ = 0.3 amp. and a voltage of 2.8 in a period of forty minutes. Six additional separations with conditions like those just indicated resulted similarly, so that we may regard this as a satisfactory procedure for the separation of mercury from nickel. The deposits of mercury were in every instance examined for nickel, but it was not found.

In the separation of bismuth from nickel 0.2772 g. of nickel and 0.2640 g. of bismuth, in the presence of 1 cc. of concentrated sulphuric acid, were exposed to the action of a current of N. D.$_{100}$ = 0.3 amp. and 2.2 volts for forty-five minutes. The deposit of bismuth weighed 0.2642 g. It was free from nickel. Six additional experiments resulted similarly. The deposits of bismuth, however, were not coherent, and the greatest care was required in washing them to avoid loss of the metal.

In separating copper from nickel, the metals were present as nitrates and there was added 1 cc. of nitric acid, specific gravity 1.4, while a current of N. D. $_{100}$ = 0.3 amp. and 2.4 volts was allowed to act upon 0.1481 g. of copper and 0.2772 g. of nickel. There was completely precipitated in forty minutes 0.1482 g. of copper. In the five additional experiments, conducted under practically the same conditions, the results were equally good, and the separation may, therefore, be considered successful. The deposit of copper was perfectly adherent and bright in color. At no time was nickel found in the copper.

In endeavoring to effect a separation in nitric acid of silver from nickel in practically the same manner as just described under copper from nickel, the silver deposits were not very adherent, but upon adding 5 cc. of ordinary alcohol to the electrolyte, containing 0.2191 g. of silver and 0.1386 g. of nickel, in the presence of 0.3 cc. of nitric acid, specific gravity 1.4, a current of N.D.$_{100}$ = 0.1 amp. and 1.1 volts, precipitated in 45 minutes 0.2192 g. of silver. Eight additional trials were conducted and with results that were very satisfactory. In the absence of alcohol, there was invariably a considerable anodic deposition.

Another interesting separation was that of mercury from nickel in a nitric acid electrolyte. The results which were observed in a number of experiments are represented in the single one which is here offered: 0.2477 g. of mercury as nitrate and 0.1386 g. of nickel as sulphate, in the presence of 3 cc. of nitric acid of specific gravity 1.4, were electrolyzed with a current of N. D.$_{100}$ = 0.3 amp. and 1 volt. In 30 minutes 0.2476 g. of mercury was precipitated. The deposits of mercury were, in all instances, bright and metallic, and in no case was the metal found contaminated with nickel.

Three trials leading to the separation of lead from nickel in nitric acid were carried out without the slightest difficulty. Lead was, of course, precipitated as dioxide upon a sand-blasted dish. In this instance the rotating cathode consisted of a perforated dish. The variation in the quantities of lead found ranged from 0.0001 to 0.0003 g.

From the many separations of zinc from nickel which were carried out in the presence of an alkaline tartrate electrolyte, one may be given. With a current of N. D.$_{100}$ = 0.3 amp. and 2.4 volts, in the presence of 1 g. of Rochelle salt and caustic potash sufficient to precipitate and redissolve the hydroxides, 0.1430 g. of zinc and 0.1386 g. of nickel as sulphates were acted upon for a period of 45 minutes. 0.1433 g. of zinc was found.

In an electrolyte containing free phosphoric acid, the separation of copper from nickel is quite satisfactory. In the same electrolyte, an attempt to separate cadmium from nickel was unsuccessful. The cadmium was deposited very slowly, and almost invariably contained nickel. The separation of mercury from nickel in a phosphoric acid electrolyte is also quite good.

In attempting to separate nickel from aluminium in the well-known ammonia and ammonium sulphate electrolyte, aluminium hydroxide invariably attached itself to the nickel deposit and was not fully removed by water. However, upon adding a little dilute sodium hydroxide the aluminium hydroxide at once disappeared, and the nickel was then washed with pure water. Proceeding in this way, three experiments gave most satisfactory results Upon attempting to separate nickel from iron in a similar electrolyte, it was discovered that the ferric hydroxide was apt to contaminate the deposit of nickel. In this electrolyte nickel may be successfully separated from magnesium and the alkaline earth metals, although, of course, in the case of the latter, some other ammonium salt than the sulphate should be used. Indeed, in separating nickel from barium, as well as from strontium and calcium, the electrolyte was introduced into a small beaker, a gauze cathode being bent so that there was a clearance of about 5 mm. between it and the anode, and about the same distance between it and the beaker. The weight of the anode was 15 g. and the cathodes were about 5 g. each. By this contrivance, the separations, ten in all, were conducted very satisfactorily, and with results that were extremely concordant.

In attempting to separate nickel from chromium in the presence of ammonium hydroxide and ammonium sulphate no deposit was observed after two hours, although a current of 0.8 of an ampere with a pressure of 2.5 volts was employed. At first chromium hydroxide, of course, separated and was soon oxidized. This peculiar retention of the nickel led to trials with cobalt in a similar electrolyte. Indeed, it was soon discovered that in an ammonium hydroxide and ammonium sulphate electrolyte containing cobalt, an electrolyte which under ordinary circumstances answers splendidly for cobalt as it does for nickel, upon the addition of potassium chromate there was absolutely no deposition of metallic cobalt. This did not take place even after several hours' passage of the current; and strangely enough, when the electrolyte was removed from the platinum dish its pink color suggested the presence of cobaltammine. When hydrochloric acid was added to the solution, and the latter warmed gently, quite an abundance of purpureocobaltic chloride separated out. As this happened in a number of trials, it was concluded to make this method of preparing a cobaltammine the subject of a special study, which is now in progress and the results of which will be reported in a later communication. Upon the addition of potassium chromate to an ammonium hydroxide and ammonium sulphate electrolyte containing copper, the deposition of metallic copper was also completely prevented. This curious behavior led us to add the same reagent, potassium chromate, to a solution of silver nitrate containing ammonium hydroxide and ammonium sulphate. Upon the passage of a current of 0.6 of an ampere with a pressure of 2.5 volts, the silver was precipitated in an adherent and weighable form upon the cathode. This difference in behavior of silver and copper in an electrolyte, such as has just been described, led to an attempt to separate these two metals. The five experiments instituted resulted most satisfactorily. The deposits of silver were perfectly coherent and light gray in color and were readily washed. This separation, however, would not be used in place of other older and just as reliable methods.

A problem of considerable interest to electro-analysts has been the separation of silver from gold. A reference to early papers communicated from this laboratory will show that on several occasions a marked difference of deportment in various electrolytes justified the hope that this separation had been realized. Upon testing out the new methods, however, they were found to be inadequate. The remarkable behavior of the metals copper, silver, nickel and cobalt when exposed to the action of the current in the presence of potassium chromate led Mr. J. T. Lay, of this laboratory, to let the current act upon a solution of gold chloride, containing ammonium sulphate and ammonium hydroxide, with a considerable quantity of potassium chromate. To our amazement, gold was not precipitated, although the current was increased to 3 amperes with a pressure of 5.6 volts.

Again, the thought came that now a separation of silver from gold in this new electrolyte might be obtained. While fairly good separations were reached, it was impossible to remove the last traces of silver without carrying down some gold, so that our hopes were cast to the ground. When for a moment one considers the new electrolyte, and the peculiar behavior of the metals, it seems altogether likely that complexes of the most varied nature must exist in the electrolyte.

A few attempts were made with the copper salt in the presence of ammonium hydroxide, ammonium sulphate and potassium chromate to determine the electromotive force of the combination, with the result that very few free copper ions were found, all of which would indicate that in such a solution there are probably complexes, the exact nature of which it is not possible for us at the present moment to give. These are receiving proper consideration.

The determination of zinc in a potassium cyanide electrolyte has been discussed at various times, and there has always been a difference of opinion as to the conditions under which success could be obtained. Our experience has shown that if to a zinc salt solution there be added sufficient caustic potash to completely precipitate the zinc as hydroxide, with enough of cyanide to just redissolve the precipitate, in the presence of 20 cc. of ammonium hydroxide of specific gravity 0.96, a current of 2 amperes with a pressure of 5 volts will precipitate 0.1487 gram of zinc in from 15 to 30 minutes. Six successful experiments confirmed this result. The deposition of the zinc was made upon a silver-coated platinum dish. The total dilution did not exceed 100 cc. With these conditions, substituting nickel and cobalt for zinc, there was no deposition of either metal, so that it was hoped that by observing the preceding conditions it might be possible to separate zinc from nickel and cobalt in such an electrolyte. All of the results proved the contrary. It is a well-known fact that lead and manganese, when deposited from solutions containing nitric acid by the current, appear in the form of peroxides at the anode. If, however, the volume of nitric acid be increased to from 15 to 30 cc. acid, specific gravity 1.46, it was found that with quantities of metal like the following, namely 0.0982 gram of lead and 0.0555 gram of manganese, and a current of 8.5 amperes with a pressure of 4.5 volts, in 20 minutes there was deposited 0.0980 gram and 0.0979 gram of lead. Eight experiments of this character were made. The deposits of lead dioxide were all that could be desired. Upon testing, however, each of these eight deposits, traces of manganese were found. Perhaps these were due to occlusion. The deposits were made upon a dish anode and the cathode made to revolve 250 times per minute. It should be added that even with twice the quantity of lead given in the preceding paragraph, the separation was apparently as exact as with the small amount, but traces of manganese were found in this larger quantity of lead.

The metal bismuth may be deposited in a perfectly adherent form, and, at the same time, separated from tungsten and from molybdenum, if conditions similar to those shown in the following examples be observed: 0.1926 gram of bismuth as nitrate, 0.1862 gram of tungsten as sodium tungstate, 3 grams of tartaric acid, 0.5 of a gram of sodium hydroxide, and a current of 0.2 ampere with a pressure of 3 volts. The anode was rotated and the bismuth was precipitated upon the platinum cathode. Its quantity was 0.1928 gram. The time of precipitation did not exceed 30 minutes. The quantity of molybdenum used in a number of successful trials was 0.1 of a gram.

A separation that has generally been regarded as difficult in the electrolytic way is that of silver from bismuth. In our study of this problem more than eighty-three determinations were made. We submit two results, showing the conditions which proved most favorable: *Experiment 1.*—To a solution containing 0.0637 gram of silver as nitrate and 0.0875 gram of bismuth as nitrate was added 0.15 of a gram of ferric alum and 0.15 of a gram of chrome alum. The dilution of the electrolyte was 100 cc. Upon adding 6 cc. of nitric acid, specific gravity 1.47, and electrolyzing with a current of 0.15 of an ampere and a pressure of 1.3

volts, there was precipitated in 30 minutes 0.0634 gram of silver. *Experiment 2.*—To a solution containing 0.1274 gram of silver as nitrate and 0.0875 gram of bismuth were added 0.1 of a gram of ferric alum and 0.2 of a gram of chrome alum. The solution was again diluted to 100 cc., and after the addition of 7 cc. of nitric acid of specific gravity 1.4, a current of 0.15 of an ampere and pressure of 1.3 volts precipitated in forty minutes 0.1274 gram of silver. It was noticed that when the pressure exceeded 1.5 volts, some bismuth peroxide appeared at the anode, and that traces of metallic bismuth were found in the silver deposit. It was noticed, also, that alum alone was not sufficient to retain the bismuth in solution. The temperature of the electrolyte varied from 25° to 30°.

Since these experiments were made, Dr. W. N. Chapin, of this laboratory, has repeated the work, with the following satisfactory results:

Silver.	Bismuth. Gram.	Ferric alum. Gram.	Chrome alum. Gram.	HNO_3. cc.	Volts.	Amperes.	Temperature. Degrees.	Time. Min.	Silver weighed.	Tests
0.0994	0.1	0.09	0.2	3	1.3	0.15	30	105	0.0990	No Bis
0.0994	0.1	0.09	0.2	3	1.3	0.15	30	105	0.0990	" "
0.0994	0.1	0.09	0.2	3	1.3	0.15	30	75	0.0996	" "
0.0994	0.1	0.09	0.2	3	1.3	0.15	30	70	0.0996	" "
0.0994	0.1	0.09	0.2	3	1.3	0.15	30	90	0.0992	" "

He has also found that the separation may be effected without the introduction of either of the alums. The conditions which he discovered to be wholly satisfactory were these: Silver 0.1 to 0.2 of a gram, bismuth 0.1 to 0.2 of a gram, 3 cc. of nitric acid in a total volume of 75 cc., temperature 60°, pressure 3 volts and current N. $D._{100}$ = 0.15 to 0.20 ampere. A dish anode was employed and placed 3 mm. from the dish cathode. The anode made 250 revolutions per minute. It is expedient to maintain the voltage constant and allow the electrolysis to proceed until the amperage falls to 0.002. By observing these conditions Dr. Chapin succeeded in making the separation in 25 minutes. The deposit of silver was perfectly free from bismuth. The electrolyte contained no silver.

Since mercury and silver are deposited under very similar conditions, it seemed probable that the preceding method would serve in the separation of mercury from bismuth. The experiments performed by Dr. Chapin prove this to be correct. The conditions observed by him were these: Total volume of electrolyte 75 cc., to which were added 10 drops of nitric acid. The pressure was 1.3 volts, the temperature of the electrolyte 50°. The dish anode was employed and rotated at the rate of 250 revolutions per minute. The current was allowed to fall to 0.002 amperes, using 0.1206 gram of mercury. The amounts obtained in two experiments with the above conditions were 0.1206 gram and 0.1208 gram. The amounts of bismuth were respectively 0.1000 and 0.2000 gram. Nitric acid exceeding the amount indicated above tends to prevent the last traces of mercury from separating.

Reference to the literature upon the separation of uranium in the electrolytic way from such metals as zinc, nickel and cobalt will disclose the fact that when using a platinum cathode with rotating anode, the uranium will be fully precipitated, but there seems to be a tendency on the part of the other metals to become enclosed in the deposit of uranium hydroxide. With this knowledge before us, it was thought worth the while to ascertain whether by employing a mercury cathode, the separations could not be made satisfactory. To this end there were made up stock solutions of zinc sulphate and uranium sulphate. Portions of these, representing 0.2071 gram of zinc and 0.1352 gram of uranium, were introduced into the mercury cup. 0.5 cc. of concentrated sulphuric acid was added, and with a current of 3.5 amperes and a pressure of 5 volts, zinc was completely precipitated in periods of time varying from 15 minutes to 60 minutes. The anode made 200 revolutions per minute. Twelve determinations were carried out with perfect success in every instance.

Cobalt and nickel sulphates were used in similar separations of these metals from uranium. The conditions were in the case of cobalt: 0.2036 gram of cobalt and 0.0322 gram of uranium, with 0.5 cc. of concentrated sulphuric acid, dilution 20 cc., current 5.6 amperes, pressure 7 volts, time 35 minutes; anode rotating 200 times per minute. The cobalt precipitated weighed 0.2034 gram. Eight determinations were made. In the case of nickel, the following conditions prevailed: 0.4290 gram of nickel and 0.0664 gram of uranium, with 0.5 cc. of concentrated sulphuric acid, and a current of 1.6 amperes, with a pressure of 5 volts. The anode performed 250 revolutions per minute. In 60 minutes there was precipitated 0 4288 gram of nickel. Eleven experiments confirmed the results of the preceding trial.

SOME DERIVATIVES OF 2-ACETYL-NAPHTHOL-1.[1]

BY HENRY A. TORREY AND E. J. CARDARELLI.

Received August 27, 1910.

The 2-acetylnaphthol-1 used in this work was prepared and converted into its 4-nitro and 4-amino derivatives according to the method of Friedländer.[2] The free base, which had an orange-red color similar to that observed by him, was treated with thioacetic acid, when the monoacetyl compound obtained melted at 212°, whereas Friedländer's acetyl derivative (of which he gives no analysis) melted at 107°. He, however, used acetic anhydride in preparing his compound, and to make sure that our higher melting point was not due to our use of thioacetic acid we repeated the experiment with acetic anhydride and again obtained the monoacetyl compound melting at 212°. It is strange that we should have obtained a different result from Friedländer, as in at least one of our preparations we did our best to follow his directions. It is probable, however, that the difference was due to some change in conditions so trifling that we overlooked it. We regret that the pressure of other work prevented us from giving more time to this interesting subject.

---

[1] This research was suggested by the late Professor H. A. Torrey, and the greater part of the work was done under his direction, but the remainder of the work and the writing of the paper were deprived of the advantage of his supervision by his untimely death. C. L. JACKSON.

[2] *Ber.*, 28, 1946 (1895).

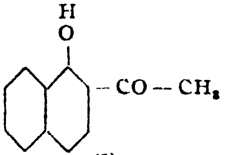
Two attempts to obtain a quinoline from the 2-acetylnaphthol-1 by the method of Skraup led to unpromising results. Accordingly, we turned our attention to the method of Döbner,[1] but upon heating our amine with benzaldehyde and pyruvic acid we obtained little or no quinoline, although we tried the experiment under a number of different conditions. We are of the opinion that the process would work if tried on a large scale, but the preparation of the amine is so troublesome that such experiments did not seem worth while. The difficulty in applying Döbner's quinoline synthesis to 2-acetyl-4-aminonaphthol-1 is the more striking, because it gives essentially quantitative results with other amines. The most obvious explanation for the inertness of this amine is to be found in steric hindrance, as the acetyl group stands in the ortho position to the atom of hydrogen which should have taken part in the synthesis. It was found in the course of these experiments that the amine acts with benzaldehyde in the cold, giving 2-acetyl-4-benzylidinamino-naphthol-1, $C_6H_5CHNC_{10}H_5(OH)COCH_3$, melting at 159°. The corresponding piperonylidine compound, melting at 178°, and that containing cinnamylidine, melting at 144°, were also made without difficulty. The yields are so good that perhaps this reaction might be developed into a method for the quantitative determination of aldehydes.

In the hope of reaching a quinoline more easily, the condensation of 2-acetylnaphthol-1 with orthonitrobenzaldehyde was undertaken, for the product by reduction and elimination of water might form a quinoline but experiments with this compound and with the meta- and paranitrobenzaldehyde showed that the reaction took place with such great difficulty that it was decided to work out the method with the cheaper meta compound before attempting to prepare the desired ortho derivative. The results of the numerous experiments tried under this head were far from inviting. The metanitrobenzaldehyde reacted with the 2-acetylnaphthol-1 with great difficulty; in fact it could not be made to act at all with most catalytic agents, potassium hydroxide in alcoholic solution being the only one found effective. With this the red 2-metanitrobenzalacetylnaphthol-1, $C_6H_4NO_2CHCHCOC_{10}H_6OH$, melting at 210°, was obtained, but in such small yields that it was not worth while to extend the research to the ortho compound. We can give no explanation of the fact that the nitrobenzaldehydes react with 2-acetylnaphthol-1 with so much more difficulty than the unsubstituted benzaldehyde.

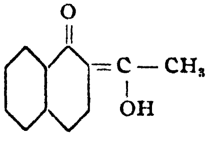
---

[1] *Ann.*, 249, 98, 110 (1888).

During the work on the action of benzaldehydes on the 2-acetylnaphthol-1 it was noticed that this latter substance was never recovered from the experiments in the form in which it had been introduced. Instead of crystallizing in very long, pale yellowish-green needles, melting at 103°, the recovered substance crystallized in brown plates melting constantly at 98°, so that at first we thought we had a new compound. We venture to suggest that the brown form may have a quinoid structure II, while the form melting at 103° is probably the phenol, I:



(I)



(II)

This view is in harmony with the observation of v. Kostanecki,[1] that in condensing benzaldehyde and acetonaphthol with 50 per cent. sodium hydroxide it was not necessary to add an acid, as the sodium salt was decomposed merely by dilution with water. The sodium salt of a substance with a structure like II would certainly act in this way, whereas it seems impossible that the salt of a true naphthol like I could be decomposed so easily.

By condensing benzaldehyde with 2-acetyl-4-nitronaphthol-1 the 2-benzalacetyl-4-nitro-naphthol-1, $C_6H_5CHCHCOC_{10}H_5NO_2OH$, was made, which melts at 203-208°, and resembles its isomer, $C_6H_4NO_2CHCHCOC_{10}H_6OH$, very closely, since that melts at 210°. In fact, the only marked difference is in the color—the first being orange-yellow, the second red. It is worth noting that the nitro group attached to the benzene in the red compound is nearer the double bond than that attached to the naphthalene ring in the orange-yellow substance. 2-Benzalacetylnaphthol-1 gave with nitric acid a nitro compound, which probably contained the nitro group on the naphthalene, to judge from its orange-yellow color and the melting point 206–208°, but it is obviously impossible to decide this point with certainty, owing to the strong resemblance between the two isomers.

As the orthonitrobenzaldehyde could be obtained only with difficulty, or at considerable expense, we next searched for some more accessible orthonitroaldehyde to replace it, and such a one was found in the 6-nitro-

[1] *Ber.*, 31, 705 (1898).

piperonal.[1] This substance had the further advantage of reacting easily even in the cold with the 2-acetylnaphthol-1, when sodium hydroxide was used as a catalyzer. The result, however, was not the condensation product expected, but the ketol, formed by direct addition of the aldehyde to the methyl of the ketone, the reaction being similar to the formation of aldol, $(CH_2O_2)NO_2C_6H_2CHO + CH_3COC_{10}H_6OH = (CH_2O_2)NO_2C_6H_2CH(OH)CH_2COC_{10}H_6OH$. An intermediate addition compound like this has been frequently assumed in considering the reactions between aldehydes and the methyl of a ketone, but, so far as we can find, none has been isolated as yet in the benzene or naphthalene series, for, if we have not overlooked some of them, only two are known, one made by the action of acetaldehyde and the other by the action of chloral on acetone. This is therefore the most important observation made in this research; and it is the more remarkable that the reaction should stop at the ketol, since with the other aldehydes that have been tried the unsaturated condensation product is formed with great ease, usually even in the cold.

This ketol may be called 2-(6-nitropiperonylalcohol)acetylnaphthol-1 or 1-(naphthol-1)-1-keto-3-hydroxy-3-(6-nitro-3,4-methylenedihydroxyphenyl)-propane. Its ketol structure is confirmed by the observation that one molecule of water is removed from it by acetic anhydride, or better, zinc chloride, leaving a substance melting at 226°; which will be described presently. Our work on the acetates is also in harmony with the ketol formula, although the end of the year cut it short, before we had removed the last doubt in regard to the nature of the diacetate. Fortunately, however, the ketol formula is firmly established without the aid of this additional confirmation. Acetic anhydride alone gave with the ketol a monoacetate melting at 188–190° (in addition to the compound melting at 226°), but, if sodium acetate was also present, what is probably a diacetate melting at 197–198° was formed. The ketol melts at 201–202°, so that the melting points of these three substances lie suspiciously near together, but their properties in other respects are so unlike that there can be no doubt they are different substances. As they contain percentages of carbon, hydrogen and nitrogen, showing differences hardly greater than the experimental errors of the analysis, it is impossible to settle their composition by analysis alone. It was proved, however, that the substance melting at 188–190° is the monoacetate by the analysis of its tribromo derivative, which would leave the formula of the diacetate for the compound melting at 197–198°, if it were not for the possibility that it may be a quinoid form of the monoacetate of the ketol. This view receives some confirmation from the fact that it crystallizes in rectangular plates, thus resembling the supposed quinoid form of 2-acetylnaphthol-1 discussed earlier in this paper;

---

[1] Fittig and Remsen, *Ann.*, 159, 134 (1871).

but it melts higher than the other form, whereas in that case the supposed quinoid melted lower; and the analysis agrees better with a diacetate than a monoacetate formula. These facts have led us to assign the formula of the diacetate provisionally to the substance melting at 197–198°, until its composition can be definitly fixed by additional experimental work, and we are the more ready to do this, because the quinoid form in the case cited rests at present only on a theoretical basis.

The substance melting at 226°, formed by treatment of the ketol with acetic anhydride or zinc chloride, differs from it by containing one less molecule of water, which might be split out in two different ways, forming either 2-(6-nitropiperonalacetyl)-naphthol-1, $C_6H_2(CH_2O_2)NO_2CH = CHCOC_{10}H_6OH$, or (6-nitro-3,4-methylenedihydroxyphenyl)-naphthoflavanone, $C_6H_2(CH_2O_2)NO_2\overbrace{CHCH_2COC_{10}H_6}^{O}$. The action of bromine on this substance gives a monobromo derivative formed with evolution of hydrobromic acid, and therefore pronounces in favor of the naphthoflavanone formula in spite of the fact that our substance is red, and all the flavanones, of which we can find accounts, are white, as it seems impossible that the dibromo addition product formed, if it were the piperonalacetyl compound, could be unstable enough to drop to the monobromo derivative spontaneously.

Experimental Part.

Acet-2-acetyl-4-aminonaphthol-1.—The 2-acetyl-naphthol-1 used in this work was prepared by the method of Friedländer[1] except that we found the boiling could be diminished from twenty to ten minutes, and a crystallization from glacial acetic acid removed most of the blue impurity thus facilitating the subsequent purification with alcohol. The nitro derivative also made by Friedlander's method was reduced with tin and equal parts of strong hydrochloric acid and water, added directly to the mixture of the ketone and the tin. Since the hydrochloride of the amino compound went into solution, as it was formed, it was easy to tell when the reduction was complete. The solution was filtered hot and the hydrochloride crystallizes on cooling in slightly yellowish needles, of which a small additional quantity was obtained by adding strong hydrochloric acid to the filtrate. On the addition of acid sodium carbonate to the aqueous solution of the hydrochloride the free base was obtained, of an orange-red color.

To convert this colored base into the acetyl compound, it was treated with thioacetic acid in molecular proportions, when a vigorous action at once set in, accompanied by evolution of hydrogen sulphide. The slightly yellow product, after crystallization from dilute alcohol, showed the constant melting point, 212°. As Friedländer obtained his acetyl com-

[1] *Ber.*, 28, 1946 (1895).

pound, melting at 107°, by the action of acetic anhydride, another portion of the 2-acetyl-4-aminonaphthol-1 was warmed gently with an excess of acetic anhydride. The product was diluted, allowed to stand, neutralized with acid sodium carbonate, and the precipitate, after crystallization from alcohol, also melted at 212°.

The analysis gave 5.86 per cent. N; calculated, 5.76 per cent.

It is therefore a monoacetyl compound, as the diacetyl derivative would give N 4.91. Whether the acetyl group is attached to oxygen or nitrogen must be left undecided in the present state of our knowledge.

Properties.—It crystallizes from dilute alcohol in microscopic needles, arranged like chestnut burs, and has a yellowish white color, which we think belongs to the compound, as it could not be removed by crystallization, even when assisted by boneblack. It melts at 212° and is soluble in alcohol, chloroform, or benzene.

2-Acetyl-4-benzylidenaminonaphthol-1, $C_6H_5CHNC_{10}H_5(OH)COCH_3$.—This substance was obtained in an attempt to convert the 2-acetyl-4-aminonaphthol-1 into a quinoline. As two experiments with Skraup's method had yielded unpromising results, we tried the method of Döbner,[1] and for this purpose made a mixture of the ketone, benzaldehyde and pyruvic acid in absolute alcohol; crystals were deposited almost immediately, which, after purification, showed the constant melting point 159°. Pyruvic acid with the ketone in absolute alcohol gave no action in 30 minutes, and even after an hour only a very small amount of a green powder had been deposited from the solution, which had turned red. On the other hand, when a solution of the ketone in absolute alcohol was mixed with benzaldehyde, crystals separated almost at once. After purification these melted as before, at 159°. The yield was 95% of the theoretical.

The analysis gave 4.89 per cent. N; calculated for $C_{19}H_{15}O_4N$, 4.84 per cent.

Properties.—The benzylidene compound forms small, lustrous plates between the colors of brass and bronze. Melting point 159°. Slightly soluble in cold, soluble in hot alcohol; soluble in ether, chloroform, tetrachloride of carbon, acetone, ethyl acetate, or benzene. Ferric chloride decomposes it, forming as one of the products benzaldehyde, which was recognized by its smell.

2-Acetyl-4-piperonylidenaminonaphthol, $C_6H_3(O_2CH_2)CHNC_{10}H_5(OH)$-$COCH_3$.—This substance was obtained in almost quantitative yield by allowing solutions of the free base and piperonal in absolute alcohol to stand for fifteen minutes. It could also be obtained from the hydrochloride and piperonal, but in this case the alcoholic solution needed heating for thirty minutes, and the product was much less pure. After crystallization from alcohol it showed the constant melting point 178°.

---

[1] *Loc. cit.*

Calculated for $C_{20}H_{15}O_4N$, N: 4.20. Found, 4.63 per cent.

Properties.—The piperonylidene compound forms lustrous brown plates from alcohol, which melt at 178°, and are very slightly soluble in cold, soluble in hot alcohol or tetrachloride of carbon; soluble in amyl alcohol, ethyl acetate, chloroform, or benzene; slightly soluble in gasoline. A solution of ferric chloride, if warmed slightly, turns it dark and splits off piperonal, to judge from the odor.

2-Acetyl-4-cinnamylidenaminonaphthol-1, $C_6H_5CHCHCHNC_{10}H_5(OH)$-$COCH_3$, was prepared by allowing cinnamic aldehyde to stand with the free base in absolute alcohol for thirty minutes. After crystallization from alcohol it melted constantly at 144° The yield was 95 per cent. of the theoretical.

Calculated for $C_{21}H_{17}O_2N$: N, 4.44. Found, 4.51 per cent

Properties.—Brownish yellow needles melting at 144°; slightly soluble in cold, soluble in hot alcohol; soluble in ether, ethyl acetate, tetrachloride of carbon, or benzene. A solution of ferric chloride set free cinnamic aldehyde, to judge by the smell.

Salicylic aldehyde gave a crystallin precipitate with an alcoholic solution of 2-acetyl-4-aminonaphthol-1, similar to those described above.

2-Benzalacetyl-4-nitronaphthol-1, $C_{10}H_5(OH, (COCHCHC_6H_5)NO_2$.—To an alcoholic solution of 10 grams of 2-acetyl-4-nitronaphthol-1 were added the equivalent amount of benzaldehyde and 20 grams of a 30 per cent. solution of sodium hydroxide and the mixture was heated on the steam bath under a return condenser for an hour. The bright red liquid thus obtained, when poured into acidified water, gave an oily precipitate, which soon crystallized. One portion of this red solid was crystallized first from glacial acetic acid and afterward from a mixture of benzene and tetrachloride of carbon; it melted between 203° and 208°. In no case did we succeed in obtaining a sharp melting point with this substance; the temperatures given are those which were not altered by subsequent crystallization. It is possible that this peculiarity of the melting point was in part due to the formation of some azoxy compound by the sodium hydroxide and alcohol, which afterward could not be removed by crystallization, and this would also explain the red color. A specimen of what we think is the same compound made by the nitric acid process (which could contain no azoxy compound) melted at 206–208°, and was orange-yellow; it therefore gives some support to this hypothesis, but it is to be observed that even this is not a sharp melting point. Another portion of the red product was recrystallized from a mixture of benzene and alcohol and melted at 202–206°. It had a reddish orange color.

Calculated for $C_{19}H_{13}O_4N$: N, 4.40. Found, 4.67 per cent.

The azoxy compound, $C_{38}H_{26}N_2O_5$, contains 4.74 per cent. of nitrogen, so that the analysis cannot distinguish between the two formulas.

Properties.—The benzalacetyl compound crystallizes from glacial acetic acid in needles of a bright orange-yellow color; but, if these yellow crystals are allowed to cool in the acid, they turn red. By heating them again with glacial acetic acid their yellow color is restored, the red form reappearing, if they are allowed to cool in the acid, whereas they remain yellow, if filtered and dried before the acid has cooled. We can offer no explanation of this phenomenon. The melting point varied according to the method of purification, 203–208° from benzene and tetrachloride of carbon, 202–206° from benzene and alcohol. Soluble in benzene; slightly soluble in alcohol, even hot, or in tetrachloride of carbon; slightly soluble in cold, much more soluble in hot glacial acetic acid.

What we suppose to be the same compound was prepared from 2-benzalacetylnaphthol-1 as follows: One gram of the ketone dissolved in hot glacial acetic acid was treated with the calculated amount of fuming nitric acid, also dissolved in glacial acetic acid. As the liquid cooled, a heavy, yellow crystallin precipitate was deposited, which, after washing with water and crystallization from a mixture of alcohol and benzene, melted at 206–208°.

Calculated for $C_{19}H_{13}O_4N$: N, 4 40. Found, 4 39 per cent

Properties.—It crystallizes in orange-yellow needles clinging together like fibers of asbestos, which melt at 206–208°, and show the same solubilities as the substance prepared by the other method. An attempt to make a bromine derivative gave a lemon-yellow product, which could not be dried without decomposition. A specimen of the nitro compound was boiled for eight hours with tin, hydrochloric acid and alcohol without reduction, as there was no change in the melting point.

2-Metanitrobenzalacetylnaphthol-1, $C_{10}H_6OHCOCHCHC_6H_4NO_2$.—The condensation of metanitrobenzaldehyde with the ketone was a difficult affair, and we obtained little or no action with aqueous solutions of sodium hydroxide of varying strengths up to 50 per cent. tried under a variety of conditions, and we were no more successful with sodium ethylate, a saturated solution of sodium hydroxide in alcohol, zinc chloride, or barium hydroxide. Sulphuric acid of 66 per cent. gave a product, but it seemed very unmanageable. A small yield of the condensation product was finally obtained by allowing the 2-acetylnaphthol-1 and metanitrobenzalaldehyde to stand for three days at ordinary temperatures with a 20 per cent. solution of potassium hydroxide in alcohol, when a black solid was obtained, which became brownish red on drying. The filtrate from it contained unaltered acetylnaphthol. The solid was treated with water, in which it was slightly soluble, and then acidified with acetic acid, which threw down a dirty orange precipitate. This, after washing, was recrystallized from a mixture of four parts of benzene to one of alcohol, until it showed the constant melting point 210°.

Calculated for $C_{19}H_{13}O_4N$: N, 4.40. Found, 4.59 per cent.

Properties.—The metanitro compound forms red microscopic needles arranged in clusters. Melting point 210°. Soluble in chloroform; slightly soluble in hot glacial acetic acid, or hot alcohol, nearly insoluble in cold alcohol. It absorbs bromine easily, forming a vermilion-colored substance.

2(6-Nitropiperonylalcohol)acetylnaphthol-1, or 1(naphthol-1)-1-keto-3-hydroxy-3(6-nitro-3,4-methylendihydroxyphenyl)-propane, $C_{10}H_6(OH)COCH_2$-$HOCHC_6H_2NO_2(O_2CH_2)$.—This ketol was formed instead of the piperonylidene compound expected, when 5 grams of the 2-acetylnaphthol-1 and 5.3 grams of 6-nitropiperonal were dissolved in hot alcohol, cooled to the temperature of the room, and treated with 25 grams of a 30 per cent. aqueous solution of sodium hydrate. The liquid began to grow dark immediately, and soon became red, depositing a yellow solid The action was promoted by frequent shaking, but heat must be carefully avoided, as it interfered with the success of the process. After four or five hours the dark yellow precipitate was filtered out and acidified with acetic acid. A preliminary washing with water, which was used, is not to be recommended, as the substance is soluble in water to such an extent that it was probably a sodium salt. After the acidification the substance was crystallized from glacial acetic acid till it showed the constant melting point 201–202°.

Calculated for $C_{20}H_{15}O_7N$: C, 62.99, ; H, 3.93, N, 3.67.
Found: C, 62.45, 62.55, H, 2.71, N, 4.03.

An acetate might possibly have been formed by the glacial acetic acid used in purifying the substance, and this would give very nearly the same percentages of carbon, hydrogen and nitrogen as the free ketol; therefore, to prove that our substance was not an acetate, it was boiled for an hour with strong hydrochloric acid and was recovered unaltered at the end of this time. For still greater certainty a sample was purified without the use of glacial acetic acid by crystallizing it from benzene and alcohol, when, with some difficulty, it was obtained with the same melting point and crystallin form.

Properties.—The ketol forms long, lemon-yellow needles which melt at 201–202°. It is moderately soluble in cold acetone, more so in hot; slightly soluble in ether or in cold glacial acetic acid, soluble in hot glacial acetic acid; somewhat soluble in cold, soluble in hot ethyl acetate; very slightly soluble in cold, slightly in hot alcohol; very slightly in cold, moderately in hot benzene; essentially insoluble in tetrachloride of carbon. Strong sulphuric acid dissolves it with a red color, but a yellow precipitate is formed on adding water; strong hydrochloric acid has no effect on it, even when hot; boiling with sodium hydroxide gives the 2-acetylnaphthol-1 to judge from its melting point, 98°.

A saturated alcoholic solution of the ketol turned red, when treated with piperidine, and the color became very dark after boiling for two minutes. This formed with water a red solution with a fine blue fluorescence, from which acidification threw down a yellow precipitate, but this was not studied further. The behavior of the ketol with acetic anhydride and with bromine is described later in the paper.

Monoacetate of the Ketol.—When the 2-(6-nitropiperonylalcohol)-acetylnaphthol-1 was heated in a flask with a return condenser with acetic anhydride for an hour to an hour and a half, and the product, after cooling, poured into water, two products were obtained, an orange one, which proved to be the monoacetate, and a red, which was found to be the flavanone, described later. The orange product was separated from the red by treatment with chloroform, which dissolved it, leaving the red behind. On evaporating the filtered solution the acetate was obtained nearly pure, and was recrystallized from a mixture of alcohol and benzene until it showed the constant melting point 188–190°.

Calculated for $C_{22}H_{17}O_8N$: C, 62.41; H, 4.02.
Found: C, 62.93; H, 5.10.

This analysis is of little value in determining the nature of the substance, as the free ketol contains 62.99 and the diacetate 61.93 per cent. of carbon, but that it was the monoacetate was shown by the analysis of its bromine derivative, described in the next section.

Properties.—The monoacetate crystallizes from glacial acetic acid in cream-colored needles, which melt at 188°–190°. It is soluble in chloroform; moderately soluble in cold, soluble in hot benzene; slightly soluble in cold alcohol, soluble with difficulty when hot; slightly soluble in cold, soluble in hot glacial acetic acid. Boiling with strong hydrochloric acid made it take on a brownish yellow color, but we were unable to raise the melting point of the small amount of product obtained above 188°.

Tribromo Derivative of the Monoacetate of the Ketol.—The monoacetate just described was dissolved in glacial acetic acid, the solution kept hot on the steam bath, and treated with an excess of bromine. When no more hydrobromic acid was given off the product was poured into water and the yellow precipitate thus obtained purified by repeated solution in glacial acetic acid and precipitation with water.

Calculated for $C_{22}H_{14}O_8NBr_3$: Br, 36.36. Found, 36.49 per cent.

The tribromo compound of the free ketol would contain 37.85, of the diacetate 34.98 per cent. of bromine, so there is no doubt that this compound is a monoacetate.

Properties.—The tribromo derivative crystallizes with difficulty from chloroform in small yellow needles. It has no definit melting point, but decomposes between 160 and 170°, although it turns pale green between 110 and 115°. It is moderately soluble in alcohol, or ligroin, when cold, soluble in either solvent if hot; soluble in ether, chloroform, glacial acetic acid, or benzene. After heating with sodium ethylate only a slight test for a bromide—little more than an opalescence was obtained. The bromine is therefore probably not attached to the side chain.

Diacetate of the Ketol.—This substance was obtained when the ketol was boiled with acetic anhydride and sodium acetate instead of with the anhydride alone. After boiling for nearly two hours, water was added which precipitated an oil, soon hardening to a pale greenish yellow solid. This was washed with water and recrystallized from benzene till it showed the constant melting point 197–198°.

Calculated for $C_{24}H_{19}O_9N$. C, 61 93; H, 4 08.
Found: C, 62 08, H, 5 64.

This analysis shows little, as the ketol and its mono- and diacetate all contain nearly the same percentage of carbon. It has been shown in the introduction to this paper that this substance is either the diacetate or a quinoid form of the monoacetate.

Properties.—The diacetate forms lustrous, golden, rectangular crystals melting at 197–198°. It is somewhat soluble in cold glacial acetic acid, or benzene, tolerably soluble in either of these solvents when hot; essentially insoluble in cold, and only slightly soluble in hot alcohol; slightly soluble in ether.

Action of Bromine on the Ketol.—This work was undertaken so near the end of the term that we have not been able to carry it beyond the preliminary stage. Bromine had no apparent action on the 2-(6-piperonylalcohol)-acetyl-naphthol-1 in the cold in chloroform suspension, but, if the ketole was dissolved in hot glacial acetic acid, and an excess of bromine added, hydrobromic acid was given off, and at the end of two or three minutes' heating on the steam bath an orange precipitate began to form, which soon became so thick that it was necessary to add more acetic acid to the pasty mass. After about three hours' heating on the steam bath, hydrobromic acid ceased to come off and the acetic acid solution was filtered from the orange-red precipitate, which formed the main product of the reaction, while a second yellow substance was obtained by the addition of water to the filtrate. That the two substances are different is shown not only by their melting point (red 252°, yellow 220°), but by their solubilities, the red compound being insoluble or nearly so in all solvents except nitrobenzene; the yellow, soluble in all the solvents tried. Two samples of the red compound gave agreeing amounts of bromine (11.83 and 11.38) on analysis, although one was purified only by washing, the other by precipitation with alcohol from a solution in nitrobenzene, but these numbers stand in no relation we can find to the monobromo ketol, which contains 17.39 per cent. of bromine. The yellow substance could not be purified sufficiently for analysis in the time at our disposal. Neither product gave up any quantity of halogen on treatment with sodium hydroxide.

2-(6-Nitro-3,4-methylenedioxyphenyl)-naphthoflavanone,

$(C_6H_2(CH_2O_2)NO_2)\overset{\ulcorner\!-\!-\;O\;-\!-\!\urcorner}{CHCH_2COC_{10}H_6}$.—This substance was made at the same time with the monoacetate by boiling the 2-(6-piperonylalcohol)-acetylnaphthol-1 with acetic anhydride. It was separated from the acetate by dissolving the latter with chloroform, in which the red flavanone was essentially insoluble. It was purified by crystallization from glacial acetic acid, until it showed the constant melting point 226°. As the yield was often very small in this process, a new method for preparing the substance was contrived, which consisted in boiling the ketol with alcohol and zinc chloride for one and a half to two hours, when the red crystals separated in good quantity.

Calculated for $C_{20}H_{13}O_6N$: C, 66.11 H, 3.59.
Found: C, 66.27, 65.95; H, 4.94, 3.39.

Properties.—The flavanone crystallizes in red needles with an orange tinge, which melt at 226°. It is essentially insoluble in ether, chloroform, or ligroin, also in alcohol, benzene, or glacial acetic acid when cold, slightly soluble in hot alcohol, very slightly in hot benzene, and soluble in hot glacial acetic acid. Bromine acts on it with the evolution of hydrobromic acid, as described in the next paragraph.

Bromine Compound of the Flavanone, $(C_6H_2(CH_2O_2)NO_2)\overset{\ulcorner\!-\!-\;O\;-\!-\!\urcorner}{C_2H_2BrCOC_{10}H_6}$. —When the flavanone was suspended in chloroform, or dissolved in glacial acetic acid, and treated with an excess of bromine, hydrobromic acid was given off, and an orange precipitate was thrown down. To purify it for analysis it was washed thoroughly with hot glacial acetic acid, after which it showed a decomposition point between 250° and 255°.

Calculated for $C_{20}H_{12}O_6NBr$: Br, 18.09; found, 17.49, 17.49 per cent.

These analyses are as near, as could be expected, when it is remembered that the substance was purified only by washing.

Properties.—An orange powder decomposing between 250° and 255°. It is essentially insoluble in alcohol, tetrachloride of carbon, or benzene; slightly soluble in hot ethyl acetate or carbon disulphide; very slightly soluble in hot glacial acetic acid, essentially insoluble in all these solvents when cold. A drop of alcoholic potassium hydroxide added to the substance suspended in alcohol turned it red—a very bright red on warming—and gave a good test for potassium bromide. The end of the year prevented us from studying the red products of this reaction.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF HARVARD COLLEGE.]

1-BENZOYLPHENYL-3-METHYL-5-PYRAZOLONE.[1]

BY HENRY A TORREY AND H. R. RAFSKY.

Received August 27, 1910.

Pyrazolones containing a radical other than phenyl in the 1-position are far from common, and in the present paper we add another member to this small class of compounds. The 1-benzoylphenyl-3-methyl-5-pyrazolone was made (following Michael's general method for making pyrazolones) from the hydrochloride of parahydrazinobenzophenone and acetoacetic ester with a few drops of hydrochloric acid. It melts at 170–171°. Unfortunately, the short time at our disposal prevented us from studying, beside the free base, more than the hydrochloride and the dimethyl compound, of which latter we did not get an analysis. We add an improvement to Döbner's method of making paraminobenzophenone, and several details which we found necessary to insure success in Ruhemann and Blackman's method of making the parahydrazinobenzophenone.

Experimental Part.

The paraminobenzophenone necessary for this work was made according to the method of Döbner[2] by the action of benzoyl chloride on phthalanil in presence of zinc chloride (the purified product being subsequently saponified into the paraminobenzophenone), but we found that the hard, pitch-like substance formed could be worked up with better results by extraction with alcohol, without boneblack, than by the treatment with glacial acetic acid and boneblack recommended by him. For this purpose several hundred grams of the crude substance were boiled with a reflux condenser for some time with 700–800 cc. of alcohol, the solution filtered boiling through a steam funnel, and the filtrate cooled in ice water, when crystals were deposited. By using two portions of alcohol the process could be run continuously, and, although it took more time than that with acetic acid, it gave much less trouble, and the product, while not quite so pure, proved to be sufficiently so for our purpose The paraminobenzophenone prepared from it with potassium hydroxide, after one recrystallization, melted at 124°, as it should; but the principal advantage of this method was that the yield was 170–180 grams as compared with 70–80 grams by the old method.

Parahydrazinobenzophenone was prepared by the method of Ruhemann and Blackmann,[3] consisting in the reduction of the diazo compound with stannous chloride and hydrochloric acid. This process, as was to be expected, gave us much trouble, but we finally succeeded in obtaining the hydrazine by observing the following precautions: The paraminobenzophenone was ground in a mortar with strong hydrochloric acid, so as to obtain a powder fine enough to remain easily in suspension in the hydrochloric acid used for the diazotization. The mixture was cooled carefully with ice and the concentrated solution of sodium nitrite added in five portions at intervals of an hour with frequent shaking. The completion of the reaction was determined by the disappearance of yellow sediment, but a white one always remained.

---

[1] This research was suggested by the late Professor H. A Torrey, and somewhat more than half of the experimental work was done under his direction, but the remainder of the experimental work and the writing of the paper were deprived of the benefit of his supervision by his too early death C. L. JACKSON.

[2] *Ann.*, **210**, 267.

[3] *J. Chem. Soc.*, **55**, 613.

The solution was allowed to stand overnight in ice, filtered, and added slowly, with constant stirring, to the solution of stannous chloride in strong hydrochloric acid (which was also well cooled with ice) at which the yellow precipitate mentioned by Ruhemann and Blackman was formed. This, after standing in the cold solution for half an hour, was filtered and dried on a porous plate. If it was dried on a steam radiator, it turned red, but this red product seemed to give the hydrazine hydrochloride as well as the orange-yellow one which was dried at ordinary temperatures.

The extraction of the hydrochloride from this product gave much trouble. The first extraction with a large amount of warm water could be filtered off without difficulty, but the second converted the residual tin salt into the colloidal state, when it was impossible to remove it by filtering, or decantation. After many experiments this difficulty was overcome as follows: The crude product was warmed with twice its volume of water at 50–60° with shaking for several minutes. As stated by Ruhemann and Blackman, heating to boiling causes some decomposition. It was then filtered rapidly, and by quick work a second similar extraction could be carried through before the precipitate had grown too fine to filter, but, when water was added for the third extraction, a colloidal solution was formed. By the addition of hydrochloric acid to this colloidal solution a precipitate similar to the original was formed which, after being filtered, and pressed on a porous plate, could be extracted three times before it became colloidal, and fortunately this was enough to extract all the hydrochloride of the hydrazine. This was precipitated from the combined water extracts by the addition of hydrochloric acid. The free hydrazine was then obtained by the addition of a concentrated solution of sodium acetate to a warm aqueous solution of the hydrazine hydrochloride. We have given an account of these additional details of the process in the hope of saving others the large expense of time and labor, which we found necessary in order to get a good result.

1-Benzoylphenyl-3-methyl-5-pyrazolone,

$C_6H_5COC_6H_4{-}\overbrace{N{-}N = C(CH_3)CH_2}^{CO}$.—As the method of Knorr[1] for the production of pyrazolones seemed to give a very impure product in this case, we tried to prepare the substance by the general method of Michael,[1] which also had the advantage of using the hydrochloride, and thus avoiding the somewhat wasteful preparation of the free hydrazine. The hydrochloride of the parahydrazinobenzophenone mixed with acetoacetic ester in molecular proportions (a slight excess of the ester does no harm) and a few drops of hydrochloric acid were heated on the steam bath for half an hour. The mixture melted, gave off vapors at first, and was converted into a yellow, pasty mass, which solidified on cooling. It was purified by crystallization from alcohol until it showed the constant melting point 170–171°.

---

[1] *Ber.*, 16, 2597 (1883)

The analyses gave 10.31 and 10.01 per cent. N; calculated for $C_{17}H_{14}O_2N_2$, gives 10.07 per cent. N.

Properties of 1-Benzoylphenyl-3-methyl-5-pyrazolone.—Brownish yellow crystals from alcohol, which melt at 170–171°. Freely soluble in alcohol; rather soluble in benzene; very slightly soluble in ether; almost insoluble in cold, slightly soluble in hot water. Dissolves on warming in strong hydrochloric acid or in an aqueous solution of sodium hydroxide, if not too concentrated. Silver nitrate gives a white flocculent precipitate with an alcoholic solution. The pyrazolone does not reduce Fehling's solution.

Hydrochloride.—The 1-benzoylphenyl-3-methyl-5-pyrazolone was dissolved in benzene and dry hydrochloric acid gas was passed into the solution. The light brown precipitate formed was dried *in vacuo*.

The analysis gave 11.55 per cent. Cl; calculated for $C_{17}H_{14}O_2N_2HCl$, gives 11.27 per cent. Cl

We obtained the salt as a pale brown powder, but the color may have been due to a trace of impurity. At 180° it turns dark, shrivels up at 193°, and melts with decomposition at 196°.

In an attempt to make the 2-3-dimethylpyrazolone corresponding to antipyrine, a method similar to Knorr's[2] was used. Three grams of 1-benzoylphenyl-3-methyl-5-pyrazolone were mixed with 3 grams of methyl iodide and 3 grams of methyl alcohol, and the mixture heated to 100° in a sealed tube for 16 hours. The product, a thick dark brown liquid, was warmed on the steam bath and treated with sulphurous anhydride, which hardened the mass, but produced no perceptible decolorization. After cooling and pulverization it was shaken with a very strong sodium hydroxide solution and then dissolved in benzene; after standing for several days the evaporation of the red-brown solution left an amorphous mass with a few embedded crystals; these were removed and used to inoculate the benzene solution of the amorphous portion, and in this way crystals were obtained which, after a second crystallization (with inoculation), were nearly white. Not enough of this substance could be obtained for analysis, because the end of the year prevented a second preparation, but there seems no question that it is the 1-benzoylphenyl-2,3-dimethyl-5-pyrazolone, from the method of its formation and the fact that ferric chloride gives a dark red color with its aqueous solution. It is very soluble in alcohol, or benzene; somewhat soluble in cold, soluble in hot water; soluble in strong hydrochloric acid. The melting point obtained by us (125°) was probably too low, as the amount at our disposal was too small to make certain of the purity of our specimen.

[CONTRIBUTIONS FROM THE CHEMICAL LABORATORY OF HARVARD COLLEGE.]

NOTE ON SOME PROPERTIES OF PIPERONYLOIN.

BY HENRY A. TORREY AND J. B. SUMNER.[1]

Received August 27, 1910.

The object of this work was to compare the behavior of piperonyloin and benzoin under similar conditions. The number of results obtained is small, partly because we had but little time at our disposal, but still more because the piperonyloin, $CH_2O_2C_6H_3COCHOHC_6H_3O_2CH_2$, proved to be much less reactive than benzoin; thus no substance corresponding to desoxybenzoin could be obtained under the usual conditions for forming that substance, or a variety of modifications of them. Most of the piperonyloin remained unaltered, the product of the reaction being little more than a trace of what seemed to be a pinacone. No oxime could be made: in fact there was no reaction, as far as we could find, under conditions which give the oxime of benzoin with ease; and no more than a trace of an acetyl compound was formed by long continued and varied action of acetyl chloride on the piperonyloin. These differences between benzoin and piperonyloin form the most important result of this research, but until more observations have been made, it is not worth while to speculate on their cause.

The only substances we have found which react easily with piperonyloin are urea and ammonium thiocyanate. The ureide decomposes at 262°, the thioureide near 260°, but the formula of the latter has not been established by us with certainty.

We also describe a modification of Perkin's method of preparing piperonyloin, which makes it possible to use larger quantities of substance.

Experimental Part.

The piperonyloin used in this work was prepared by the method of Perkin,[2] but we found that we obtained a better result, when instead of heating the mixture of 5 grams piperonal, 20 grams of 50 per cent. alcohol, and 2 grams of potassium cyanide for 6–8 hours, as recommended by him, the heating was carried on for only 3 hours, or the materials were allowed to stand at ordinary temperatures a few days. Under these latter conditions a yield of 80 per cent. of crude piperonyloin was obtained from 100 grams of piperonal, whereas Perkin states that the amount of piperonal used must be restricted to 5 grams in order to get a good result.

---

[1] This research was suggested by the late Professor H. A. Torrey, and somewhat more than half of the experimental work was done under his direction, but the remainder of the experimental work and the writing of the paper were deprived of the benefit of his supervision by his too early death. C. L. JACKSON.

[2] *J. Chem. Soc.*, 59, 164.

Treatment of piperonyloin with zinc and 80 per cent. alcohol, saturated with hydrochloric acid, under the same conditions, which give desoxybenzoin, gave on dilution a black tar, which could not be purified by distillation. Treatment with ether dissolved the tarry impurities, leaving a mass of yellow crystals, which proved to be unaltered piperonyloin, and made up the greater part of the product. It follows, therefore, that piperonyloin is much less affected by this reducing agent than benzoin. On trying to distil under a pressure of 1.5 cm. the tar obtained from the ether, a drop of distillate came over at 110°, and after this nothing till 246°, when about two-thirds of the substance passed over, leaving a black viscid mass. By crystallization of this distillate a body melting at 170° was obtained, probably a pinacone, but we did not obtain it in sufficient quantity for investigation. Many of the reducing processes were tried, but with no success.

According to Goldschmidt and Polonowska,[1] the oxime of benzoin is obtained with no difficulty; but with the piperonyloin we could obtain no reaction, although the conditions were varied in a number of different ways. In every case the piperonyloin was recovered unaltered.

Zinin[2] made the acetate of benzoin by heating it with acetyl chloride at 40-50° and finally at 100°, until there was no more action. Piperonyloin gave no perceptible action with acetyl chloride under these conditions, or any others we could find. By extracting the product with ether, in which piperonyloin is nearly insoluble, a trace of a yellow substance melting near 135° was obtained, but the quantity was so small that it was useless to think of obtaining enough for study.

Piperonyloinureide, $C_{17}H_{12}O_5N_2$.—This substance was made by heating 5 grams of piperonyloin with an excess of urea and amyl alcohol in a sealed tube at about 190° for three hours. The tube contained some large crystals and a black liquid. The crystals were washed with cold water and recrystallized four times from glacial acetic acid, after which the acid was washed off with alcohol and the substance dried at 110° for analysis.

The analyses gave 7.78 and 8.90 per cent. N; calculated, 8.64 per cent.

Properties.—The ureide forms pale pinkish crystals, as obtained by us, which decompose at about 265°. The substance is slightly soluble in hot alcohol, moderately soluble in hot amyl alcohol; slightly soluble in cold, very soluble in hot glacial acetic acid; essentially insoluble in water, or benzene, even if hot.

---

[1] *Ber.*, **20**, 492.

[2] *Ann.*, 104, 120.

The *thioureide* was prepared by heating piperonyloin with an excess of ammonium thiocyanate in a sealed tube to 170°. The crystals obtained in this way were washed with cold water and purified by crystallization from hot methyl alcohol.

The analyses gave 8.61 and 8.50 per cent. S; calculated for $C_{17}H_{12}O_4N_2S$, 9.41; for $C_{17}H_{14}O_5N_2S$, 8.99.

The analyses cannot distinguish between the two formulas, and we are inclined to adopt the first in spite of the fact that it agrees less well with the percentages found than the second, since this formula is analogous to that of the ureide, and the difference in results might be caused by a little of some impurity, which could not be removed from the small amount of substance at our disposal.

Properties.—The thioureide crystallizes in long, felted, nearly white needles, which decompose near 260°; slightly soluble in ethyl alcohol, methyl alcohol, acetone, or glacial acetic acid, when cold; moderately soluble in hot methyl alcohol, or carbon disulphide; very soluble in pyridine; insoluble in water.

[CONTRIBUTIONS FROM THE HAVEMEYER LABORATORIES OF COLUMBIA UNIVERSITY, No. 182.]

SOME DERIVATIVES OF *p*-AMINOBENZONITRILE.

BY MARSTON TAYLOR BOGERT AND LOUIS ELSBERG WISE.

Received September 11, 1910.

In 1903, Bogert and Kohnstamm[1] published a brief article on *p*-aminobenzonitrile, giving its method of preparation and properties, and describing also its acetyl and propionyl derivatives.

The present paper is a continuation of this work. In it are described improved methods for the production of the *p*-nitro- and *p*-aminobenzonitriles and of the acetyl derivative of the latter, as well as certain new substances.

By the action of glacial formic acid, of benzoyl chloride, and of benzenesulphonyl chloride, upon the aminonitrile, the corresponding acyl derivatives were obtained, while with oxalic esters, cyano-oxanilic esters and cyano-oxanilide were secured. The acetaminonitrile yielded the acetaminobenzamide with alkaline hydrogen dioxide, and the *m*-nitro-*p*-acetaminobenzonitrile on direct nitration. By reduction of the latter, the 3,4-diaminobenzonitrile was prepared, a most interesting orthodiamine.

The work is being continued and another paper will appear shortly. The fact that other chemists are working in closely related fields, or are approaching this field from other directions, has made it seem to us advisable to publish this preliminary paper.

---

[1] THIS JOURNAL, 25, 478 (1903)

Experimental.

p-Nitrobenzonitrile, $(4)O_2N.C_6H_4.CN(1)$, is best prepared by the well-known Sandmeyer method[1] from pure *p*-nitroaniline. It may be prepared also from the commercial "Nitrosamine" paste.

The latter, placed at our disposal through the courtesy of the Badische Company, contains about 25 per cent. of the sodium salt of *p*-nitrophenylnitrosamine mixed with the necessary amount of nitrite[2] and was converted into the diazo compound by mixing 60 parts of the paste with 200 parts cold (not over 18°) water, then adding 21 parts dilute hydrochloric acid (about 30 per cent. HCl) in a fine stream, stirring gently. This diazo solution was allowed to stand for about a half hour, with occasional gentle stirring, was filtered (from diazoamino compounds and other contaminants), and the filtrate added to the copper cyanide solution in the usual way. The temperature of the diazo solution must at no time rise above 18°. The crude nitronitrile was separated from mineral salts by extraction with boiling carbon tetrachloride. Orange crystals were thus obtained, which were still impure. The yield of these orange crystals varied from about 31 to 43 per cent. of the theory. Further purification was effected by recrystallization from water, distillation with steam, or sublimation.

A much more satisfactory method is to distil the original crude nitrile direct with steam. The product thus obtained is practically pure (m. p. about 148°, cor.), and the yield about 50 per cent. of the theory if pure *p*-nitroaniline was used as the initial material.

The pure nitronitrile forms nearly colorless, fluffy crystals, melting at 147.5-8.5° (cor.). It is soluble in water, acetic acid, chloroform, and carbon tetrachloride, at their boiling points, volatil with steam, and can be sublimed. It has an odor recalling that of a mixture of nitrobenzene and benzonitrile.

p-Aminobenzonitrile, $(4)H_2N.C_6H_4.CN(1)$.—The nitronitrile was reduced with stannous chloride and hydrochloric acid.[3] It is important that a pure nitronitrile be used in this reduction, as it is not so easy to separate the aminonitrile from impurities, and the yield is thus considerably decreased. After reduction, no excess of concentrated hydrochloric acid was added, but the mixture was left in the refrigerator overnight, the separated tin double salt of the aminonitrile then filtered out, dissolved in cold water in a separatory funnel, ice and ether added, the solution carefully made alkaline with dilute ice-cold sodium hydroxide solution, and the mixture well shaken. The ethereal layer was separated, and the extraction with ether repeated several times. The ethereal extracts were united and the ether driven off, leaving the aminonitrile in deeply colored crystals. Purified by recrystallization from water, it was obtained in colorless needles or long prisms. The best yield of aminonitrile was about 75–6 per cent. of the theory.

[2] *Ber.*, **27**, 514 (1894); U. S. Patents 531973, 531974, 531975, 531976 and 531977.

[3] Bogert and Kohnstamm, *Loc cit.*; Bogert and Hand, THIS JOURNAL, **24**, 1033 (1902); Bogert and Beans, *Ibid.*, **26**, 469 (1904).

An attempt to prepare the aminonitrile by distilling a dry and intimate mixture of potassium cyanide and potassium sulphanilate proved unsatisfactory.

The pure aminonitrile forms colorless crystals, melting at 85.5–86° (cor.), as reported by Bogert and Kohnstamm.[1]

p-Formaminobenzonitrile, $(4)HCONH.C_6H_4.CN(1)$, from the nitrile and glacial formic acid, was purified by repeated crystallization from water and decolorization with boneblack. It forms small colorless crystals, melting at 188–9° (cor.) in a sealed tube.

Found: N, 19.31. Calculated for $C_8H_8ON_2$: N, 19.18.

p-Acetaminobenzonitrile, as stated, was described in the paper of Bogert and Kohnstamm.[1] The following is a somewhat better method of preparation:

The aminonitrile is added gradually to an excess of hot acetic anhydride and the mixture heated for ten or twenty minutes. The excess of anhydride is then destroyed by the addition of water to the hot solution and, on cooling, the acetyl derivative crystallizes out practically pure. A small additional amount, less pure, may be recovered from the mother liquor. Yield, 77–85 per cent. of the theory. Crystallized from water until the melting point remained constant, colorless needles were obtained, melting at 205.5° (cor.). Bogert and Kohnstamm[1] found an uncorrected melting point of 200°.

p-Acetaminobenzamide, $CH_3CONH.C_6H_4.CONH_2$.—*p*-Acetaminobenzonitrile was added to a solution of hydrogen dioxide made slightly alkaline with potassium hydroxide, and the mixture heated for half an hour or an hour at 100°. A clear yellow solution resulted. This was filtered hot and the filtrate allowed to cool. The amide which separated was recrystallized first from water and then twice from dilute alcohol. It forms colorless prisms, melting at about 274.5°, with preliminary softening and sublimation. Further crystallization did not alter this melting point or diminish sensibly the tendency to a preliminary drag and sublimation.

Found: N, 15.95. Calculated for $C_9H_{10}O_2N_2$: N, 15.73.

Heated with potassium hydroxide solution, it is saponified with evolution of ammonia.

---

[1] *Loc. cit.*

3-Nitro-4-acetaminobenzonitrile, $(4)CH_3CONH.C_6H_3(NO_2)(3)CN(1)$.—Five grams *p*-acetaminobenzonitrile were gradually stirred into a paste prepared by adding 6.7 g. finely pulverized potassium nitrate to 30 cc. concentrated sulphuric acid, and the whole kept at a temperature of —10° to 0° by a freezing mixture. After all the nitrile had been added, the mixture was held at about 0° for an hour or two longer, and the sirupy mass then poured slowly upon cracked ice. After standing for a short time, the yellow precipitate was washed with water, a little very dilute ammonium hydroxide solution, and again with water. Without previous drying, it was added to warm acetic anhydride, the solution boiled for a few minutes, water added to destroy the excess of anhydride, and on cooling the nitrile separated in beautiful yellow prisms. Recrystallized from 95 per cent. alcohol, long, lustrous, pale-yellow needles were obtained, melting at 131.5° (cor.), softening somewhat at 130°. Yield, about 64 per cent. of theory. The crystals are soluble in water or alcohol, less readily in benzene, and practically insoluble in carbon tetrachloride.

Found: N, 20.74. Calculated for $C_9H_7O_3N_3$: N, 20.49.

The process just described must be followed closely to get a good yield of pure substance. We have tried various other methods of nitration, but none proved as satisfactory as the above.

To locate the nitro group, the nitroacetaminobenzonitrile was saponified by boiling it with alcoholic potassium hydroxide solution. During the boiling, ammonia was evolved and the solution turned purple. On cooling, orange needles separated, corresponding in properties to the description in the literature of potassium 3-nitro-4-aminobenzoate. The free acid liberated from this salt by the action of hydrochloric or sulphuric acid crystallized from dilute alcohol in orange-yellow needles which, carefully dried in vacuum and heated in a sealed tube, began to sublime at about 190–200°, forming a yellow coating on the sides of the tube. At 277–8° (cor.), the sides of the tube began to clear, and at 290–1° (cor.) the substance decomposed. Salkowski[1] and Ritsert[2] give the melting point of 3-nitro-4-aminobenzoic acid as 284°.

Found: N, 15.05 and 15.27 Calculated for $C_7H_6O_4N_2$, 15.39.

As a further check on the correctness of the work, some 3-nitro-4-aminobenzoic acid was prepared according to the method of Ritsert[3] by nitrating pure *p*-acetaminobenzoic acid, and the product was found to be identical with that obtained by the saponification of the above nitroacetaminobenzonitrile.

p-Benzoylaminobenzonitrile, $C_6H_5CONH.C_6H_4.CN$, from *p*-aminobenzonitrile and benzoyl chloride, in presence of sodium carbonate, was purified by crystallization from dilute alcohol, after treating with boneblack. The pure substance melts at 170°–170.5° (cor.), with very slight previous softening.

---

[1] *Ann.*, 173, 54.

[2] D. R. P., 151725.

[3] *Loc. cit.*

Found: N, 12.94 and 12.78. Calculated for $C_{14}H_{10}ON_2$: N, 12.62.

p-Benzenesulphoneaminobenzonitrile, $C_6H_5SO_2NH.C_6H_4CN$.—*p*-Aminobenzonitrile was heated for a few minutes with excess of benzenesulphone chloride. The crude product was washed with ether and crystallized from alcohol to constant melting point. Colorless arborescent crystals, melting at 175–6° (cor.), with very slight preliminary softening.

Found: N, 10.90; S, 12.74. Calculated for $C_{13}H_{10}O_2N_2S$: N, 10.85; S, 12.42.

Methyl p-Cyano-oxanilate, $CH_3OCOCONH.C_6H_4.CN$.—A mixture of 4 g. methyl oxalate and 1.5 g. *p*-aminobenzonitrile was heated for three and a half hours at 110°. The crude product crystallized from methyl alcohol in nacreous leaflets, melting at 208.5–9.5° (cor.).

Found: N, 14.0. Calculated for $C_{10}H_8O_3N_2$: N, 13.73.

Ethyl p-Cyano-oxanilate, prepared similarly to the methyl ester, crystallizes from alcohol in small, nearly colorless, flat prisms, softening somewhat at 187° (cor.), and melting at 188.5–9° (cor.).

Found: N, 13.13. Calculated for $C_{11}H_{10}O_3N_2$: N, 12.85.

Di-p-cyano-oxanilide, (*p*)$NC.C_6H_4.NHCOCONH.C_6H_4.CN$(*p*).—A mixture of equal parts by weight of *p*-aminobenzonitrile and ethyl oxalate was heated five and a half hours at 160–210°. Ethyl *p*-cyano-oxanilate was extracted from the crude product with alcohol, and the residual insoluble product dried and analyzed:

Found: N, 19.33. Calculated for $C_{16}H_{10}O_2N_4$: N, 19.32.

The compound melts above 288°, and is insoluble or very difficultly soluble in water, alcohol, glacial acetic acid, ether, benzene, nitrobenzene, aniline, amyl alcohol or phenol.

3,4-Diaminobenzonitrile, $(3,4)(NH_2)_2C_6H_3.CN$.—Five grams 3-nitro-4-acetaminobenzonitrile were added gradually to a solution of 35 g. stannous chloride in 75 cc. concentrated hydrochloric acid at a temperature of 30–40°. Complete solution resulted, the deep yellow color gradually growing paler. Nothing separated from this solution even after standing in the refrigerator for several days. It was, therefore, poured into a separatory funnel, covered with a layer of ether, and carefully made alkaline by adding cold dilute sodium hydroxide solution. A voluminous precipitate appeared, not easily soluble in the ether. The mixture was repeatedly extracted with ether, the extracts combined, dried with calcium chloride, and the ether driven off. The colorless residue, dried in vacuum, rapidly turns pink in the air. Crystallized from water, it forms colorless needles, softening at 146° and melting at 147.5° (cor.). This melting point could not be changed by further recrystallization. The compound is soluble in boiling water, hot alcohol or boiling chloroform, but dissolves in ether with difficulty.

Found: N, 31.64. Calculated for $C_7H_7N_3$: N, 31.58.

DERIVATIVES OF CAMPHOROXALIC ACID. XIII.[1]

By J. Bishop Tingle and S. J. Bates.

Received September 10, 1910.

In some of the earlier papers on this subject it has been pointed out that the condensation compounds of camphoroxalic acid and of its esters with amines may be formulated either as  $C_8H_{14}\left\langle\begin{array}{l}C : CCO_2H\ (alkyl)\\ |\quad\ \ |\\ CO\ NHR\end{array}\right.$ I., or  $C_8H_{14}\left\langle\begin{array}{l}CHCCO_2H(alkyl)\\ |\quad\ \ |\\ CONR\end{array}\right.$ II. The balance of evidence being in favor of the first of these formulas, it has been employed by the senior author and his colleagues in their publications.

The work described in the present communication had, for one of its objects, the accumulation of more direct positive proof of the constitution of the amino condensation compounds in question; we therefore directed our attention to the investigation of reactions which should show the presence of an imino —NHR, or hydroxyl $>C(OH)—$ group in the condensation compounds.

Our first experiments were carried out with phenylcamphoformeneaminecarboxylic acid,  $C_8H_{14}\left\langle\begin{array}{l}C : CCO_2H\\ |\quad\ \ |\\ CONHC_6H_5\end{array}\right.$; it is prepared very readily from camphoroxalic acid and aniline, is easy to purify and is relatively stable. We obtained it by a slight modification of the method described by the senior author and A. Tingle.[2] The acid is attacked immediately by bromine, in chloroform solution; hydrobromic acid is evolved in quantity, 3,4-dibromoaniline hydrobromide is deposited in crystals and the solution contains camphoroxalic acid. The probable mechanism of this reaction appears to be the more simple on the assumption of the first of the above formulas for phenylcamphoformeneaminecarboxylic acid, although it is by no means conclusive. The readiness with which the hydrogen atoms of the benzene nucleus undergo substitution is noteworthy.

---

Williams, *Amer. Chem. J.*, **39**, 105, 277 (1908).

[2] *Loc. cit.*

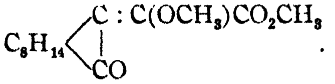
Chromic anhydride, in acetone or in acetic anhydride solution, at the ordinary temperature, is without appreciable effect on phenylcamphoformeneaminecarboxylic acid, but potassium permanganate, dissolved in moist acetone, oxidizes it to camphorquinone. As camphoroxalic acid itself has been shown to suffer attack at the position of the double linkage, it is probable that this reaction follows a similar course, the molecule of the carboxylic acid suffering dissolution into the complexes  $C_8H_{14}\left\langle\begin{array}{l}C<\\ |\\ CO\end{array}\right.$ and $>C(NHC_6H_5)CO_2H$, the former of which then yields the quinine.

The only product which could be obtained by the action of phosphorus trichloride on phenylcamphoformeneaminecarboxylic acid was camphoroxalic acid. Phosphorus pentachloride reacts like the trichloride, ultimately, therefore, the reaction may be expressed as one of simple hydrolysis of the CN linkage

A considerable number of experiments were made, under varying conditions, on the interaction of methyl sulphate and phenylcamphoformeneaminecarboxylic acid. It was, of course, to be expected that a methyl group would replace the hydrogen of the carboxyl, so giving the methyl ester, but we hoped that, in addition, the hydrogen of the $—NHC_6H_5$ (formula I) might be substituted, thus giving the compound  $C_8H_{14}\left\langle\begin{array}{l}C:CCO_2CH_3\\ |\quad\ |\\ CON\left\langle\begin{array}{l}CH_3\\ C_6H_5\end{array}\right.\end{array}\right.$. This would afford direct evidence in favor of the formula in question. Unfortunately, this double substitution could not be realized, the only product which we could obtain was *methyl phenylcamphoformeneaminecarboxylate*,  $C_8H_{14}\left\langle\begin{array}{l}C:CCO_2CH_3\\ |\quad\ |\\ CONHC_6H_5\end{array}\right.$ It is deposited in yellow crystals, melting at 127°. Under the varied conditions of our experiments it does not react with methyl sulphate.

We failed to obtain any reaction between methyl sulphate and phenyl camphoformeneamine,  $C_8H_{14}\left\langle\begin{array}{l}C:CH\\ |\quad\ |\\ CONHC_6H_5\end{array}\right.$. These results, apart from other evidence, appear, therefore, to decide effectively against any formula such as  $C_8H_{14}\left\langle\begin{array}{l}C:C(OH)CO_2H\\ |\\ C:NR\end{array}\right.$, for the condensation products of camphoroxalic acid and amines.

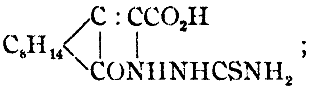
Methyl sulphate and camphoroxalic acid give the methyl ester. On one occasion, by the further action of the sulphate, this ester yielded a small quantity of what appears to be methyl methoxycamphoroxalate,



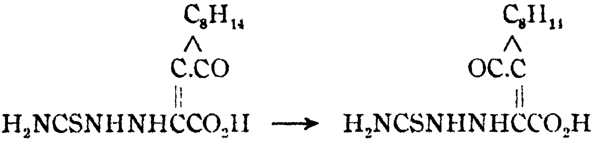
. Hitherto we have not succeeded in obtaining this substance in quantity sufficient for adequate study.

Attempts to obtain compounds from nitrous acid and phenyl camphoformeneaminecarboxylic acid, camphoroxalic acid, or its ethyl ester were unsuccessful. We employed sodium nitrite and also amyl nitrite, under varied conditions.

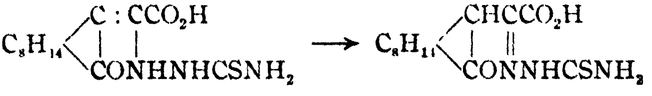
Camphoroxalic and thiosemicarbazine react readily in hot alcohol, more slowly at the ordinary temperature, to form *thiosemicarbazylcamphoformeneaminecarboxylic acid*,



; in benzene, the combination occurs much more slowly at the boiling point of the solution and is inappreciable at the ordinary temperature. The acid exists in two modifications which melt at 120–5° and 148–9°, respectively. The lower melting form (A) is the more readily soluble in benzene, it is somewhat viscid and is produced by adding hydrochloric acid to an aqueous solution of the sodium salt of the carboxylic acid. It is also formed by recrystallizing the higher melting modification (B) from water. It changes slowly at the ordinary temperature, more rapidly when heated alone or with benzene, to the (B) form. A mixture of (A) and (B) melts at 140–5°. The modes of formation of (A) and (B) suggest that the former is an unstable hydrate of the latter. From the nature of the case it is impossible to determine this fact with certainty. There are also the possibilities of *cis-* and *trans-*isomerism,



and of tautomerism,

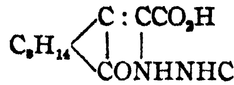


to be considered.

Our chief object in preparing thiosemicarbazylcamphoformeneaminecarboxylic acid was to compare its behavior with the similar derivative of semicarbazine,[1] *i. e.*, to determine the effect of exchanging an oxygen for a sulphur atom. The contrast between the two compounds is most marked in the relative readiness with which they form closed chain derivatives. Whereas semicarbazylcamphoformeneaminecarboxylic acid,

---

[1] Bishop Tingle and Robinson, *Loc. cit.*



$C_8H_{14}<\begin{matrix}C:CCO_2H\\ CONHNHCONH_2\end{matrix}$, undergoes further condensation without difficulty, the thio derivative exhibits comparatively little tendency to change in this direction. When fused, a portion of the acid is recovered and the remainder is converted into resinous products. Absolute alcohol and dry hydrogen chloride give only *ethyl thiosemicarbazylcamphoformeneamine-carboxylate*, $C_8H_{14}<\begin{matrix}C:CCO_2C_2H_5\\ CONHNHCSNH_2\end{matrix}$, which is deposited from benzene in white crystals, melting at 150–1°.

Thiosemicarbazylcamphoformeneaminecarboxylic acid is dehydrated by the action of acetic anhydride, quickly at about 100°, more slowly at the ordinary temperature. The yield is almost quantitative and the compound is deposited in bright red crystals, melting at 181–2°. When treated with a warm aqueous solution of potassium hydroxide or a boiling aqueous solution of sodium carbonate the parent acid is regenerated. These reactions make us inclined to regard the compound as being *thiosemicarbazylcamphoformeneaminecarboxylactimide*, $C_8H_{14}<\begin{matrix}C:C-CO-NH\\ CONH.NH.CS\end{matrix}$, its deep color, which appears to be characteristic of the compound itself and not due to traces of ferric thiocyanate, suggests that it probably exists in a tautomeric form, such as $C_8H_{14}<\begin{matrix}C:C-CO-N\\ CONH.NH.CSH\end{matrix}$ or $C_8H_{14}<\begin{matrix}C:C.C(OH):N\\ CONH.NH.CS\end{matrix}$.

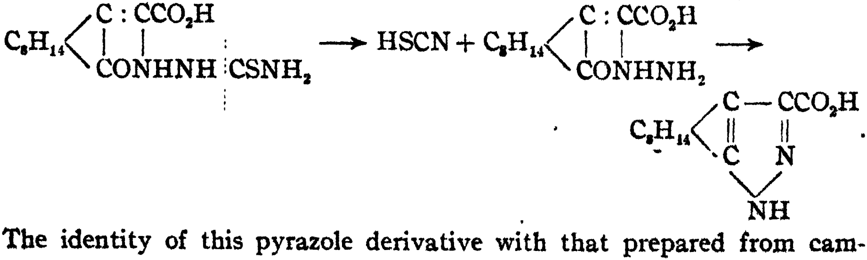
Acetic anhydride, to which a few drops of conc. sulphuric acid have been added, hydrolyzes thiosemicarbazylcamphoformeneaminecarboxylic acid to thiocyanic acid, the presence of which was shown by means of a ferric salt, and aminocamphoformeneaminecarboxylic acid, which latter then condenses to camphylpyrazolecarboxylic acid (m. p. 261–2°),



$$C_8H_{14}<\begin{matrix}C:CCO_2H\\ CONHNH\vdots CSNH_2\end{matrix} \longrightarrow HSCN + C_8H_{14}<\begin{matrix}C:CCO_2H\\ CONHNH_2\end{matrix} \longrightarrow C_8H_{14}<\begin{matrix}C-CCO_2H\\ C\quad N\\ NH\end{matrix}.$$

The identity of this pyrazole derivative with that prepared from camphoroxalic acid and hydrazine, or semicarbazine by Bishop Tingle and Robinson,[1] was shown by direct comparison. Our acid melted at 261–2°, whereas the melting point observed previously was 255–8°. The difference is undoubtedly due to variation in the rapidity of heating, because the carboxylic acid evolved carbon dioxide at a temperature below its melting point.[1]

---

[1] *Am. Chem. J.*, 36, 259.

A slight modification of Bishop Tingle and Robinson's process for the preparation of camphylpyrazolecarboxylic acid is described in the experimental portion of this paper (vide p. 1511).

Only resinous products could be obtained by the action of concentrated sulphuric acid alone, at the ordinary temperature, on thiosemicarbazylcamphoformeneaminecarboxylic acid. We propose to make a further examination, under other experimental conditions, of the ability of this carboxylic acid to form cycloids containing sulphur.

In the hope of obtaining material suited for further investigation, we have examined the interaction of camphoroxalic acid with a number of amines. With 1,3,4-xylidine it gives *1,3,4-xylidine 1,3,4-xylidylcamphoformeneaminecarboxylate*,  $C_8H_{14}\left<\begin{array}{l}C : CCO_2NH_3C_6H_3(CH_3)_2\\ | \qquad |\\ CO\ NHC_6H_3(CH_3)_2\end{array}\right.$, which is deposited in brown crystals, melting at 93–4°. By the action of sodium carbonate, followed by hydrochloric acid, on this salt, *1,3,4-xylidylcamphoformeneaminecarboxylic acid*,  $C_8H_{14}\left<\begin{array}{l}C : CCO_2H\\ | \qquad |\\ CO\ NHC_6H_3(CH_3)_2\end{array}\right.$, is produced. The acid is deposited in yellow crystals, melting at 117–8°. The third member of the series, the amine,  $C_8H_{14}\left<\begin{array}{l}C : CH\\ | \qquad |\\ CO\ NHC_6H_3(CH_3)_2\end{array}\right.$, is probably formed at a temperature above the melting point of the acid, but it could not be isolated in a crystalline condition.

Comparing these compounds with the corresponding derivatives of aniline, it is evident that they crystallize with greater difficulty and are, therefore, less suited for our projected investigations.

p-Chloroaniline and camphoroxalic acid combine readily to form *p-chlorophenylcamphoformeneaminecarboxylic acid*,  $C_8H_{14}\left<\begin{array}{l}C : CCO_2H\\ | \qquad |\\ CO\ NHC_6H_4Cl\end{array}\right.$, which was obtained in yellow needles, melting at 182–3°. Its crystallizing power is considerable. With a larger proportion of *p*-chloroaniline it failed to form a *p*-chloroaniline salt, although possibly one could be obtained at a low temperature.

When camphoroxalic acid and *p*-chloroaniline are heated gradually up to 155–60°, without a solvent, carbon dioxide is evolved and *p-chloro-*

---

[1] *Loc cit.*

phenylcamphoformeneamine,  $C_8H_{14}\left\langle\begin{array}{l}C : CH\\ |\quad\ \ |\\ CO\ NHC_6H_4Cl\end{array}\right.$, is produced. It is also formed by heating *p*-chlorophenylcamphoformeneaminecarboxylic acid above its melting point. The amine is deposited in white crystals, melting at 194–5°.

Dibenzylamine and camphoroxalic acid react quickly, in equimolecular proportion, to form an additive compound. It gives an intense reddish purple color with an alcoholic solution of ferric chloride and is resolved somewhat slowly into its constituents by the action of an aqueous solution of sodium carbonate, or by hydrochloric acid. In spite of the slowness of this decomposition, we regard the substance as being dibenzylamine camphoroxalate,  $C_8H_{14}\left\langle\begin{array}{l}C : C(OH)CO_2NH_2(CH_2C_6H_5)_2\\ |\\ CO\end{array}\right.$, rather than an acid condensation product such as  $C_8H_{14}\left\langle\begin{array}{l}C - C(OH)CO_2H\\ \|\quad\ \ |\\ COHN(CH_2C_6H_5)_2\end{array}\right.$. See Bishop Tingle and Williams.[1] The compound is deposited in white crystals, melting at 135–6°. It is also formed by the action of 2 molecular proportions of dibenzylamine on camphoroxalic acid.

When dibenzylamine camphoroxalate is heated with aniline (2 mols.) and benzene, under pressure, at 100°, it is converted into *dibenzylamine phenylcamphoformeneaminecarboxylate*,  $C_8H_{14}\left\langle\begin{array}{l}C : CCO_2NH_2(CH_2C_6H_5)_2\\ |\quad\ |\\ CO\ NHC_6H_5\end{array}\right.$, which was obtained in white crystals, melting at 185°. Its composition and nature is established both by its mode of formation and by the fact that it is decomposed into dibenzylamine and phenylcamphoformeneaminecarboxylic acid, when treated with dilute hydrochloric acid.

The dibenzylamine camphoroxalate described above, when fused for some time, gives the dibenzylcamphoformeneamine described by Bishop Tingle and Williams.[2] It is also produced when a mixture of camphoroxalic acid and dibenzylamine is heated at 135–40°. The use of 2 molecular proportions of dibenzylamine is without effect on the nature of the product.

m-Aminobenzoic acid and camphoroxalic acid form *m-carboxyphenylcamphoformeneaminecarboxylic acid*,  $C_8H_{14}\left\langle\begin{array}{l}C : CCO_2H\\ |\quad\ |\\ CONHC_6H_4CO_2H\end{array}\right.$; it is deposited in white crystals, melting at 136–7°. This acid is hydrolyzed rather easily to its constituents; when heated at its melting point carbon dioxide is evolved; the other product of the reaction consists of *m-carboxyphenylcamphoformeneamine*,  $C_8H_{14}<\begin{matrix}C:CH\\ |\quad|\\ CONHC_6H_4CO_2H\end{matrix}$. It is deposited in long yellow needles, melts at 116–7° and dissolves completely in a cold aqueous solution of sodium carbonate.

---

[1] *Am. Chem. J.*, 39, 113.

[2] *Ibid.*, 39, 117.

Bishop Tingle and Hoffman[1] described a condensation compound of benzidine and camphoroxalic acid which they found to melt at 190°. We have repeated this work, but have observed that better results are obtained, as regards the purity of the product, by the use of benzene as the solvent. Our condensation compound was obtained in yellow crystals, which melted at 208°. The melting point of the substance varies considerably with the rate of heating, but the identity of the two specimens was shown by their melting point when mixed. The compound is only slowly dissolved by boiling with aqueous solutions of potassium hydroxide, or of sodium carbonate and it is reprecipitated on acidifying the solutions. This behavior suggests that it is an *inner salt*,  $C_8H_{14}<\begin{matrix}C:C\text{—}CO_2.NH_3\\ |\quad|\qquad\quad|\\ CONH.C_6H_4.C_6H_4\end{matrix}$, rather than *benzidylcamphoformeneaminecarboxylic acid*,  $C_8H_{14}<\begin{matrix}C:CCO_2H\\ |\quad|\\ CONHC_6H_4C_6H_4NH_2\end{matrix}$.

When this salt (or acid) is heated at its melting point, water and carbon dioxide are evolved and *benzidylcamphoformeneamine*,  $C_8H_{14}<\begin{matrix}C:CH\\ |\quad|\\ CONHC_6H_4C_6H_4NH_2\end{matrix}$, is obtained, but it is prepared more conveniently by mixing the salt (or acid) with nitrobenzene and heating at 150–5°. The amine is deposited in crystals, melting at 317–8°.

Camphylamine and camphoroxalic acid react readily, but the product is mostly resinous under the conditions which we employed. We succeeded, however, in isolating a white crystalline *compound*, which melted at 105°. It appears to be formed by the condensation of the constituents, because it dissolves readily in an aqueous solution of sodium carbonate, at the ordinary temperature, and gives no coloration with an alcoholic solution of ferric chloride. Its quantity was too small for further investigation.

Only resinous substances could be obtained from *p*-aminobenzaldehyde and camphoroxalic acid.

Experimental.

Preparation and Reactions of Phenylcamphoformeneaminecarboxylic

---

[1] *Am. Chem. J.*, 34, 231–50.

Acid,  $C_8H_{14}\!<\!\begin{matrix}C:CCO_2H\\ |\quad\ |\\ CONHC_6H_5\end{matrix}$.—This compound was prepared according to the directions of Bishop Tingle and A. Tingle,[1] from camphoroxalic acid and aniline, but instead of decomposing the resulting aniline phenylcamphoformeneaminecarboxylate with dilute hydrochloric acid, it was found to be more convenient to dissolve the salt in an aqueous solution of sodium carbonate and precipitate the acid by means of dilute hydrochloric acid. The yield is quantitative.

Action of Bromine on the Acid.—The bromine (4 atoms) was added gradually to phenylcamphoformeneaminecarboxylic acid, both substances being dissolved in dry chloroform. The solution was heated gently, hydrobromic acid was evolved immediately and white crystals soon deposited. These dissolve readily in alcohol or ethyl acetate, more sparingly in ether, acetone, or chloroform and they are insoluble in benzene. The purified material melts at 227–228°; it was identified as 3,4-dibromoaniline hydrobromide, $Br_2C_6H_3NH_2.HBr$.

Found: N, 4.30. Calculated: N, 4.22.

When mixed with water, the hydrobromide is dissociated into hydrobromic acid and 3,4-dibromoaniline, which crystallizes from the hot solvent in long needles, melting at 80–81°.

Found: C, 28 83; H, 2.07. Calculated: C, 28.46; H, 1.97

The compound was identified further by the preparation of the acetyl derivative, melting at 127°. This latter was obtained by heating the 3,4-dibromoaniline at 150°, during 30 minutes, with anhydrous sodium acetate and acetic anhydride. The substance (m. p. 216°) described by Bishop Tingle and A. Tingle[2] as being formed from bromine and phenylcamphoformeneamine,  $C_8H_{14}\!<\!\begin{matrix}C:CH\\ |\quad\ |\\ CONHC_6H_5\end{matrix}$, is, doubtless, 3,4-dibromoaniline hydrobromide.

The chloroform filtrate obtained after the separation of the 3,4-dibromoaniline hydrobromide, as described above, contains camphoroxalic acid, amounting, in some experiments, to 50 per cent. of the theoretical quantity. It was separated by evaporating the chloroform and extracting the tarry residue with an aqueous solution of potassium hydroxide. No unchanged phenylcamphoformeneaminecarboxylic acid could be detected.

Oxidation Experiments.—Phenylcamphoformeneaminecarboxylic acid does not appear to be attacked by chromic anhydride, at the ordinary temperature, during several days. Experiments were made in which acetone and also acetic anhydride were employed as solvents. With potassium permanganate, in moist acetone, a slow action takes place at the ordinary temperature. The permanganate solution was added gradually to the acid and the mixture allowed to remain during 24 hours, throughout which time the permanganate was in excess. During the evaporation of the acetone an odor of isocyanide was noticed; steam distillation of the tarry residue yielded camphorquinone, which was fully identified.

---

[1] *Am. Chem. J.*, **21**, 250.

[2] *Ibid.*, **21**, 248.

Action of Chlorides of Phosphorus on Phenylcamphoformeneaminecarboxylic Acid.—Phosphorus trichloride (2 mols.) and the acid were allowed to react at the ordinary temperature, during two days, in benzene which had been dried over sodium wire. After removal of the solvent a tarry material was obtained. It was extracted with an aqueous solution of sodium carbonate and then with one of potassium hydroxide. The undissolved residue was viscous and no crystals could be isolated from it. The alkaline solutions yielded camphoroxalic acid.

The action of phosphorus pentachloride appears to be exactly similar to that of the trichloride.

Action of Methyl Sulphate on Phenylcamphoformeneaminecarboxylic Acid.– The acid was dissolved in the calculated quantity of an aqueous solution of potassium hydroxide, and methyl sulphate (2.5 mols.) was added, while shaking, potassium hydroxide solution being run in at intervals so as to keep the mixture alkaline. An oil soon separates and after a time solidifies; it proved to be *methyl phenylcamphoformeneaminecarboxylate*,  $C_8H_{14}\left\langle\begin{matrix} C:CCO_2CH_3 \\ |\quad\;| \\ CONHC_6H_5 \end{matrix}\right.$. This ester dissolves without difficulty in acetone, ethyl alcohol, ethyl acetate, or benzene and is deposited from hot methyl alcohol, or ligroin in somewhat yellow crystals, melting at 127°.

Found: C, 72.14; H, 7.23. Calculated: C, 72.84; H, 7.35.

The ester is hydrolyzed rather slowly to the parent acid by boiling it with an aqueous solution of potassium hydroxide.

Methyl sulphate (1.1 mols.) reacts immediately, at the room temperature, with dry sodium phenylcamphoformeneaminecarboxylate (1 mol.) and sodium hydrogen carbonate (1 mol.). The product consists of the methyl ester described above; it was extracted by means of benzene.

A number of other experiments were carried out in which the conditions of temperature, etc., and of the relative proportions of acid and methyl sulphate were varied within somewhat wide limits, the object being to attack the NHC_6H_5 or the : COH group of the parent acid (see pp. 1500). In each case the only product which could be isolated was the ester described above.

A further effort in the same direction was made by heating at 140°, methyl phenylcamphoformeneaminecarboxylate (1 mol.) and dry potassium carbonate (1.5 mols.) and adding methyl sulphate (1.5 mols.). The mixture darkened immediately; ligroin extracted from it a quantity of unchanged methyl ester and left a black powder which melted above 270°.

No reaction appears to take place between phenylcamphoformeneamine,  $C_8H_{14}\left\langle\begin{array}{l} C:CH \\ | \quad\; | \\ CONHC_6H_5 \end{array}\right.$, and methyl sulphate, at 100°, in presence of dry sodium carbonate.

EXPERIMENTS WITH CAMPHOROXALIC ACID.—*Action of Methyl Sulphate.*—The acid was dissolved in a warm, aqueous solution of potassium hydroxide (1 mol.), and methyl sulphate and an aqueous solution of potassium hydroxide were added gradually and alternately, while shaking. An oil soon separates and finally solidifies. It consists of methyl camphoroxalate,  $C_8H_{14}\left\langle\begin{array}{l} C:C(OH)CO_2CH_3 \\ | \\ CO \end{array}\right.$.[1] The same product was also formed by heating dry sodium camphoroxalate, methyl sulphate and sodium hydrogen carbonate, in benzene, during one hour.

Methyl camphoroxalate, methyl sulphate and dry sodium carbonate, at 150–80°, gave a small quantity of an oil which was extracted by means of ether. The oil produced no coloration with alcohol and a solution of ferric chloride. It was treated with an alcoholic solution of potassium hydroxide, at the ordinary temperature, and the residue acidified. Ligroin extracted from the product an oil which gave a deep red coloration with ferric chloride and alcohol. These results indicate that the first oily material was *methyl methoxycamphoroxalate*,  $C_8H_{14}\left\langle\begin{array}{l} C:C(OCH_3)CO_2CH_3 \\ | \\ CO \end{array}\right.$.[2] Further experiments not only failed to improve the yield of this substance, but showed that its formation apparently depended on conditions which are rather difficult to duplicate, consequently the matter was not pursued further.

Nitrous acid, from sodium nitrite, or amyl nitrite, failed to react with phenylcamphoformeneaminecarboxylic acid, or with camphoroxalic acid and ethyl camphoroxalate. The experiments were made under varied conditions as to solvents and at temperatures ranging from —5° to that of the room.

Camphoroxalic Acid and Thiosemicarbazine.—The acid (2.25 g.) and the amine (0.91 g.) were mixed in alcoholic (95%) solution (30 cc.) and the liquid boiled in a reflux apparatus, during about 20 minutes, until a drop of it failed to give any color with ferric chloride. The reaction also proceeds slowly at the ordinary temperature, in presence of alcohol. A solution similar in concentration to that described above, gave a slight color with ferric chloride after 35 days, but no color was developed after 53 days. In benzene the reaction does not take place to any appreciable extent after 2 months at the ordinary temperature, but it proceeds slowly when heated on a boiling water bath. In all cases the product was viscous; it was purified by dissolving in a cold, aqueous solution of sodium carbonate, adding hydrochloric acid in excess and allowing the precipitate to remain over night in contact with the mother liquor. The solid material was then washed with water, dried and recrystallized from benzene. It is deposited in white flakes, melting at 148-9°. Analysis indicates that the substance is *thiosemicarbazylcamphoformeneamine-carboxylic acid*,

---

$$C_8H_{11}\left\langle\begin{array}{l} C : CCO_2H \\ \,|\quad\;\; | \\ CONHNHSNH_2 \end{array}\right..$$

Found: N, 14.16 Calculated: N, 14.14.

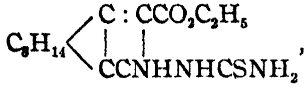
The yield is quantitative.

A study of the carboxylic acid shows that it exists in two modifications. The crystals (m. p. 148-9°) dissolve readily in a cold, aqueous solution of sodium carbonate. On adding dilute hydrochloric acid to this solution a sticky precipitate is deposited which is soluble in excess of the mineral acid. The precipitate hardens on standing and then melts at about 120-5°. This lower melting material dissolves readily in warm benzene, 100 cc. of which, at the boiling point, dissolve about 20 g. of the acid. After a short time crystals appear in the boiling liquid; these melt at 148-9° (the original melting point) and require more than 20 parts of boiling benzene for solution. The lower melting material (m. p. 120-5°) when heated on the water bath for a few hours, or if allowed to remain at the ordinary temperature during several days, shows a rise in melting point to 135-40° and a diminished solubility in benzene. A mixture of approximately equal quantities of the lower (m. p. 120-5°) and of the higher (m. p. 148-9°) melting varieties melts at 140-5°. The higher melting form dissolves readily in warm water and is deposited in the lower melting modification. Both forms are soluble without difficulty in ethyl acetate, acetone, alcohol (95%), ether and chloroform.

The carboxylic acid gives a slight greenish tint with alcohol and ferric chloride, the color disappears on adding ether. When a small crystal of the acid is placed on moist iron a red color is produced, doubtless due to the formation of a little ferric thiocyanate. No coloration was observed, under similar conditions, with metallic lead, zinc, or copper.

Fusion of the carboxylic acid leads to the production of resinous matter; in addition, a *compound* was formed which begins to melt at about 170°. Its quantity was too small to permit of its purification.

Ethyl thiosemicarbazylcamphoformeneaminecarboxylate,



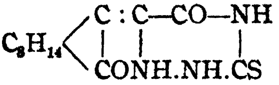
$$C_8H_{14}\left\langle\begin{array}{l} C:CCO_2C_2H_5 \\ |\quad | \\ CCNHNHCSNH_2 \end{array}\right.$$

, is prepared by dissolving the carboxylic acid in a small quantity of absolute alcohol and passing dry hydrogen chloride into the solution. The ester is deposited either by exposing the liquid to air, or by allowing it to remain overnight in a closed vessel. It forms white crystals from benzene and melts at 150–1°. Its distinction from the parent acid (m. p. 148–9°) was shown by a mixed melting point and also by the insolubility of the ester in an aqueous solution of sodium carbonate. In a warm aqueous solution of potassium hydroxide it dissolves slowly.

Found: C, 55.23; H, 7.18. Calculated: C, 55.38; H, 7.07.

Under certain conditions, which were not specifically determined, a small quantity of a white material is also formed together with the ester. It dissolves readily in cold water, melts above 300° and contains ionizable chlorine. Quite possibly it is ammonium chloride.

Action of Acetic Anhydride on Thiosemicarbazylcamphoformeneaminecarboxylic Acid.—The acid (1 g.) was heated on a boiling water bath, during 5 minutes, with acetic anhydride (5 cc.). A deep red solution was obtained, from which a resinous material separated when the liquid was poured into water (100 cc.). The solid was washed several times with water, then dried and recrystallized from glacial acetic acid; it is deposited in bright red crystals, melting at 181–2°. The compound is obtained in quantitative yield by dissolving the carboxylic acid in a little acetic anhydride and allowing the solution to remain at the room temperature until the anhydride and acetic acid have evaporated. This red compound is *thiosemicarbazylcamphoformeneaminecarboxylactimide,*

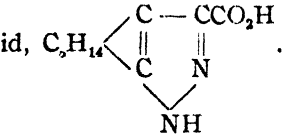


$$C_8H_{14}\left\langle\begin{array}{l} C:C\text{—}CO\text{—}NH \\ |\quad |\qquad\qquad | \\ CONH.NH.CS \end{array}\right.$$

; it dissolves readily in benzene, ligroin, alcohol, glacial acetic acid and also in a warm aqueous solution of potassium hydroxide; in a boiling aqueous solution of sodium carbonate dissolution takes place more slowly; when acidified each of these alkali solutions deposits the original carboxylic acid, m. p. 148–9°.

Found: C, 55.61; H, 6.14. Calculated: C, 55.91; H, 6.09.

Action of Acetic Anhydride and Concentrated Sulphuric Acid on Thiosemicarbazylcamphoformeneaminecarboxylic Acid.—The carboxylic acid (1 g.) was mixed with acetic anhydride (1.5 cc.), well shaken and concentrated sulphuric acid (3 drops) added. Heat is generated and a light brown solution is formed. After remaining during 15–20 minutes it was poured into water; a viscid solid is deposited which was washed with water, then with a dilute aqueous solution of sodium carbonate and finally purified by recrystallization from ethyl acetate. The crystals obtained in this manner melted at 261–2° and were shown, by analysis, by their properties and by a mixed melting point, to consist of camphylpyrazolecarboxylic acid,

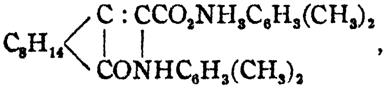


The material for comparison was prepared by a slight modification of the method of Bishop Tingle and Robinson.[1] Semicarbazylcamphoformeneaminecarboxylic acid was fused; the resulting product was finely divided and mixed with a cold, dilute aqueous solution of sodium hydrogen carbonate. The resinous material fails to dissolve, but the carboxylic acid slowly passes into solution and is reprecipitated by dilute hydrochloric acid.

The aqueous filtrate, obtained after the removal of the pyrazolecarboxylic acid which was prepared from the thiosemicarbazyl derivative, was tested with a ferric salt and was shown to contain thiocyanic acid.

Action of Concentrated Sulphuric Acid on Thiosemicarbazylcamphoformeneaminecarboxylic Acid.—A little of the carboxylic acid was ground to a paste with conc. sulphuric acid, and a solution, which was formed in the course of a few minutes, was allowed to remain during 3 days in an atmosphere dried by means of sulphuric acid. At the end of this period it was diluted with water; a precipitate was produced which consisted of unchanged carboxylic acid and a resin. From this no crystals could be separated.

Action of 1,3,4-Xylidine on Camphoroxalic Acid.—The acid (1 mol.) and the amine (2 mols.) were warmed together in benzene solution, during 10 minutes; after cooling, the liquid deposits a jelly-like material which was drained and dissolved in ligroin (b. p. below 90°). When the ligroin solution is allowed to evaporate moderately quickly, at the ordinary temperature, it deposits only a tarry substance, but if the liquid is placed in a small covered beaker and allowed to remain during 3 or 4 days, brown crystals of *1,3,4-xylidine 1,3,4-xylidylcamphoformeneaminecarboxylate*,



are deposited. The salt melts at 93–4° and dissolves readily in benzene, ligroin, acetone, ether, ethyl alcohol, chloroform, or ethyl acetate. An aqueous solution of potassium hydroxide decomposes the salt into an oil (1,3,4-xylidine) and the acid, which, however, is prepared more conveniently in the manner described below.

---

[1] *Am. Chem. J.*, 36, 259.

Found: N, 6.49. Calculated: N, 6.25 per cent.

1,3,4-Xylidylcamphoformeneaminecarboxylic acid,  $C_8H_{14}\Big\langle\begin{matrix}C:CCO_2H\\ |\quad\ |\\ CONHC_6H_3(CH_3)_2\end{matrix}$, is obtained from the salt mentioned above, but is produced more readily by dissolving equimolecular proportions of camphoroxalic acid and 1,3,4-xylidine in benzene and warming the solution until a drop of it fails to produce a red color with alcohol and ferric chloride. The warming is continued while the liquid is well stirred with an aqueous solution of sodium carbonate; the two liquid layers are ultimately separated and the aqueous portion is acidified with dilute hydrochloric acid. The resulting sticky precipitate is purified by slow crystallization from low boiling ligroin. In this manner we obtained yellow crystals, melting at 117–8°. The acid dissolves readily in benzene, ligroin, ether, ethyl alcohol, acetone, chloroform, or ethyl acetate and also in an aqueous solution of sodium carbonate, from which mineral acids always precipitate it in a resinous condition. It gives no coloration with an alcoholic solution of ferric chloride.

Found: N, 4.41. Calculated: N, 4.28 per cent.

At 130°, a mixture of camphoroxalic acid and 1,3,4-xylidine evolves water and carbon dioxide; the product gave no coloration with an alcoholic solution of ferric chloride and it doubtless contained the compound  $C_8H_{14}\Big\langle\begin{matrix}C:CH\\ |\quad\ |\\ CONHC_6H_3(CH_3)_2\end{matrix}$, but no crystals could be isolated.

p-Chloroaniline and Camphoroxalic Acid.—When equimolecular proportions of these two substances are dissolved in benzene and heated during five minutes, crystals soon appear. They were purified by recrystallization from benzene, being deposited in yellow needles, melting at 182–3°. The compound consists of *p-chlorophenylcamphoformeneaminecarboxylic acid*,  $C_8H_{14}\Big\langle\begin{matrix}C:CCO_2H\\ |\quad\ |\\ CONHC_6H_4Cl\end{matrix}$. This acid, and not the *p*-chloroaniline salt, is also formed when camphoroxalic acid and *p*-chloroaniline are brought together in the ratio of 1 : 2 mols. The acid dissolves readily in benzene, ether, ethyl alcohol, acetone, or ethyl acetate. In ligroin the solubility is smaller. At the ordinary temperature, it dissolves easily in an aqueous solution of sodium carbonate and is reprecipitated by hydrochloric acid. The carboxylic acid gives no coloration with an alcoholic solution of ferric chloride.

Found: N, 4.29. Calculated: N, 4.20 per cent.

Camphoroxalic acid and *p*-chloroaniline were ground together in equimolecular proportion and the mixture heated slowly by means of an oil-bath. At 65–70° the material melts; water is evolved at about 110° and the product then solidifies. It undoubtedly consists of the carboxylic acid, because it dissolves without difficulty, at the ordinary temperature, in an aqueous solution of sodium carbonate and it gives no coloration with an alcoholic solution of ferric chloride. As the heating is continued the material melts again at about 155° and evolves carbon dioxide. The temperature was maintained at 155–60° during 20 minutes, then allowed to fall to 110°, ligroin (b. p. 110–20°) was now poured onto the fused material and the mixture was shaken vigorously. Working in this manner, crystals were obtained immediately and were not seriously contaminated with resinous material. The compound consisted of *p-chlorophenylcamphoformeneamine*, 
$$C_8H_{14}\left\langle\begin{array}{l}C:CH\\ \vdots\quad\ \vdots\\ CONHC_6H_4Cl\end{array}\right.$$

, it is deposited from acetone, on the addition of ligroin, in white crystals, melting at 194–5°. Yield, 61 per cent. of the calculated quantity. The compound dissolves readily in acetone, ether, ethyl acetate, alcohol, or chloroform, but it is less soluble in ligroin. It gives no coloration with an alcoholic solution of ferric chloride and is not changed by boiling with an aqueous solution of potassium hydroxide, or of hydrochloric acid. The same amine may also be obtained by heating *p*-chlorophenylcamphoformeneaminecarboxylic acid (see above), until carbon dioxide ceases to be evolved.

Found: N, 4.69 Calculated: N, 4.83 per cent

Dibenzylamine and Camphoroxalic Acid.—Equimolecular proportions of dibenzylamine and camphoroxalic acid were dissolved in benzene and heated during 15 minutes. After remaining, at the ordinary temperature during 2 hours, the liquid deposits a white, crystallin precipitate. It was washed with more benzene and dried and then melted at 135–6°. This melting point was lowered rather than raised by recrystallizing the substance. The same compound is obtained by the use of 2 molecular proportions of dibenzylamine. The compound dissolves readily in benzine, ethyl acetate, alcohol, acetone, ether, or chloroform. When warmed with dilute hydrochloric acid the substance is resolved into camphoroxalic acid and dibenzylamine and a similar decomposition is produced by an aqueous solution of sodium carbonate, slowly at the ordinary temperature, more rapidly when heated. The dibenzylamine produced in this way was identified by means of its hydrochloride. The analytical results given below show that the substance is formed by the direct addition of dibenzylamine to camphoroxalic acid, without the elimination of water. It gives a deep reddish purple coloration with an alcoholic solution of ferric chloride. These facts and the reactions described below lead us to regard the substance as *dibenzylamine camphoroxalate,*  $C_8H_{14}\left<\begin{array}{l} C{:}C(OH)CO_2NH_2(CH_2C_6H_5)_2 \\ | \\ CO \end{array}\right.$.

Found: N, 3.34. Calculated: N, 3.32 per cent.

The above dibenzylamine camphoroxalate was dissolved in benzene, aniline (2 mols.) added and the mixture heated at 100°, during 5 hours, in a sealed tube. After evaporation of the benzene, white crystals are deposited, they were washed with alcohol and, after being dried, melted at 185°.

The compound dissolves very readily in benzene, more sparingly in alcohol. When treated with an aqueous solution of sodium carbonate it is resolved into dibenzylamine and phenylcamphoformeneaminecarboxylic acid (m. p. 172°). The amine was identified by the preparation of its hydrochloride (m. p. 256°) and the acid by a mixed melting point determination. These results show that the compound in question (m. p. 185°) is *dibenzylamine phenylcamphoformeneaminecarboxylate,*  $C_8H_{14}\left<\begin{array}{l} C:CCO_2NH_2(CH_2C_6H_5)_2 \\ |\quad | \\ CONHC_6H_5 \end{array}\right.$. The quantity of substance at our disposal was insufficient for an analysis.

A mixture of camphoroxalic acid and dibenzylamine, in equimolecular proportion, when heated, melts about 85°; it then becomes solid again and remelts about 125°. It was maintained at 135-40°, during 30 minutes. On cooling crystals are formed, they were washed with ligroin, and recrystallized from acetone. The compound melts at 152°; it is not changed by boiling with aqueous solutions of potassium hydroxide or of hydrochloric acid. Analysis shows that it is the dibenzylcamphoformeneamine,  $C_8H_{14}\left<\begin{array}{l} C:CH \\ |\quad | \\ CON(CH_2C_6H_5)_2 \end{array}\right.$, described by Bishop Tingle and Williams.[1] The yield is 75 per cent. of the calculated quantity. This substance is one of the most easily obtainable of its class and is well adapted for further study. The same amine is also formed by fusing either dibenzylamine camphoroxalate (see above), or a mixture of camphoroxalic acid (1 mol.) and dibenzylamine (2 mols.).

m-Aminobenzoic Acid and Camphoroxalic Acid.—Equimolecular alcoholic solutions of these substances were mixed and boiled during 5 minutes; after standing overnight a white solid separates, which is ultimately obtained in white crystals; melting at 136–7°; the melting point varies somewhat, according to the rapidity of the heating. The same compound is produced by the use of 2 molecular proportions of *m*-aminobenzoic acid. The substance consists of *m-carboxyphenylcamphoformene-*

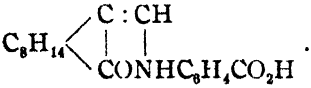
---

[1] *Am. Chem. J.*, 39, 117.

aminecarboxylic acid,  $C_8H_{14}\left\langle\begin{array}{l} C:CCO_2H \\ |\quad| \\ CONHC_6H_4CO_2H \end{array}\right.$; it dissolves readily in alcohol, ethyl acetate, or water, forming, in each case, a yellow solution. Rapid cooling, or quick evaporation of its solution causes the acid to be deposited in a gummy condition, but if the deposition takes place slowly crystals are produced. When dissolved in alcohol (95 per cent.) the acid gives no coloration with ferric chloride, but in water, or in 50 per cent. alcohol a portion of it is hydrolyzed to camphoroxalic acid, as is shown by its reaction with ferric chloride. A similar hydrolysis is produced by an aqueous solution of sodium carbonate, in which the dicarboxylic acid dissolves and liberates carbon dioxide; when acidified this solution reprecipitates the dicarboxylic acid in an impure condition.

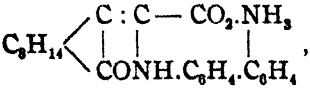
Found N, 4.37 Calculated. N, 4.08 per cent.

The above dicarboxylic acid evolves carbon dioxide when heated at its melting point; the residue is deposited from benzene in long, yellow needles, melting at 116–7°. It dissolves completely in a cold, aqueous solution of sodium carbonate, is reprecipitated by dilute hydrochloric acid and gives no coloration with an alcoholic solution of ferric chloride. These properties indicate that the compound is *m-carboxyphenylcamphoformeneamine,*

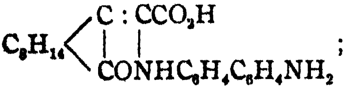


$C_8H_{14}\left\langle\begin{array}{l} C:CH \\ |\quad| \\ CONHC_6H_4CO_2H \end{array}\right.$.

Benzidine and Camphoroxalic Acid.—When equimolecular benzene solutions of these substances are mixed and warmed for a short time, yellow crystals are soon deposited. After recrystallization, the compound melts at about 208°, depending somewhat on the rapidity with which the temperature is raised. The substance is only slightly soluble in alcohol, or ethyl acetate, it gives no color with an alcoholic solution of ferric chloride and dissolves only slowly in a boiling aqueous solution of potassium hydroxide, or of sodium carbonate. After remaining overnight, these clear alkaline solutions deposit a slimy material. If this is removed and the liquid acidified with hydrochloric acid the original compound is reprecipitated. Boiling, concentrated hydrochloric acid slowly hydrolyzes the compound to its constituents. Analysis shows that the substance is either an inner *ammonium salt,*



$C_8H_{14}\left\langle\begin{array}{l} C:C-CO_2.NH_3 \\ |\quad|\qquad\quad| \\ CONH.C_6H_4.C_6H_4 \end{array}\right.$, or *benzidylcamphoformeneaminecarboxylic acid,*



$C_8H_{14}\left\langle\begin{array}{l} C:CCO_2H \\ |\quad| \\ CONHC_6H_4C_6H_4NH_2 \end{array}\right.$; its behavior towards alkalies is, we think, in better accord with the salt formula.

Found: N, 6.98. Calculated: N, 7.18 per cent.

The melting point (208°) which we observed for the above compound is 18° higher than that recorded by Bishop Tingle and Hoffman[1] for a substance which they obtained from benzidine and camphoroxalic acid, in alcoholic solution. A repetition of their work shows that the two compounds are identical, except for the fact that ours is more nearly pure. A mixture of the two substances melts at the same temperature as either one alone. The difference in the melting point is due partly to this greater degree of purity and partly to the rather large variation which is produced in the melting, or more accurately, the decomposing point, by a difference in the rate at which the temperature is caused to rise. That some of the compounds of this series are extremely sensitive in this respect has been pointed out previously by Bishop Tingle and Robinson.[2]

Benzidylcamphoformeneamine, $C_8H_{14}\left<\begin{array}{l}C:CH\\ |\quad\ |\\ CONHC_6H_4C_6H_4NH_2\end{array}\right.$, is formed by direct fusion of the preceding compound, but is best prepared by grinding a quantity of it with 5 parts of nitrobenzene, the mixture being then slowly heated on an oil bath. At about 135° a clear red solution is obtained; at 150° water and carbon dioxide are evolved. The temperature was maintained at 150-5° during 15 minutes and the solution then filtered and allowed to cool. The crystals which separated were collected, washed with benzene by means of a centrifuge and, finally, they were boiled with alcoholic potassium hydroxide. The purified material melts at 317-8°, it is not attacked by boiling with concentrated aqueous solutions of potassium hydroxide, or of hydrochloric acid. The analytical results given below and the method by which the compound is formed can leave no doubt as to its nature, but concordant data could not be obtained for its nitrogen content; the gas is evolved very slowly during the course of the combustion and some of it is evidently occluded in the filling material of the combustion tube. See K. Holdermann and R. Scholl.[3]

Found: C, 79.00; H, 7.79. Calculated: C, 79.77; H, 7.54.

Camphylamine and Camphoroxalic Acid.—A well-marked evolution of heat takes place when these substances are mixed, in benzene solution; the residue, obtained after evaporating the solvent, is evidently a condensation product, because it fails to give any coloration with an alcoholic solution of ferric chloride, but we were unable to obtain the substance in a crystallin condition. When camphoroxalic acid is heated at 150-5°, with 2 molecular proportions of camphylamine, most of the product is also tarry, but a while, crystalline *sublimate* is obtained in small quantity. It melts at 105°, dissolves readily in alcohol and also in an aqueous solution of sodium carbonate, at the ordinary temperature. It gives no coloration with an alcoholic solution of ferric chloride.

No definite compound could be isolated from the reaction products of *p*-aminobenzaldehyde and camphoroxalic acid, at 125–30°.

Some further experiments which have been made with acetylphenylhydrazine and camphoroxalic acid have failed to improve the yield of the condensation compound described by Bishop Tingle and Williams.[1]

Summary.

(1) We have studied the action of bromine, of the chlorides of phosphorus, of various oxidizing agents, of nitrous acid and of dimethyl sulphate on certain of the condensation compounds of camphoroxalic acid and amines, in order to obtain further data in respect to their constitution.

(2) The results which we have obtained are in accord with the formula,  $C_8H_{14}\left\langle\begin{array}{l} C:CR \\ \;|\quad| \\ CONR_1R_2 \end{array}\right.$, ($R = H$ or CO_2H; R_1 and $R_2 = H$, alkyl or aryl), which has been previously assigned to these condensation compounds by the senior author and his colleagues.

(3) The interaction of thiosemicarbazine and camphoroxalic acid has been studied in order to compare the resulting compounds with those derived from semicarbazine. The replacement of CO (semicarbazine) by CS (thiosemicarbazine) greatly reduces the tendency of the primary condensation compounds to form cyclic derivatives.

(4) A considerable number of new condensation compounds have been prepared from camphoroxalic acid and the following amines: *1,3,4-xylidine, p-chloroaniline, dibenzylamine, m-aminobenzoic acid, benzidine* and *camphylamine*. Some of these new substances are well adapted for further study. No crystalline compound could be obtained from camphoroxalic acid and *p*-aminobenzaldehyde.

The investigation will be continued in various directions.

THE DEVIATION OF FERMENT ACTION FROM THE MONOMOLECULAR LAW WITH ESPECIAL REFERENCE TO THE ESTERASES.

By George Peirce.

Received July 28, 1910.

During the course of an investigation into the effect of the fluorides on the action of lipase, it became necessary to study the kinetics of the lipolytic action. The results obtained were so unexpected that it seemed worth while to publish them separately.

The reaction

$$\text{Ester} + \text{Water} \rightleftarrows \text{Acid} + \text{Alcohol}$$

is in its most general form a reaction of the second order, since we have two substances changing their concentrations in each semi-reaction. As usually studied, the water is present in large excess and may therefore be regarded as constant.

The semi-reaction

$$\text{Ester} + \text{Water}$$

should then be written

$$\text{Ester} + \text{Water (in excess)} \longrightarrow$$

and the whole reaction takes the form

$$\text{Ester} + \text{Water (in excess)} \rightleftarrows \text{Acid} + \text{Alcohol} + \text{Water (in excess)}.$$

Thus on the left side we have only one substance, the ester, changing its concentration, while on the right side we have two, the acid and the alcohol. Under these conditions, the reaction from left to right is better studied as a reaction of the first order. For such reactions we expect the following equation to hold:

$$\frac{1}{t} \log \frac{a}{a - x} = k.$$

Here k is a constant, a is the amount of ester present at the beginning of the reaction and x the amount of ester split up during the time t. In the following experiments a and x are measured in terms of 0.05 N NaOH.

The reaction from right to left has been studied qualitatively in several researches but so far as I know Bodenstein and Dietz[1] have been the only ones to investigate its kinetics. We will consider, therefore, in this discussion only the reaction from left to right or the hydrolytic reaction.

The researches fall into two divisions, reactions in homogeneous and reactions in heterogeneous solutions. We will consider briefly examples of each class and take up first the reaction in homogeneous solutions.

Kastle and Loevenhart[2] and later Kastle, Johnston and Elvove,[3] using a clear liver extract and ethyl butyrate found that when an attempt was made to calculate their results according to the first-order equation $k = 1/t \log [a/(a - x)]$, k fell off steadily from the beginning to the end of the reaction. They attributed this fact to the inhibiting influence of the acid on the enzyme. Towards the end of Kastle Johnston and Elvove's paper, however, occurs a series of experiments where the function falls off only very slightly. In this series, moreover, the value of *k*, though nearly constant for any given concentration of ethyl butyrate, is, roughly speaking, inversely proportional to the initial concentration of the esterase, when this is varied. Thus though the monomolecular law is closely followed in one concentration of zymolyte, the reaction taken as a whole is at total variance with the law.
